Ammonia deposition in the neighbourhood of an intensive cattle feedlot in Victoria, Australia

Jianlin Shen[1,2], *Deli Chen*[2], *Mei Bai*[2], *Jianlei Sun*[2], *Yong Li*[1]
1. Institute of Subtropical Agriculture, Chinese Academy of Sciences
2. Faculty of Veterinary and Agricultural Sciences, The University of Melbourne

We conducted the first study in Australia to measure ammonia (NH_3) deposition within 1 km from a commercial beef feedlot in Victoria. NH_3 concentrations and deposition fluxes decreased exponentially with distance away from the feedlot. The mean NH_3 concentrations decreased from 419 μg N m^{-3} at 50 m to 36 μg N m^{-3} at 1 km, while the mean NH_3 dry deposition fluxes decreased from 2.38 μg N m^{-2} s^{-1} at 50 m to 0.20 μg N m^{-2} s^{-1} at 1 km downwind from the feedlot. These results extrapolate to NH_3 deposition of 53.9 tonne N yr^{-1} in the area within 1 km from the feedlot, accounting for 8% of the annual NH_3-N emissions from the feedlot. This high NH_3 deposition rate nearby the cattle feedlot had caused the increase of soil inorganic nitrogen content, especially for NO_3^- (from 33 mg N kg^{-1} at 1000 m from the feedlot to 124 mg N kg^{-1} at 50 m from the feedlot). Higher N content (4.0% to 5.7%) in the above-ground part of grassland species and high cover rate of single species (e.g., a cover rate of 31% to 42% at 50 to 200 m from the feedlot for *Cymbonotus lawsonianus*) were found in the grassland transect to the southeast of the feedlot. Our results suggest that NH_3 deposition is significant nitrogen (N) nutrient input for surrounding croplands and natural ecosystems.

Ecophysiological responses of urban plants to increasing O_3 concentrations

Sheng Xu
Institute of Applied Ecology, CAS

By using open-top chambers (OTCs), the effects of elevated O_3 concentration on the growth and photosynthesis of urban trees were studied. The results showed that elevated O_3 concentration significantly inhibited the growth of *Catalpa ovata*. Compared to the ambient air control (OA), relative water content, dry weight, fresh weight, specific leaf weight, dry weight increment and fresh weight increment were significantly decreased in leaves of *C. ovata* after 20 days exposure to O_3 (160 nmol·mol^{-1}). The net photosynthetic rate (P_n) of *C. ovata* gradually decreased with the extension of time. The decrease in photosynthesis of *C. ovata* was related to non-stomatal factors. The change trends of intercellular CO_2 concentration (C_i) and transpiration rate (T_r) and stomatal conductance (G_s) were consistent, with decline first and then increase. The maximal photochemistry efficiency of PS II (F_v/F_m) and quantum yield of PS II electron transport ($\Phi_{\mathrm{PS\ II}}$) decreased significantly over the time ($P < 0.05$), the decline of *C. ovata* photosynthesis correlated markedly with the excess of light energy, and photoinhibition phenomenon under O_3 stress occurred. Superoxide dismutase (SOD) and ascorbic acid peroxidase (APX) activities showed no significant change during the whole O_3 stress, which implied that it was quite difficult for *C. ovata* to tolerate excessive O_3 concentration, and two antioxidant enzymes did not make positive physiological response to the acute stress of O_3.

Effects of grazing on CO_2, CH_4 and N_2O fluxes in three temperate steppe ecosystems

Huiqiu Shi[1,2], *Longyu Hou*[1], *Liuyi Yang*[1,2], *Dongxiu Wu*[1], *Lihua Zhang*[1], *Linghao Li*[1]
1. Institute of Botany, CAS
2. University of the Chinese Academy of Sciences

Terrestrial ecosystems play a critical role in regulating the emission and uptake of the most important greenhouse gases (GHGs) of CO_2, CH_4 and N_2O. However, the effects of grazing on these GHG fluxes in different steppe types remain unclear. Here we compared the effects of grazing on seasonal CO_2, CH_4, and N_2O fluxes in meadow (MS), typical (TS), and desert (DS) temperate steppe ecosystems in Northern China. CO_2 emission rates increased from 311.4 ± 73.2 to 349.6 ± 55.4 mg m^{-2} h^{-1} in MS, but decreased in TS (from 341.3 ± 93.0 to 239.5 ± 81.9 mg m^{-2} h^{-1}) and DS (from 212.1 ± 53.7 to 163.0 ± 83.4 mg m^{-2} h^{-1}) in response to summer grazing. N_2O emission rates increased in MS from 4.7 ± 2.2 to 8.1 ± 3.4 μg m^{-2} h^{-1}, but no significantly changed in TS (9.2 ± 4.2 VS 8.4 ± 2.4 μg m^{-2} h^{-1}) and DS (6.3 ± 1.5 VS 5.7 ± 1.6 μg m^{-2} h^{-1}) by summer grazing. CH_4 uptake rates increased in MS from 33.0 ± 11.7 to 47.1 ± 10.4 μg m^{-2} h^{-1} and decreased from 64.4 ± 7.6 to 56.2 ± 5.9 μg m^{-2} h^{-1} in TS in response to summer grazing. In MS and DS, N_2O emissions were positively related to seasonal CO_2 emissions and negatively related to CH_4 uptakes. No significant relationships were found between GHG fluxes in TS. Summer grazing did not affect the relationship between CO_2 and N_2O emissions in MS, but reduced the relationship by enhancing the effect of aboveground biomass (AGB) on N_2O emission in DS. The significant negative relationship between CH_4 uptake and N_2O emission in MS and DS could be attributed to the significant relationship between soil temperature (ST) and AGB in MS and to the significant effects of soil moisture (SM) on both CH_4 uptake and N_2O emission in DS. The decrease in the magnitude of the correlation coefficients between CH_4 uptake and N_2O emission by summer grazing was due to the negative relationship between ST and AGB simultaneously in MS and DS. Our results suggest that effects of summer grazing on GHG fluxes were varied in different steppes and the relationship among GHGs was steppe-dependant and summer grazing also changed the relationship by affecting GHG fluxes induced by varied soil and environmental factors.

Proposed model for understanding evolution of mangroves along the central West Coast of India based on ecological and palaeoecological studies.

Mahesh Shindikar

College of Engineering, Pune

Mangrove represents one of the sensitive ecosystems to analyze climatic, edaphic and biotic changes along the continental margins of tropics and subtropics. West Coast of India is continuously subjected to naturally occurring geological and climatic changes in its past and anthropogenic pressures in recent times. Mangroves are found to be very sensitive to such challenges in all time scales. An attempt has been made to use past and present mangrove floristics in addressing various environmental changes occurred along the Maharashtra coast at the spacio-temporal scale. Palynological assemblages available at Neogene, Late Pleistocene–Holocene and recent past are correlated with contemporary geological episodes, climatic alterations and anthropogenic interventions. Based on available fossil records, presence of sheltered habitats, extensive mangrove cover, diverse floristic elements and conducive wet-humid climate has been inferred during Neogene time from the Sindhudurg Formation (or Ratnagiri beds). The geological activities like tectonic upliftment and subsidence along the coast that has resulted into subsequent geomorphological changes *viz*. change in the river courses (freshwater diversions) or loss of sheltered bays. As such these geomorphic alterations have caused loss of habitat of specific species like *Nypa* and *Eugeissona* from the coast. Contemporary climatic changes in the hinterland have resulted in loss of wet evergreen species like *Cullenia*, *Ctenolophon* from the catchment areas. In addition to this, the transgression-regression of sea level has significantly affected the extent of mangrove habitats along the coast. In the second phase, the geochronological information from available cores along the coast is mostly restricted to the Late Pleistocene–Holocene period after the Neogene. In the present investigation, recovery of mangrove dominated palynological assemblage from the lignite material that is evident for tectonic upliftment of near shore deposits at higher altitudes along the coast. Quaternary deposits along the coast, though very limited in their occurrence, provide excellent spatial pattern of distribution of species which can be correlated to present day distribution also. Palynological data, chronology and environmental magnetism studies on the sediments obtained from the subsurface levels of mangrove deposits are found to be significant and useful while considering their palaeoclimatic implications during the Late Quaternary. Further, the anthropogenic threats provide recent picture of forces on these ecosystems. Thus, on this background of past, the knowledge about present status of mangroves from the central west coast of India becomes useful as a proxy for tracing their antiquity and probable changes in the future.

Cold tolerance in two species of mangrove, *Bruguiera gymnorhiza* and *Rhizophora apiculata*

Aidan William Short, *Alison K.S. Wee*

Plant Ecophysiology & Evolution Group, College of Forestry, Guangxi University

As the climate warms the distribution of species is shifting, the general movement being towards higher latitudes and elevations. Cold stress tolerance is vital to the prediction of a species' future range limits, because cold stress limits the poleward distribution of a species (MacArthur 1972). Mangroves are a useful system for the study of clinal trait variation because they are found throughout the world in tropical and subtropical regions, and have recently displayed northward range expansion across the world. In this study, we examined the cold tolerance of, and measured changes in gene expression in response to cold stress in two mangrove species, *Bruguiera gymnorhiza* and *Rhizophora apiculata*. *Bruguiera gymnorhiza* and *Rhizophora apiculata* were chosen as focus of this study because they frequently co-occur and are widely distributed throughout the eastern Indo-West Pacific area, yet display differing latitudinal limits. *Bruguiera gymnorhiza*'s latitudinal limit being farther north (Kagoshima prefecture, Japan) than that of *Rhizophora apiculata* (Hainan, China). This study experimentally examined whether *Bruguiera gymnorhiza* and *Rhizophora apiculata* varied predictably in freeze tolerance, whether physiological traits could explain this variation, and whether changes in genetic expression level would occur in response to cold stress. Three hypothesis were tested (1) freeze tolerance will vary with latitudinal limit, (2) variation in mortality, biomass and photo-inactivation will be linked to freeze tolerance, and (3) cold stress response is the result of changes in the expression of genes. The prediction is that the species with the more northern limit range will have a higher freeze tolerance than that of the more southern species, that the higher freeze tolerance of the more northern species will be the result of differences in the functional traits between the species, and that exposure to cold stress will induce changes in the expression of genes related to cold tolerance. Through the contrast of the physiological and molecular response of each species to cold stress, a better understanding of the mechanisms of cold tolerance can be gained, providing a basis for the prediction of plant movement in response to climate change.

Functional attributes of planted woody species on coal mine spoil for ecological restoration in a dry tropical environment, India: An implication for C management in a changing environment

Anand Narain Singh
Panjab University Chandigarh

Due to mining operation significant areas of land are degraded and existing ecosystems replaced by undesirable waste materials in the form of dumps or mine spoil with low concentration of C, N and P nutrients. Therefore, the primary aim was to rehabilitate the soil component by planting certain desirable plant species as well as counteracting emission of CO_2 to the atmosphere. Thus, present study was conducted on young plantations of four native species (*Albizia lebbeck, Albizia procera, Tectona grandis* and *Dendrocalamus strictus*) raised on mine spoil. We examined both component of the ecosystem (plant and soil). From soil part, total SOC (soil organic carbon) and their accumulation rates in deferent soil depth, bulk density, WHC, and microbial biomass C were analyzed. Whereas from plants, total plant biomass production and standing state of C nutrient stock in different plant components were estimated at ages 3, 4, 5 and 6 years respectively. The soil bulk density, SOC and accumulation rates at 0-10 and 10-20 cm soil depth were significantly varied among plantations, therefore, nutrient stock C (kg ha^{-1}) was also varied in the corresponding way but values were substantially low in the plantation of *T. grandis* followed by *A. lebbeck, D. strictus and A. procera.* Total tree layer C stock (t ha^{-1}) significantly increased in all plantations as they aged from 3-yr to 6-yr. Plantations of *A. lebbeck* and *D. strictus* supported much more biomass than that of *A. procera* and *T. grandis* which indicates different species have different sequestering pattern. Biomass allocation in different components (leaf, stem and root) was widely different in both species. However, larger partitioning of leaf biomass contributed high amount of C input to the soil surface indicated high quality of C deposition in the soil layer that could be formed as organic layer of the soil in long term. Therefore, rapid biomass accumulation efficiency and faster growth rates in the plant species evidently indicates rapid deposition of C. Furthermore, it might be more beneficial step if we consider as in the way of ecological economics of managing C as well as restoring degraded ecosystems in top priority approach in the current scenario.

Investigation of rare endemic *Verbascum calycosum* Hausskn. ex Murb. in terms of soil-plant relationship

Muhip Hilooğlu[1], ***Emel Sözen***[1], *Ersin Yücel*[1], *Ali Kandemir*[2]
1. Anadolu University
2. Erzincan University

Verbascum calycosum Hausskn. ex Murb. (Scrophulariaceae) is a rare and endemic plant species that shows narrow distribution around Erzincan, Turkey. *V. calycosum* was first collected from Kemaliye/Erzincan district in 1890 by Sintenis. Later, this species was recorded as extinct (EX) in Turkish Plants Red Data Book. However, it was rediscovered from its original locality by different investigators. At present, only two populations of different size (5,437 and 2,512 individuals) exist in Kemaliye. In this study, physical and chemical characteristics of soils that *V. calycosum* naturally distributed were determined. The soil types of this species were serpentine and loamy, between 2.5Y-10YR in color, very dry, saltless, slightly alkaline and low in organic matter and lime content. In addition, correlation between micro and macro element (N, K, Mg, P, Ca, Fe, Mn, Zn, Cu) contents of plant and soil samples were studied. Obtained results will provide valuable data for ex-situ conservation studies for rare and narrow endemic species of *V. calycosum.*

Bee pollination increases yield and quality of cash crops in Burkina Faso, West Africa

Katharina Stein[2], *Drissa Coulibaly*[3], *Souleymane Konate*[3], *Dethardt Goetze*[1], ***Stefan Porembski***[1], *Karl Eduard Linsenmair*[2]
1. University of Rostock
2. University of Wuerzburg
3. University Nangui Abrogoua Abidjan

Insect pollination constitutes an ecosystem service of global importance, providing significant economic benefits to human society alongside vital ecological processes in terrestrial ecosystems. A growing human population especially in developing countries places rising demand for food and income security under rapidly changing environments. 75% of agricultural crop species rely, to some degree, on animal pollination. Bees are the most important pollinators worldwide; a complete loss of their pollination service could reduce yields by ca. 40% for fruits. The study aimed to investigate the contribution of pollination by bees for yield and quality in cotton and sesame. Field research was carried out in 2015 in south-west Burkina Faso. Pollination experiments were conducted to determine the rate of self-compatibility and the pollinator dependence of the crops. On 11 fields for each crop pollinator exclusion and outcrossing experiments were conducted on 50 flowers per field. The efficiency of various bee pollinator species for fruit set and quality was investigated. Germination experiments with seeds resulting from self or outcross pollination were conducted to test for seed quality in terms of inbreeding depression. Honey bees and one wild bee species were the most effective pollinators.

Exclusion of pollinators caused a yield gap of 37% in cotton and 59% in sesame. Pollination by bees increased the economically most important fiber weight of cotton by 62%, and seed weight of sesame was tripled compared to pollinator exclusion. The germination rate of seeds resulting from self-pollination decreased significantly in both species, which is a clear sign of inbreeding depression and economical important, since the seeds are used for the next sowing season. The gratis pollination service by bees was thus beneficial, contributing to cotton and sesame production by enhancing the quantity and quality of these major cash crops in Burkina Faso.

Evolution of labellar secretory structures and pollinator food-rewards in Old World *Bulbophyllum Thouars*

Małgorzata Stpiczyńska[1], *Kevin L. Davies*[2], *Marcin Zych*[1], *Bartosz Płachno*[3]
1. University of Warsaw, Faculty of Biology, Botanic Garden
2. School of Earth and Ocean Sciences, Cardiff University
3. University of Warsaw, Faculty of Biology, Botanic Garden
4. Department of Plant Cytology and Embryology, Jagiellonian University in Kraków

Floral food-rewards are relatively uncommon amongst orchids, the most frequent being nectar. Some species, however, provide insect pollinators with other food-rewards, such as pseudopollen, oil, volatiles and resin-like secretions. *Bulbophyllum Thouars* is widely distributed, and is the largest genus of orchids, estimated to contain some 2,200 species. Its great size and highly specialized ecological relationships make this genus a rich source of new information concerning plant adaptations. It includes some of the smallest plants in the orchid family, but has also some of the most intricate flowers, often displaying very diverse and complex pollination strategies. Remarkably, given the enormity of the genus, very little is known about its floral, and in particular, its labellar anatomy and associated secretory activity. Furthermore, detailed micromorphological studies of *Bulbophyllum* flowers are scarce. Our studies have shown that the labellum of *Bulbophyllum* has the capacity to produce a greatly diverse range of food-rewards and associated compounds, such as proteins, lipids, mucilage and nectar. For example, unlike the labella of most species of *Bulbophyllum* investigated to date, which secrete lipid-rich material, those of representatives of section *Racemosae* produce a protein-rich, mucilaginous secretion. This, like the secretion of many other species of *Bulbophyllum*, is produced in specialized, palisade-like epidermal cells which line the labellar groove or sulcus. Although lipids are absent from this secretion, lipid droplets were observed in both secretory cells and sub-secretory parenchyma, and our more recent work has shown that not only do these secretory cells produce food-rewards, but also fragrance. Here we extend our investigations to embrace a number of other florally diverse species, and this represents the first detailed comparative account of labellar secretory tissues and their associated secretions for such a large range of Asiatic *Bulbophyllum* species assigned to a number of sections. Histochemical analyses used in conjunction with micromorphological and ultrastructural investigations enable us to compare the structure of secretory tissues, the composition of the secretory product and details of the secretory process. Given its size, diversity and very wide distribution, it is hoped that our investigations will shed light on the evolution of food-reward production in *Bulbophyllum* in response to pollination pressure and pollinator selection.

Nectaries on inflorescences and leaves of Malpighiaceae endemic genera from Brazilian dry and wet environments: How different are they?

Isabel Guesdon[1,2], *Ítalo Antônio Cotta Coutinho*[3], ***Renata Maria Strozi Alves Meira***[1]
1. Universidade Federal de Viçosa, UFV, Departamento de Biologia Vegetal, Viçosa, Minas Gerais, Brazil.
2. Universidade Federal do Amazonas, UFAM, Instituto de Ciências Exatas e Tecnologia, Itacoatiara, Amazonas, Brazil.
3. Universidade Federal do Ceará, UFC, Departamento de Biologia, Campus do Pici., Fortaleza, CE, Brazil

Nectaries may be classified as floral (FN) and extrafloral (EFN), according to their position, or as nupticial and extranuptial, based on the involvement of nectar with pollination. However, FN have been used as a synonymous with nuptial nectaries while EFN with extranuptial nectaries. Such approach is not appropriate and might be misleading, especially for nectaries that clearly occur on floral parts (e.g., axis of the inflorescence, pedicel, bracts and petals) but are not involved with pollination. In Malpighiaceae, the mcvaughioid clade is a Neotropical lineage composed of three genera *Burdachia*, *Glandonia* and *Mcvaughia* with a peculiar biogeography as Burdachia and Glandonia are endemic trees to the Amazon while *Mcvaughia* is represented by endemic shrubs to "Caatinga" (Brazilian savanna) and "Restinga" (sandy coastal plains). Species of the mcvaughioid clade present both leaf and bracteolar nectaries what makes such a clade a model for comparative studies regarding the secretory and ecological roles of nectaries. This study aims to characterize the anatomy, the nature of secretion and record insect visitation on leaf and bracteolar nectaries in the mcvaughioide species. Samples of leaves and inflorescences at different stages of maturity were collected in field and submitted to standard anatomical techniques for light and scanning electron microscopy. Histochemical tests were performed to detect polysaccharides, proteins, lipids and phenolic compounds. The glucose concentration of the secretion was measured in the field with aid of glucose reagent strips. Leaf nectaries are immersed, sessile or short-stalked while bracteolar are sessile or subsessile. The morphoanatomy and nature of the secretion are similar in both leaf and bracteolar nectaries. Nectaries are vascularized, present a secretory epidermis with thick cuticle and a nectary parenchyma and show positive reaction to polysaccharides, proteins and phenolic compounds, including tannin. Droplets of lipids in the secretory epidermis and nectary parenchyma were also detected. Bracteolar nectary development is precocious, when flowers are not completed formed, and the secretory activity is persistent throughout fructification. The concentration of sugar was higher in bracteolar nectar than in the leaf ones. Ants of eight genera were identified being *Dolichoderus* the most common. Nectar produced by nectaries on the inflorescences was generally consumed by the ants that foraged each one of the nectaries on the inflorescence axis. The differences found among the nectaries could not be related to the biogeography of species. (CAPES, CNPq, FAPEMIG, FAPEAM)

The spatial heterogeneity of light effect on micro-environment and specific leaf area within the gap, subtropical forest, China

Supaporn Buajan[1], *Jinfu Liu*[1], *Zhongsheng He*[1], *Xueping Feng*[1], *Abrar Muhammad*[2]

1. College of Forestry, Fujian Agriculture and Forestry University

2. Fujian Provincial Key Laboratory of Insect Ecology, Department of Plant Protection, Fujian Agriculture and Forestry University

Each gap has its own environment, which effect on species growth. Light is the most changes when gap creates. Hence, this study explored whether light has effect on micro-environment and determined the effect of light on specific leaf area (SLA) of species regeneration layer within nine sampling gaps and non-gap. In growing season, environment factors such as light intensity (LI), air temperature (AT), air relative humidity (RH), soil temperature (ST), and soil water content (SWC) were collected. Leaf samples were collected to measure the SLA, nitrogen (N) and phosphorous (P) content. We found that LI had a positive significant correlation with the ST and AT but negative significant correlation with the RH, which these correlation were inversed in non-gap area. The significant different of LI between gap size were found, which the highest average LI occurred in the large gap size meanwhile, the lowest average LI occurred in the small gap size. The spatial heterogeneity of LI differ among the gap depends on the topography, slope direction, and location of trees at each direction. In medium and large gap size, LI had a negative significant correlation with the SLA ($r = -0.248$, $p = 0.04$ and $r = -0.264$, $p = 0.008$). At all directions, the SLA increases with a decreasing LI. Our results concluded that LI had effect on micro-environment in different gap size and SLA in each direction within the gap when compared with non-gap. In addition, SLA had a positive significance with N and P content.

Allelopathic effects of *Trianthema portulacastrum* L. on seed germination and early growth of Jute (*Corchorus olitorius* L.) seedlings

Jhuma Sutradhar[1], *Abhaya Prasad Das*[2], *Adani Lokho*[1]

1. Department of Botany, Visva-Bharati, Santiniketan, West Bengal

2. Taxonomy & Environmental Biology Laboratory, Department of Botany, University of North Bengal, Siliguri, West Bengal

The Bardhaman district of West Bengal, India, is generally referred as granary of the state. Large part of the state is under the cultivation of wide range of crops. These include cereals, pulses, potato, sugarcane, fibre and oil-crops, *etc.* A detail work on survey of major crop field weeds of Bardhaman district was carried out during the years 2013–2015 and a taxonomically rich weed flora has been recognized. It was predicted that some of these weeds might have allelopathic effects on one or more crop plants under cultivation. Earlier, the allelopathic effects of *Trianthema portulacastrum* L., a major weed of the area, was confirmed on a oil-crop, *Sesamum indicum* L. Jute (*Corchorus olitorius* L.) is another important cash crop in Bardhaman and its nearby districts. *Trianthema portulacastrum* is a major weed also with jute all over the district. Now, to understand the allelopathic effects of *this weed* on jute, if any, the seed germination and the early growth of root and shoot of its seedlings were studied under the aqueous extract and leachate of the whole plant in different concentration gradients (1:2.5,1:5,1:10 and 1:20 w/v). The jute seeds were allowed to germinate separately in petridishes with different concentration of test solution. Distilled water was used to maintain a control set. Germination percentage, root and shoot length of each set was compared with control. In high concentration of *Trianthema portulacastrum* aqueous extract and leachate revealed a significant inhibitory effect on Jute seed germination. In 1:2.5 concentration (i.e highest concentration of extract and leachate) showed the lowest value for germination percentage, mean root, shoot and seedling length. Allelopathic effects on germination and thus root and shoot growth increases with increasing concentration of test solutions. Inhibitory effects of extract is significantly severe than the leachate.

Detection of distribution changes of evergreen broad-leaved trees in an old-growth forest in a vegetational transition zone over 44 years for assessment of climate change impacts

Masatsugu Yasuda[1], *Etsuko Nakazono*[2], ***Nobuyuki Tanaka***[3], *Hiromu Daimaru*[4]

1. Asia Air Survey

2. The University of Tokyo

3. Tokyo University of Agriculture

4. Forestry and Forest Products Research Institute

The globally averaged combined land and surface temperature showed a warming of 0.85℃, over the period 1880 to 2012 (IPCC, 2013). More rapid temperature rise is predicted in the next 100 years due to greenhouse gas emission. There have been a number of studies on predicting potential habitat shifts of plants/vegetation under future climate change scenarios. However, studies on detecting real distribution shifts driven by past climate change are still a few (cf. Yasuda *et al.,* 2007, Lenoir *et al.,* 2008, Shimazaki *et al.,* 2012). Especially, distribution shifts of tall forests are not so reported, probably because technical and ecological problems. The distribution shift of tall forests, which are multi-story communities, are technically more difficult to detect than that of low vegetation such as swamp and alpine vegetation. Tall forests are usually changing under vegetation succession, which obscures the magnitude of climate change impact. To detect distribution changes of evergreen broad-leaved trees (EBTs) in an old-growth forest in the transitional zone between cool-temperate deciduous broad-leaved forest zone and warm-temperate evergreen broad-leaved forest zone, we used orthophoto images converted from aerial photos taken between 1961 and 2005. The study area we selected is an old-growth forest preserved by a religious reason on

the southern slope of Mt. Tsukuba in Japan. The crowns of EBTs in plot A (125 ha) increased from 1,820 pieces to 2,424 pieces (1.3 times). The total crown area in plot B (20 ha) located within plot A increased from 28,336 m^2 to 46,480 m^2 (1.6 times). The upper limit elevation, below which ratio of total crown area of EBTs is more than 40%, moved upward from 627 m to 677 m a.s.l. over 44 years. According data of two meteorological stations on the mountain, three critical boundaries, that is, the lower limit elevation of the deciduous broad-leaved forest zone estimated by 85 of Kira's warmth index, the upper limit elevation of the evergreen broad-leaved forest zone estimated by -10 of Kira's coldness index, and the upper limit elevation of Quercus acuta, a single dominant EBT species, estimated by -4.7 of minimum temperature of the coldest month, move upward by 98 m, 147 m and 146 m over 100 years. These past changes occurring in this old-growth forest, which had been not under anthropogenic pressure and was proximate to being a climax forest, could be caused by past climate change much more than by vegetation succession. Thus, we conclude that the distribution shift and increase of EBTs on Mt. Tsukuba are explained by the past climate warming.

Report of fungal endophyte in anthers of *Stigmaphyllon* subgenus *Ryssopterys* (Malpighiaceae)

David William Taylor[1], *Gregory J. Anderson*[2]
1. University of Portland
2. University of Connecticut

In summer 2016 we carried out Scanning Electron Microscopy analysis of pollen grains in *Stigmaphyllon* subgenus *Ryssopterys* (Malpighiaceae), a group of woody vines endemic to island chains in Southeast Asia and Oceania, and found the presence of basidiomycete hyphae as well as basidia and spores. The hyphae were found wrapped around pollen grains. Furthermore, fungal spores were found on the surface of pollen grains. Given that this pollen was collected from anthers in closed flower buds, we propose that this fungal species is an endophyte that is producing spores in association with the pollen grains of its host, presumably, as in some bird and bee pollinated plants, in order that the spores be dispersed along with the grains of pollen. Due to the showiness of the flower and the pollen grains apparently adhering in groups to fungal hyphae, it is likely that the pollen and spores are dispersed by an animal pollinator, whose identification is a part of ongoing studies.

P0907

Cryptic dioecy in *Stigmaphyllon* subgenus *Ryssopterys* (Malpighiaceae)

David William Taylor[1], *Gregory J. Anderson*[2]
1. University of Portland
2. University of Connecticut

Stigmaphyllon subgenus *Ryssopterys* (Malpighiaceae) is a group of 22 species of woody vines endemic to coastal and other low-elevation sites in parts of island chains in Southeast Asia and Oceania. These species have been characterized as being androdioecious, but studies have not been carried out to test if these species do indeed manifest this rare sexual system, or if the apparently hermaphroditic flowers are functionally female. If confirmed, the latter would recast these species as functionally dioecious. In the summer of 2016 we carried out Scanning Electron Microscopy analysis of pollen grains of 11 of these species and found results that correspond to the presence of cryptic dioecy, with pollen grains in morphologically hermaphroditic flowers bearing inapeturate, and thus sexually nonfunctional, pollen grains. This is the first known observation of dioecy in *Stigmaphyllon. Stigmaphyllon* subgenus *Ryssopterys* is nested within *Stigmaphyllon* subgenus *Stigmaphyllon*. The latter is endemic to South America and has functionally hermaphroditic flowers. Thus, our discoveries suggest that the dioecious condition in this genus evolved after dispersal to island chains in Southeast Asia and Oceania. The pollen-bearing sexually-nonfunctional stamens in subgenus *Ryssopterys* female flowers might serve as attractants for pollinators, as landing platforms for pollinators (as is the case for functionally dioecious species of *Solanum*) or fodder for pollinators, whose identification is a part of ongoing studies.

Melia azedarach is a medium-sized to large deciduous tree with bipinnately compound leaves, native to Asia and Australia but has become naturalized in several other parts of the world including South Africa where it is invasive. Despite its wide distribution, there appears to be very little known about the structure or development of the extrafloral nectaries (EFNs). Several minute, circular, green EFNs were found to be present on both sides of the leaflets. These have not previously been reported. In transverse sections of actively secreting EFNs, the glandular tissue is seen to be composed of cells which stain dark blue in the outermost portion and green-blue in the innermost with Schiff's reagent and toluidine blue. Stomata are absent. The cuticle appears to be absent in the middle of the EFN. However, material staining the same as the cuticle is concentrated at the periphery where it extends amongst cells of the dark blue layer. Druses of calcium oxalate are present in the vicinity of the EFNs in small numbers. The innermost portion of the EFN is very close to, if not in direct contact with, the vascular tissue. An analysis of the exudate confirmed the presence of glucose, fructose and sucrose, sugars characteristic of nectar. EFNs, occurring in pairs, in recesses at the petiole base have previously been reported but not studied anatomically or developmentally. We found each petiolar 'EFN' to consist of a group of several individual EFNs. They are structurally similar to the laminar EFNs but differ in usually protruding somewhat beyond the surface of the recess and being composed of more anticlinally elongated cells. Their initial development appears to differ in that cells of both the epidermis and subepidermal tissue divide in various directions in the formation of the laminar EFNs whereas, in the formation of the petiolar EFNs, the subepidermal cells divide mainly periclinally. Both laminar and petiolar EFNs attract ants of different species. Members of the Meliaceae (including *M. azedarach*) are well known sources of limonoids, compounds with insect antifeedant properties. However, it is generally accepted that plants with EFNs, by providing food for ants, get protection from herbivores. It is therefore noteworthy that despite already having a chemical defense against herbivores, a further considerable investment is made by the plant to produce and sustain EFNs. It is suggested that EFN's provide a first line of defense, resulting in the removal or deterring of potential herbivores even before any damage is inflicted on the plant.

P0909

Fungi involved in pelotons colonization in *Vanilla* species from different cultivation systems

Ma. Del Carmen González-Chávez[2], *Andrea Porras-Alfaro*[1], ***Terry J. Torres-Cruz***[1]
1. Western Illinois University
2. Colegio de Postgraduados, Campus Montecillo

Vanilla is an orchid native to Mexico but is widely cultivated in tropical regions; for example, India, China and especially in Madagascar. Despite of the economic importance and pantropical distribution of *Vanilla*, little is known about its endophytic and mycorrhizal fungi. This study involved the evaluation of fungal colonization of *Vanilla* species (*V. planifolia*, *V. pompona*, *V. insignis*, *V. planifolia* var. 'rayada'), the identification of fungi associated to pelotons in terrestrial roots of *Vanilla* plants under flowering stage through culture dependent (fungal isolation from pelotons), and culture independent (sequencing directly from pelotons) techniques. Plants were established in crop systems located in Totonacapan (Puebla and Veracruz states). DNA was extracted directly from 40 pelotons for molecular identification based on ITS rDNA sequencing. Fungi identified directly from pelotons were mainly *Fusarium, Pyrenophora seminiperda* and *Scleroderma aerolatum*. The later fungus has been reported as a typical ectomycorrhizal fungus associated with trees and shrubs. All *Vanilla* species were colonized by pelotons without any apparent influence by crop system. Pelotons in different degradation stages were confirmed by electron microscopy. This research enhances the knowledge related to fungal colonization in *Vanilla* species established under different management systems in Mexico.

Surface pollen deposition in Keibul Lamjao National Park and Loktak Lake of Manipur, Northeast India and their bearing on paleoclimate assessment

Swati Tripathi[1], *Yengkhom Raghumani Singh*[2], *Kamlesh Kumar*[1]
1. Birbal Sahni Institute of Palaeosciences, Lucknow, India.
2. Department of Earth Sciences, Manipur University, Imphal, India.

Manipur is one of the most sensitive area to climate change of the Indo-Burma Range, owing to its unique topographic features and ecosystem. Soil pollen analysis is an important component of paleoecological research, while pollen preservation and the relationship between pollen and vegetation can influence the correct interpretation of fossil pollen spectra. In this paper, 32 surface pollen samples from more or less open-land (Loktak Lake, Ramsar site) and forested (Keibul Lamjao National Park) areas, have been analyzed to determine the relationships between pollen, vegetation and pollen preservation in Bishnupur district of Manipur. The Keibul Lamjao National Park is the only floating national park in the world and famous as a solitary habitat of endangered brow-antlered deer, *Cervus eldi*. The palynodata reflect the tropical moist deciduous and semi-evergreen forest comprising *Syzygium, Schleichera, Mimusops*, Dipterocarpaceae, *Terminalia, Dauabanga, Ilex, Sterculia* and *Lagerstroemia* under a warm and humid climate in response to rainfall variations in the region. Presence of Euphorbiaceae, *Strobilanthes*, *Adhatoda*, Moraceae and *Syzygium* inferred high monsoonal activity in and around the region. We observe a strong relationship between local herbaceous vegetation and pollen data. However, arboreal pollen tends to weaken this 1:1 relationship, due to the differential dispersal and deposition pattern. Physical parameters of the soil (pH, temperature, salinity, conductivity and TDS) were used to understand the preservation of modern pollen taxa, and to identify pollen indicators of tree cover and anthropogenic influence. Pollen frequency decrease sharply when the soil pH values are over 7.1. Frequent pollen clumping is highly significant and suggests their native genesis and entomophilous nature. Thus, an attempt has been initiated to precisely observe the behavioural pattern of modern pollen deposition which could in turn help in assessing the expanse of pastoral practices and the depth of deterioration of pristine forests as well as in the reconstruction of past climate and vegetation shifts in central valley region of Manipur. A correlation of regional palyno-data with other parts of the Indo-Burma Range is very needful for better interpretation.

Late Holocene vegetation change, monsoonal fluctuations and anthropogenic influence in Barak Valley of Assam, Northeast India based on pollen data synthesis

Swati Tripathi
Quaternary Palynology Department, Birbal Sahni Institute of Palaeosciences

Paleoclimate records traversing the past millennium unveil manifestations of two distinct climate anomalies – the Medieval Warm Period (MWP), also known as the Medieval Climate Anomaly (MCA) in the context of tropical and sub-tropical regions, followed by the Little Ice Age (LIA). The occurrence of these warm and cool periods differs from region to region, in terms of timing, duration and magnitude of the temperature anomalies. However, attempts to trace the signature of these anomalies in Southeast Asia are still sparse, despite the fact that this region contains numerous lakes and wetlands that may hold potential sedimentary archives. Thus, the pollen analyses of soil samples from a 90-cm deep sedimentary core from Chatla floodplain of Southern Assam has provided insight into the changing vegetation and climatic scenario in the region during the Late Holocene. The Palyno-investigation has revealed that between 1,470 and 1,200 cal yrs BP, the occurrence of major riparian tree taxa like *Barringtonia, Syzygium, Duabanga* and Sapotaceae along with marshy taxa like

Cyperaceae and *Polygonum* indicates humid climate attributable to strong southwest monsoon. An evidence of agricultural practices evinced in the presence of cereal and other cultural pollen taxa. Later, more humid climate took over during 1,200 and 602 cal yrs BP, as evinced by an exceptional increase in major arboreal group (*Syzygium-Schleichera-Duabanga-Barringtonia-Terminalia*-Moraceae), marshy and aquatics (*Impatiens, Polygonum* and *Lemna*) and annual herbs (Euphorbiaceae and Convolvulaceae) suggesting the consolidation of vegetation around the lake under warm and increased humid climate, which is well corroborated to global MWP that is known between AD 740 and 1,150 worldwide. Between 602 to 387 cal yrs BP, inclination in cereal and other heath land taxa is observed indicating relatively little humid climate, reduction in southwest monsoon precipitation is invoked to explain this which is further supported by a steep fall in major arboreal group, also suggesting an anthropization. From 387 cal yrs BP onwards, decline in arboreal continued with an exponential rise in cereal and shrubby pollen displaying the ongoing landscape changes due to human settlement under warm and relatively dry climate. Thus, in the tropical regions where monsoon plays an important role in determining the regional climate, these temperature anomalies (MWP and LIA) primarily impact monsoonal dynamics and hence are expressed as hydroclimatic variability.

Habitats and growth characteristics of cluster-root-forming *Helicia cochinchinensis* (Proteaceae) in Japan

Hiromi Tsubota[1], *Tomonori Moroishi*[2], *Tadashi Okamura*[3], *Shinji Uchida*[4], *Jun Wasaki*[3]

1. Miyajima Natural Botanical Garden, Graduate School of Science, Hiroshima University

2. Department of Biological Science, Graduate School of Science, Hiroshima University

3. Graduate School of Biosphere Science, Hiroshima University

4. Technical Center, Hiroshima University

The genus *Helicia* (Proteaceae) consists of ca. 100 species of trees and shrubs with its predominant distribution in the Southern Hemisphere. Most species of the genus naturally grow in rainforests in tropical Asia and Australia. Only a single species of the genus *Helicia*, *H. cochinchinensis* Lour., is present in Japan. This represents the northernmost distribution of the genus with the species occurring from southwest Japan to the Indochina Peninsula. *H. cochinchinensis* is a rare species in Japan and listed in some prefectural Red Lists with the status of Near Threatened (NT) or Vulnerable (VU). Recently, we found cluster roots formed by *H. cochinchinensis* at one of the UNESCO World Heritage sites, Miyajima Island (alias Itsukushima), Hiroshima, Japan (Yamauchi *et al.,* 2015). It is still unknown what environmental determinants define the distribution of this cluster-root-forming species. We present here habitats and growth conditions of *H. cochinchinensis* to investigate the growth conditions, morphological properties of roots, and phosphate mobilizing abilities of this species growing in Miyajima Island. Phytosociological data with or without *H. cochinchinensis* trees were obtained from a forest reserve at Miyajima Island and its surrounding protected area. The data were used for the analyses were obtained from over 500 phytosociological stands (Suzuki *et al.,* 1975). Total phosphorus (P) and Olsen P content of soils for *Helicia* habitats were also measured; plant P and N (nitrogen) of leaves were also measured after chemical digestion. Cluster roots and their rhizosphere soils were collected to investigate root morphology and exudates. Ordination and clustering analyses of the phytosociological data showed that the habitat of *H. cochinchinensis* is in the company of some evergreen trees and shrubs such as *Symplocos* spp. Available P in soils with *H. cochinchinensis* ranged from 0.46–3.7 mg-P/kg-soil (Olsen-P). We found cluster roots from P deficit *H. cochinchinensis* in natural and hydroponic conditions. It was shown that acid phosphatase activity was elevated in the rhizosphere soil. Activity staining revealed a higher activity of acid phosphatase in root tips of each rootlet. A strong decrease of pH in the rhizosphere of matured cluster roots was also shown, suggesting that the cluster root enhanced organic acid exudation like other Proteaceae plants. P concentration of leaves of *H. cochinchinensis* was low; those of mature and senesced leaves ranged from 0.34–0.69 mg-P/gDW and 0.15–0.29 mg-P/gDW, respectively. We conclude that the P mobilization by cluster roots supported P uptake from unavailable P in the soil at Miyajima Island. P remobilization from senesced to mature leaves may sustain the growth of *H. cochinchinensis* under P deficient conditions. The ecological and physiological significance will be discussed by the comparison between *H. cochinchinensis* at Miyajima and other Proteaceae plants at Western Australia and Chile.

Seed germination traits in alpine grasslands play a part in species' assembly

Maria Tudela-Isanta[1], *Malaka Wijayasinghe*[1], *Graziano Rossi*[1], *Simone Orseningo*[3], *Eduardo Fernández-Pascual*[2], *Hugh W. Pritchard*[2], *Andrea Mondoni*[1]

1. University of Pavia

2. KEW

3. University of Milan

Alpine environments are characterized by rich and diverse habitats, resulting in many plant species along with their many adaptation mechanisms. Seed germination has shown to play a crucial role in the regeneration and maintenance of such plant communities, though it has been difficult to identify a typical behavior for "alpine germination". There is not any bioregion in the world that we find the steep environmental gradients that are typical in the alpine habitats. These different gradients create a mosaic of microenvironments covered by different plant communities. For this reason, alpine habitats provide an ideal context to assess the role of germination niche in plant distribution. To this end, seeds of 53 species from alpine grasslands belonging siliceous (♯6230 Directive 92/43) and calcareous (♯6170 Directive 92/43) habitats were exposed to different temperature treatments in a controlled laboratory conditions (i.e., 15/5ºC and 25/15ºC, 12-h daily photoperiod after 0, 3 and 5 months of cold wet stratification, and with gibberellic acid). Then, phylogenetic least squares correlations (PGLS) were fitted to assess relationships between germination traits and habitat, chorology, microenvironment and ecological traits. Also, the germination strategies in each habitat were identified by clustering with k-means. As a result, we identified that germination traits are correlated with the species' ecological traits, chorology and microenvironments. In particular, high dormancy scores were identified in the seeds produced by species inhabiting in heaths, growing in moist and low or medium nutrient soils contents and having an Artic-Alpine distribution. Meanwhile, the species with high germinability scores belong mostly to the generalist and inhabit in medium nutrient soils. The habitat analyzed revealed higher germination in the siliceous habitat and three common germination strategies and one habitat-related, though species from calcareous germinate more during the cold stratification. These results highlight the importance of considering germination traits when studying alpine grasslands, because alpine species show different regeneration strategies depending on habitat provenances, species' ecological traits and chorology. The patterns found here may have important implication in developing good practices for restoration and conservation activities in alpine habitat and also for a better understanding of the response of alpine plants in the regeneration from seeds due to global warming.

Quantitative and qualitative foliar flavonoid survey of *Suaeda maritime*, which sink in the sea on high tide

Ayumi Uehara[1,3]*, Hiroaki Setoguchi*[2]*, Tsukasa Iwashina*[3]

1. Division of Life Science and Engineering, School of Science and Engineering, Tokyo Denki University

2. Graduate School of Human and Environmental Studies, Kyoto University

3. Department of Botany, National Museum of Nature and Science

Suaeda maritima (L.) Dumort (Amaranthaceae) is an annual halophytic herb, which is widely distributed in the Northern Hemisphere. This plant grows on coastal sandy land in which partial or whole plant body stay sunk in the seawater on high tide. This plant continually exposed to UV and/or salinity stresses. Flavonoids are important secondary metabolites and those in the leaves act as the protectants to various environment stresses, e.g., UV, poor nutrition, lower temperature and/or seawater. In this study, we investigated the flavonoids accumulation in the leaves of *S. maritime* plant that did not sink in the seawater on high tide. We collected the leaf samples of *S. maritima*, which sink area (sink) or not (non-sink) on high tide, in June, August and November. The MeOH extracts were surveyed by UV-Vis spectrophotometer for total flavonoid content, and were also qualitatively surveyed each flavonoid by HPLC. Their flavonoids were isolated by various chromatographies (CC, TLC, PC and HPLC) and identified by various spectra such as UV and LC-MS *etc*. Moreover, their leaf segments were stained by 2-aminoethyldiphenylborinate, for the observation of flavonoid accumulation with fluorescence microscope. The environmental factors as such EC value and accumulated solar radiation were also surveyed. The flavonoids were significantly accumulated at samples of "non-sink" area. Three major flavonoids were identified as flavonol glycosides, quercetin 3-*O*-rutinoside, 3-*O*-glucoside and isorhamnetin 3-*O*-glucoside, and three flavone glycosides, luteolin 7-*O*-glucuronide, apigenin 7-*O*-glucuronide and chrysoeriol 7-*O*-glucuronide. Their flavonoids were reported from the leaves of *S. maritima* for the first time. They were formerly reported as effective antioxidants in sea buckthorn (*Hippophae* sp.), buckwheat (*Fagopyrum esculentum*) and so on. Flavonoids were qualitatively the same between "non-sink" and "sink" areas. Observation of flavonoids with fluorescence microscope showed the existence of intracellular flavonoids in adaxial side. Soil of "sink" area showed the higher EC values, which mean salt concentration. On the other hand, "non-sink" area showed the higher solar radiation. Thus, we presumed that foliar flavonoids of *S. maritima* were accumulated as UV protectants.

Effects of some heavy metal mixture on mineral nutrient status of an aquatic plant *Tonina* sp. Belem

Mehmet Emin Uras[1]*, Ibrahim Ilker Ozyigit*[1]*, Ugur Sen*[1]*, Recep Vatansever*[1]*, Gamze Gerez*[1]*, Ibrahim Ertugrul Yalcin*[2]

1. Marmara University, Faculty of Science and Arts, Department of Biology, Istanbul, Turkey

2. Bahcesehir University, Faculty of Engineering and Natural Sciences, Department of Molecular Biology and Genetics, Istanbul, Turkey

Heavy metal pollution puts heavy pressure on water and land ecosystems. In water ecosystems, this pressure may negatively affect organism, e.g., reducing the number of organisms especially autotrophs. To determine pollutant types and sources are initial steps in terms of remediation and rehabilitation of polluted areas. In this sense, heavy metal accumulation and mineral element status of *Tonina* sp. Belem have been investigated. Aquatic environment of *Tonina* sp. Belem was artificially contaminated with 100, 200 and 400 µM concentrations of Cd, Cr, Cu and Zn for each and also included a non-treated control group. All plants were supplied by 0.2% Hoagland solution as nutritional media. Then, Ca, Cd, Cr, Cu, F, K, Mg, Na and Zn levels were analyzed by using ICP-OES. It was revealed that concentrations of heavy metals (Cd, Cr, Cu and Zn) were increased in plant leaves and stems while mineral elements (Ca, Fe, K, Mg and Na) were decreased. The lowest and highest levels (mg/kg) for Ca were as 3,021.963 ± 70.11 in stem (400 µM - treated samples) and 9,422.902 ± 199.375 in leaf (in control groups), for Cd as 0.386 ± 0.021 in stem (control) and 52.283 ± 1.338 in leaf (400 µM), for Cr as 1.629 ± 0.032 in stem (control) and 90.007 ± 3.005 in leaf (400 µM), for Cu as 35.082 ± 0.866 in stem (control) and 128.307 ± 4.561 in leaf (400 µM), for Fe as 421.235 ± 6.605 in stem (400 µM) and 1,340.082 ± 22.110 in leaf (control), for K as 3,898.766 ± 45.529 in stem (400 µM) and 1,1286.552 ± 129.367 in leaf (control), for Mg as 1,025.369 ± 26.611 in stem (400 µM) and 5,114.951 ± 135.554 in leaf (control), for Na as 355.835 ± 8.881 in stem (400 µM) and 1,352.811 ± 37.625 in leaf (control), for Zn as 56.924 ± 1.035 in stem (control) and 176.934 ± 4.118 (leaf/400 µM). Treatment with heavy metals has notably affected the uptake and accumulation of other mineral elements. Accumulation of macro elements like Ca, Fe, K and Mg were reduced with accumulation of Cd, Cr, Cu and Zn. In addition, based on control groups, Cd demonstrated the higher accumulation levels in 400 µM-treated leaf (127 times higher) and stem (115 times higher) tissues. In light of obtained results, *Tonina* sp. Belem stood as a good accumulator for Cd.

Salt tolerance mechanism in *Urochondra setulosa*

Elena Voznesenskaya[1], *Nouria Koteyeva*[1], *Anna Berim*[2], *David Gang*[2], *Gerald Edwards*[2]
1. Komarov Botanical Institute
2. Washington State University

Urochondra is a genus of plants in the grass family with the only one known species *Urochondra setulosa*, native to northeastern Africa and southwestern Asia. This species grows in coastal sand dunes, salt marshes and estuaries and has high tolerance to salt. In this study mechanisms of tolerance to salinity in *Urochondra* were analyzed in comparison to *Spartina anglica,* a serious invasive species endemic to natural saltmarsh ecosystems of Britain. The leaf anatomy and ultrastructure of salt glands, pattern of salt excretion, features of gas exchange, accumulation of key photosynthetic enzymes, leaf water content, Na^+ and K^+ accumulation, and osmolality along with levels of some osmolytes and betaine aldehyde dehydrogenase expression, were compared in the two species grown without salt, with 200 mM NaCl, and with 200 mM KCl. Measurements of gas exchange showed photosynthesis in both species had even some stimulation under NaCl treatment while some suppression of photosynthesis was shown under KCl treatment. Both species have distinct ridges on the adaxial leaf side and C_4 type of photosynthesis with Kranz anatomy; abaxial side is flat in *S. anglica* while it is undulated with small ridges in *U. setulosa*. Both species have salt glands on both leaf sides; they are mostly located on the sides of leaf ridges but in *Urochondra* large salt glands are also located on the adaxial leaf side between the ridges above the band of colorless cells. In both species glands are bicellular with basal and cap cells but they have some differences in their positioning and structure. Thus, salt glands are sunken under the leaf epidermis in *S. anglica* and only cap cells are located on the epidermal level and hardly could be seen from the surface. In *Urochondra* all salt glands are located on one level with epidermal cells and represent their modification. Some differences also could be seen in the internal structure of gland cells: while in both species basal cells have intensive development of endoplasmic reticulum and numerous mitochondria in the distal part, the distinctive feature of basal gland cells in *Spartina* is the presence of the longitudinal cell wall labyrinths absent in *Urochondra*. Sodium and potassium ion contents increase about twice during corresponding treatments. Both species increase osmolality in response to compatible solutes accumulation. Under salt treatments they accumulate glycine-betaine (with increasing of betaine aldehyde dehydrogenase expression) and proline while the proline content is significantly higher in *Spartina*. In summary, *U. setulosa* and *S. anglica* show high tolerance to salt in function of photosynthesis, maintenance of water content, and in excretion of salt from leaves; but, they have distinct differences in the positioning and structure of salt glands.

Climate change causes secondary contact of willow species in the Alps – radseq data reveal insights in recent hybridization and introgression patterns on glacier forefields

Susanne Gramlich*, Natascha D. Wagner, Elvira Hoerandl*
Department of Systematics, Biodiversity and Evolution of Plants; Albrecht-Haller-Institute for Plant Sciences; Georg-August-University of Goettingen

Little attention has been paid to the evolutionary consequences of colonization dynamics and succession processes triggered by climate change. The retreat of glaciers due to climate change leaves behind devastated glacier forefields as a novel territory for colonization by pioneer species like willows. Another effect of global warming is that lowland species start to move upwards and colonize higher elevations resulting in overlapping ecological niches of lowland and alpine species. Given the lack of postzygotic crossing barriers due to previous ecological isolation by altitude, this often results in the formation of hybrids. Transgressive segregation in the F2 or later hybrid generations may lead to the formation of novel genotypes that are able to establish in extreme habitats outside the ecological optimum of their parents. Additionally, if hybrids and the parental species co-occur in so-called secondary contact zones, backcrossing can facilitate introgression. This study investigates these processes in the model genus *Salix* by analyzing hybrids that have recently formed on glacier forefields of the European Alps. In the secondary contact zone of the lowland colonizer *S. purpurea* and the subalpine species *S. helvetica* hybrids as well as the parental species were collected. RADseq data were used to analyze the composition of the hybrid population and to study segregation patterns in hybrid offspring raised from seeds that had been collected from naturally pollinated catkins. Our results revealed that most hybrid individuals are F1 hybrids, probably due to the recent emergence of the hybrid population. The offspring of those hybrids mainly consisted of backcrosses with both parental species. Thus, the most likely evolutionary trajectory is introgression of genes between the hybridizing species probably facilitating adaptation to a changing environment.

Genetic validation of Janzen-Connell recruitment patterns of dominant species (*Castanopsis eyrei*) in a subtropical forest of China

Fang Wang[1,2], *Yu Liang*[1], *Walter Durka*[3], *Jianhua Xue*[1], *Wubing*

Xu[1,2], *Xiangcheng Mi*[1], *Keping Ma*[1]
1. State Key Laboratory of Vegetation and Environmental Change, Institute of Botany, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences
3. Department Community Ecology, Helmholtz Centre for Environmental Research - UFZ

Recruitment is an important process affecting community composition and dynamics. The Janzen-Connell hypothesis, as a model describing the process of recruitment, has been considered as an important mechanism of species co-existence and diversity maintenance, which hypothesizes that the offspring dispersed near the mother trees have lower survival rate due to the existence of host-specific enemies and thus make space for other species. Most studies testing Janzen-Connell hypothesis in natural ecosystems, however, based on homo-specific data rather than verified mother-offspring relationship and focused only on seedlings or saplings separately. In this study, twelve microsatellite markers were used to assign parentage of offspring to evaluate the Janzen-Connell effect on seedling recruitment of *Castanopsis eyrei* in a natural subtropical forest. Our results showed that, (1) Janzen-Connell effect was strong in the early life stages of *C. eyrie*; (2) offspring dispersal distance kernels shifted across life stages, implying a decreased Janzen-Connell effect from seedlings to adults; (3) the spatial genetic autocorrelation was highest for seedlings and decreased for later offspring life stages, which indicated that offspring with close genetic similarity tended to be excluded during early life stages.

Vascular plants in tourist area of Lushan Mountain: Status, threats and conservation

Hui Wang
Huazhong Agricultural University

Lushan Mountain was declared World Geopark and hotspot of biodiversity. As a great tourist resort for natural landscape and historic culture, Lushan may be disturbed by human activities especially tourism and plant introductions. In order to illustrate the conservation status of rare species and influence of human disturbance on plant diversity, we carried out an extension survey on vascular plants along main tourism routes in the Lushan Mountain. A total of 572 species were recorded, belonging to 118 families. Dominant species and constructive species belong to Lauraceae (13 species), Fagaceae (11 species), Camelliaceae (11 species) and Magnoliaceae (9 species). Ancient tree species, such as *Liriodendron chinense*, *Ginkgo biloba* and *Metasequoia glyptostroboides*, were well preserved. At least 158 species were endemic to China and 3 of them were endemic to Lushan. 7 species were endangered and 15 species were near threatened. 76 introduced species had established in surveyed area (represented by species of Compositae, Iridaceae and Scrophulariaceae), and 26 of them were invasive species. For the surveyed area, most of the forest community are well conserved, but more attention should be paid on the possible influences of plant introduction and plantation on native plants.

Patterns of urban development and socio-economic factors drive plant diversity- A case study in Shanghai, China

Meng Wang[1], *Guanhai Xiang*[1], *Haiyu Li*[1], *Junxiang Li*[1,2]
1. East China Normal University
2. Shanghai Key Laboratory of Urbanization and Eco-restoration

Urbanization is one of the major causes for plant diversity loss. Cities have been studied as hotspots for local species conservation. The patterns of urban sprawl is drastic and different depending on urban development and urban structure. In this paper, we try to test the effects of urban development and urban structure on plant diversity. 251 sample sites generated using stratified random sampling method covered the entire city of Shanghai which is composed of 10 districts. Changxing Island (belongs to Baoshan) and Chongming Island are all excluded in our study. Plant diversity index including α diversity (Species richness, Shannon-wiener diversity and Heip evenness) and β diversity (species accumulation rate) were calculated. Each administration districts were used as a city unit. We choose the distance to each district center from samples points and the socio-economic factors of each districts as the proxy to measure the urban development and urban structure. Linear Regression analyses, stepwise regression analyses, Sample-based rarefaction curve, ANOVA (Followed by a Tukey's test) analyses were conducted between plant diversity and variables factors. Our findings are: 676 Vascular plant species were recorded in 251 plots and the percentage of exotic species richness is 60.65%. The plant diversity indices are different in different administration districts of Shanghai. Of all the samples in different district, all plant richness (62.85 ± 12.66) and exotic plant richness (31.46 ± 8.62) both are the highest in Minhang districts. The richness of all plant (46.47 ± 12.36) and perennial herbaceous (11 ± 3.73) both are the lowest in Qingpu district. Woody plant richness (18.87 ± 7.33) and perennial herbaceous richness (16.9 ± 4.72) both are the highest in Urban center district. On the contrary, the annual herbaceous richness (15.03 ± 7.01) is significantly lowest in urban center district ($P < 0.05$). Native plant richness didn't show any significant differences in all districts, but it is lowest in urban center (26.97 ± 7.89). Shannon-wiener diversity (22.18 ± 8.05; 11.61 ± 5.72) and Heip evenness (0.37 ± 0.08; 0.19 ± 0.11) both are highest in Jinshan district and lowest in Jiading district. β diversity of the whole shanghai is lowest (β diversity = 0.2917) compare to each districts and showed a severe homogenization phenomenon. Followed by Pudong district (β diversity = 0.3877), the area of which is the biggest. The fitting between the distance to district center and α diversity indices exhibited significant linear, log and quadratic polynomial relationship depends on different plant groups. It showed that the pattern of urban development is a force driving plant composition and distribution in different districts. Moreover, of all the socio-economic factors, we also demonstrated that the total areas and built-up area of each district, GDP, Total Investment in fixed assets, Investment in real estate both significantly influence the β diversity respectively ($P < 0.05$) and GDP is the most explanatory variable. As a case study, this is the first time to explore the effects of urban development, urban sprawl thus the socio-economic factors on urban plant composition and homogenization process in regional scale. We suggest that the decision makers and urban designers should recognize the integral role of cities in driving the composition and distribution of plant diversity in future urban planning and investment

Environmental divergence and difference of stomatal characteristics among mainly *Picea* species in China

***Minghao Wang**, Changming Zhao*
Lanzhou University

Ecological speciation played a prominent role in speciation and reflected as closely related species developed both environmental vicariance and morphological differences. But previous analysis of ecological speciation seldom took phenotypic data into account. With an example from Chinese mainly *Picea* species, we collected their geolocation and built phylogenetic tree, used SEEVA to test the correlations between the ecological divergences and the phylogenetic splits. And then, we discussed the differentiation of stomatal characteristics by leaf anatomy and the relationship between stomatal features and environment divergences for *Picea* species in China. The result indicated that temperature variables (maximum temperature of warmest month and temperature annual range) splited at basal nodes, precipitation variables (annual precipitation and precipitation of driest quarter) splited at terminal nodes following the uplift of Qinghai-Tibet Plateau. Linear stomatal densities (LSD), number of stomatal rows (N), pore depth (L) and mean maximum stomatal theoretical area ($S_{\max}$) of species displayed significant difference on both surfaces in common garden. LSD was positively correlated with N on both two surfaces. Furthermore, relationship between stomatal characteristics and annual precipitation of *P. crassifolia, P. meyeri, P. asperata* and *P. koraiensis* reflected select pressure of stomata that species diverged to drier environment with higher stomatal density and smaller stomata. These results might imply that the climate influnce of QTP uplift could explain the ecological divergence of species during this geological time. Stomatal characteristics might be selected by environment variables at least in *Picea*.

Accumulation of heavy metals in current-year old needles of *Pinus tabuliformis* Carrière. and *Pinus bungeana* Zucc. in different atmospheric environment

***Runxi Wang**, Xin Wang, Hongrui Wu, Lihong Zu, Fuchen Shi*
College of Life Sciences, Nankai University

Heavy metals in different atmospheric environment had adverse impact on green-plants growing in varying degrees. In this study, the concentrations of Cu, Mn, Zn and Cd in current-year old needles of *Pinus tabuliformis* Carrière. and *Pinus bungeana* Zucc. that are widely planted in northern China, were determined. The resistance indexes: malonic aldehyde (MDA), soluble protein, soluble sugar, and free proline levels were also determined. The Pearson coefficients between the resistance indexes and the concentrations of heavy metals were analyzed to compare the abilities of two plants to accumulate heavy metals and their resistance characteristics. The topsoil and unwashed and washed needles were from urban, suburban and rural sites in Tianjin where the atmospherc conditions are significantly different according to the environmental monitoring results. The results indicated that there is a significant trend among the concentrations of heavy metals in current-year old needles and topsoil as follows: urban areas > suburban areas > rural areas ($P < 0.05$). In urban areas, the Mn concentration in *P. tabuliformis* and *P. bungeana* were as high as 122.72 $\text{mg}\cdot\text{kg}^{-1}$ and 128.91 $\text{mg}\cdot\text{kg}^{-1}$ which were almost as 20 times as in rural areas. Compared with *P. tabuliformis*, the accumulation of Mn and Zn were higher in *P. bungeana*, but as to Cu and Cd no significant differences were found between the two species. Pearson correlation coefficients among the absorption of Cu, Mn, Zn and Cd in needles are at quite a high level ($P < 0.01$). The concentrations of heavy metals in the unwashed needles were higher than that in the washed needles in the urban and suburban sites, which indicated that the surface of the needles could adsorb many heavy metals. The MDA, soluble protein, soluble sugar, and free proline contents increased as the concentrations of heavy metal rose along the rural-urban gradient, and were highly correlated with the concentrations of plant heavy metal in both *P. tabuliformis* and *P. bungeana*. In conclusion, high concentrations of Cu, Mn, Zn and Cd in aerial parts were mostly a consequence of atmospheric deposition, though other factors could affect this accumulation in plants. *P. tabuliformis* and *P. bungeana* could absorb and accumulate heavy metals, mainly through increased physiological resistance to stress.

NaCl improved the nutritional status in *Zygophyllum xanthoxylum* responding to drought compared with *Arabidopsis thaliana*

***Wenying Wang**, Weiwei Chai, Changyu Zhao, Qing Ma, Suomin Wang*
State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University

Zygophyllum xanthoxylum is a salt-accumulating xerophytic species with excellent adaptability to adverse arid environments. Our previous studies showed that *Z. xanthoxylum* absorbed, from low-salinity soil, a great quantity of Na^+ that transported to leaves and efficiently compartmentalized into vacuoles as an osmoregulatory substance under arid field conditions. Further investigations revealed that *Z. xanthoxylum* responded to salt with increased growth and moreover, became more tolerant to drought in the presence of moderate salinity, with improved photosynthesis and water status, is a totally different strategy from the glycophytes. To further reveal the special mechanisms underlying how Na^+ accumulation stimulate the growth and improves the drought resistance of *Z. xanthoxylum*, in this work, the effects of NaCl on the nutritional status in *Z. xanthoxylum* subjected to osmotic stress were investigated compared to that in the typical glycophyte *Arabidopsis thaliana*. Results showed that compared with control, either 50 mM NaCl or osmotic stress (-0.5 MPa) significantly increased the Na^+ concentration in leaves and roots in *Z. xanthoxylum*; while 5 mM NaCl had no significant effect on the Na^+ concentration in *A. thaliana*, and osmotic stress significantly decreased the Na^+ concentration in shoots in *A. thaliana*. Under osmotic stress, the addition of 50 mM NaCl significantly increased Na^+ concentration in leaves and roots by 6.2 and 3.7 fold in *Z. xanthoxylum*, resulting in improved growth with enhanced biomass and tissue water content; nevertheless, such beneficial effect was not observed in *A. thaliana* treated with 5 mM NaCl under osmotic stress. Compared to the control, root and leaf K^+ concentrations remained unchanged in *Z. xanthoxylum* exposed to osmotic stress with or without additional 50 mM NaCl; in contrast, osmotic stress disturbed cellular K^+ homeostasis in *A. thaliana*, with a significant decrease in shoots K^+ concentrations in the presence of 5 mM NaCl. Moreover, 50 mM NaCl promoted the absorption and accumulation of N, P, Fe, Si, Ca^{2+} and Mg^{2+} in *Z. xanthoxylum*, whereas these nutrients in *A. thaliana*, treated with 5 mM NaCl, almost unchanged. Furthermore, compared with -0.5 MPa osmotic stress, osmotic stress plus 50 mM NaCl significantly increase the concentrations of N, P and Si in whole plant, the Ca^{2+}, Mg^{2+} in leaves and Fe in roots of *Z. xanthoxylum*. However, no differences on the concentrations of these nutrients were observed in *A. thaliana* treated with osmotic stress plus 5 mM NaCl, compared with that under osmotic stress. These results further highlighted the positive roles of NaCl in drought resistance of *Z. xanthoxylum* probably due to the beneficial effect on the nutritional status, including maintaining stable intracellular K^+ and enhancing the concentrations of N, P, Fe, Si, Ca^{2+} and Mg^{2+} in plants.

Aerosol increases both sunlit and shaded leaf photosynthesis rate but with different mechanisms

Zhenhua Wang[1,2], *Bin Wang*[1,2], *Xin Wang*[1,2], *Lingli Liu*[1,2]
1. Institute of Botany, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Aerosol pollution is one of the most serious environmental challenges facing by many regions around the world. Previous studies found aerosols could increase carbon sequestration in many ecosystems, but the underlying mechanism was still in debate. We conducted a field experiment to assess the response of sunlit and shaded leaf carbon assimilation to aerosol-loadings during the growing season in 2014 and 2015 in Beijing. Our study found that averaged over daytime hours, aerosols decreased the sunlit leaf temperature by 2.71 ± 0.22°C, increased the photosynthetically active radiation (PAR) by 113.3 ± 18.6% within the canopy but reduced the global radiation outside the canopy by 10.7 ± 1.2%. Meanwhile, both sunlit and shaded leaf net photosynthesis rate (Pn) increased during most of daytime, with the mean daily Pn of sunlit leaf and shaded leaf enhanced by $2.08 \pm 0.23\ \mu mol\ CO_2\ m^{-2}\ s^{-1}$ and $0.87 \pm 0.15\ \mu mol\ CO_2\ m^{-2}\ s^{-1}$, respectively. And the light use efficiency of both sunlit and shaded leaf increased significantly. Our study further demonstrated that, for sunlit leaf, the increment in mean daily Pn was mainly attributed to the mitigations of the high temperature inhibition, whereas for shaded leaf, the high Pn was due to the alleviation of the light limitation. Overall, our study suggests that the aerosol's cooling effect via enhancing plant C assimilation should be taken into account seriously as well as its radiation effect in the future climate change research.

Asymmetrical mating pattern and reproductive success of heterodichogamouos tree *Machilus thunbergii*.

Shuntaro Watanabe[1], *Yuko Kaneko*[2], *Koh-Ichi Takakura*[3], *Naohiko Noma*[3], *Nishida Takayoshi*[3]
1. Kyoto University
2. Toyo University
3. The University of Shiga prefecture

A substantial proportion of plant species arrange the female and male organs at different locations or timings. Such species sometimes exhibit two or more floral sexual morphs that differ in reproductive traits, which can promote pollination between morphs. Heterodichogamy is defined as the presence of two flower morphs that exhibit male and female functions at different times among individuals within a population, and is regarded as a temporal analogy to heterostyly. As is the case with heterostyly, heterodichogamy is regarded as an adaptation to promote outbreeding through enhanced inter-morph pollination, together with 1:1 ESS morph ratio. However, in highly fragmented populations, the morph ratio may be more likely to be biased by chance alone. In such situations, we address the following hypotheses: (1) the intra-morph mating is more frequent within majority-morph trees than within minority-morph trees, (2) the proportion of selfing is greater in majority-morph trees than in minority-morph trees, and (3) the average seed-set rate is greater for the minority morph trees based on pollen availability of the opposite morph. After confirming heterodichogamy by observing flowering behavior and phenology, we tested these hypotheses in a highly fragmented population of *Machilus thunbergii*, a broad-leaved evergreen laurel tree, using paternity analysis and direct observation. Our observations confirmed that *M. thunbergii* is heterodichogamous, consisting of two types of protogynous and bisexual flowers; a morning female (MF)–afternoon male morph and a morning male (MM)–afternoon female morph at the individual level. Sexual expression of the two morphs was highly synchronized and reciprocal. The estimated flower number was 2.02 times biased to MM in the study site. Paternity analysis revealed that heterodichogamy in *M. thunbergii* promoted outbreeding via inter-morph mating and restricted selfing. The probability of occurrence of intra-morph mating was 40% of that of inter-morph mating. We also confirmed following results (1) the intra-morph mating rate was significantly higher in mother trees of the majority-morph than in those of the minority-morph, (2) the selfing rate observed in the seed stage was not significantly different between the two sexual morphs, but the percentages of immature seeds was higher in mother trees of the majority-morph than those in the minority-morph, (3) the minority morph trees showed significantly higher seed-set rate than did the majority morph trees. These results indicate that (1) heterodichogamy in *M. thunbergii* efficiently promotes outcrossing and restricts selfing, (2) owing to the early-stage inbreeding depression which acts on the gamete to seed life stages, the majority morph mothers, suffering a shortage of the opposite morph pollen, could compensate partly the reduced reproductive success by intra-morph mating rather than by selfing, (3) negative-frequency dependent selection may be involved for maintenance of the two morphs.

Identification of an ABC transporter involved in cuticular wax accumulation for xerophyte *Zygophyllum xanthoxylum* responding to abiotic stresses

***Li Wei**, Jing Zhang, Pei Wang, Ye Tian, Qing Ma, Jin-Lin Zhang, Ai-Ke Bao, Suo-Min Wang*
State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University

Cuticular wax is a key component of the plant cuticle, which covers the outer surface of all the primary aerial organs of plants, and serves as a waterproof barrier that protects plants from abiotic stresses, such as salt, drought and heat. However, most researches have focused on glycophytes with less developed cuticular wax. *Zygophyllum xanthoxylum*, a succulent xerophyte growing in desert areas of northwest China and Inner Mongolia, possesses a thick cuticle in their leaves. Therefore, this xerophyte species is an ideal material to study the function of cuticular wax in stress adaptation. Several members of ATP-binding cassette (ABC) transporters have been proved to be involved in the export of cuticular lipid from the plasma membrane into the apoplast in glycophytes. In this study, we cloned and characterized *ZxABCG11* from *Z. xanthoxylum*. The results showed that the full length of *ZxABCG11* was 2,416 bp, including ORF 2,100 bp, which encoded 700 amino acids. The amino acid sequence contains ABC transporters characteristic motif, the nucleic acid binding domain, transmembrane domain composed of six hydrophobic alpha helixes and shared high similarity (73%-85%) with the identified ABCG11 of the other plant species. The quantitative real-time PCR analysis revealed that *ZxABCG11* was preferentially expressed in young leaves. And salt treatment (50 mM NaCl), osmotic (-0.5 MPa) and heat (35 °C) stresses significantly induced the expression of *ZxABCG11* in a short time period (0.5-6 h after treatments). The transcript abundance of *ZxABCG11* raised to its maximum amount under the dual stresses of osmotic and heat, which was 8 times compared to the control, indicating that ZxABCG11 possibly plays an important role in response to different stress. The SEM analysis showed wax crystal density increased by salt treatments (50 and 150 mM NaCl), osmotic and heat stresses in the middle layer leaves. Taken together, our results indicate that the expression levels of *ABCG11* are strongly associated with cuticular wax accumulation in *Z. xanthoxylum* under abiotic stresses.

The U.S. National Vegetation Classification for dry coniferous forests and woodlands of the southern Appalachian Mountains: A reassessment

***Thomas Wentworth**[1], Raafiah Haroon[2], Kimberly Israel[3], Michael Lee[4], Brooklynn Newberry[1], Robert Peet[4], Michael Schafale[5], Alan Weakley[4]*
1. North Carolina State University
2. Perll Diagnostics, Inc.
3. North Carolina Division of Parks and Recreation
4. University of North Carolina at Chapel Hill
5. NC Department of Natural and Cultural Resources

Xeric to subxeric coniferous forests and woodlands of the southern Appalachian Mountains with a substantial component of yellow pines (*Pinus echinata*, *P. pungens*, *P. rigida*, and *P. virginiana*) have declined in area during recent decades because of fire suppression, drought, and outbreaks of southern pine beetle. The net result of these processes has been a shift in many yellow pine communities to dominance by drought-tolerant broadleaved trees and shrubs. The possibility of a change in the global conservation status of yellow pine communities from vulnerable to imperiled prompted us to reconsider their existing classification, given the important supporting role of classification in conservation efforts. Even prior to widespread decline of yellow pine communities, classification efforts were hampered by their dynamic nature and their tendency to intergrade with a variety of other communities. We have been exploring numerical classification of a dataset consisting of over 1,000 permanent plot records extracted from the Carolina Vegetation Survey database, selected using criteria of location in the southern Appalachian region and having at least 10% combined cover of the four yellow pines. After homogenizing species' taxonomic treatments and identifying outlier stands, we have used a combination of a priori assignments and quantitative methods (hierarchical cluster analysis and fuzzy clustering) to identify subsets of plot records corresponding best to the principal associations currently in use for these communities in the US National Vegetation Classification (USNVC). Our current focus is on the utility of a core group of 11 USNVC associations currently recognized and the potential need to modify the existing classification structure. Ongoing analyses include numerical classification, ordination, determination of diagnostic species, and the identification of environmental constraints and dynamic trends affecting the distribution of southern Appalachian yellow pine communities.

To be on the safe site – ungroomed spots on the bee's body and their importance for pollination

***Petra Wester**, Laura Koch, Klaus Lunau*
Institute of Sensory Ecology, Heinrich-Heine-University

Bees, by far the most important group of pollinators, visit flowers to collect nectar and pollen in large quantities. Pollen, on the one hand, serves as food provision in bees, and on the other hand, pollen is essential for the plants' reproduction, serving as a transport container for male genetic information. Pollen is expensive, and, different to nectar, emptied pollen resources cannot be refilled. Collected pollen that has been stored in the bees' transport organs is lost for the flowers' pollination. It has been hypothesized that specific body areas, that bees cannot groom, serve as 'safe sites' for pollen transfer between flowers. For the first time, we experimentally demonstrate the position, area and amount of pollen grains on safe sites at the examples of the Western Honeybee *Apis mellifera* and the Buff-tailed Bumblebee *Bombus terrestris*. For that purpose, we combined artificial contamination of the bees' body with pine or sunflower pollen and observations of the subsequent bees' grooming. We found localised safe sites on the forehead, the dorsal thorax and waist, and the dorsal and ventral abdomen. These areas were not or less groomed by the bees' legs. A particularly large amount of pollen was found on the waist, followed by the dorsal areas of thorax and abdomen. At the example of *Salvia pratensis*, *S. officinalis* and *Borago officinalis*, we experimentally demonstrated using fluorescent dye as a pollen substitute that the flowers' pollen-sacs and stigma contact identical distinct safe sites. This provides evidence that pollen deposition on safe sites is more likely to be transferred to intraspecific floral stigmas by pollen-collecting bees. Future research will demonstrate the significance of safe sites under field conditions.

Structural equation modelling reveals winter sensitivity influencing species richness and community composition of mangrove forests across China

Yingtong Wu, *Zijian Huang, Shixiao Yu*
Sun Yat-sen University

Mangrove forests have been considered as "coast guard" and essential carbon sink. However, ecological conservation of mangrove ecosystems is challenged by global climate change. Thus, it is urgent to understand the effects of climatic conditions on both species richness and community composition in mangrove forests. In this research, we investigated the distribution pattern of true mangrove species across coastal China and explored the effects of abiotic environmental factors on species richness and community composition. Our study aims to address the following questions: (1) What is the spatial pattern of mangrove species richness and composition in China; (2) what and how environmental factors dictates its local species richness and community composition in mangrove ecosystems. To answer these questions, we collected occurrence records of true mangrove species in China from peer-reviewed articles. Species composition was indicated using non-metric multidimensional scaling (NMDS) and structural equation modelling was used to study the interactive effects of geological location, seasonal air temperature, precipitation, sea water temperature and salinity on species richness and community composition. Our results revealed the decrease of species richness with increasing latitudes and decreasing mean annual temperature. Structural equation modelling identified direct negative effect of latitude on species composition, as well as its indirect effects through winter air temperature, winter precipitation and winter sea water temperature. The model also indicated that both the richness and composition of mangrove forests were sensitive to winter environmental conditions, rather than summer ones. Our findings implies the potential shift of species richness and species composition in mangrove forests within the context of climate change. On the other hand, properly-managed reforestation of mangrove forests should be supported by species distribution modelling and future climate predictions.

Phenotypic selection on flowering phenology and pollination efficiency trait among *Primula* populations

Yun Wu[1], *Qing-Jun Li*[2]
1. Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences
2. Laboratory of Ecology and Evolutionary Biology, Yunnan University

Phenotypic selection on floral traits has largely been attributed to in plant-pollinator interactions. However, the strength of this link has rarely been ascertained with actual pollinators. We conducted pollinator observations and estimated selection through female fitness on flowering phenology and floral traits among two *Primula secundiflora* populations. We quantified pollinator-mediated selection by subtracting estimates of selection gradients of plants receiving supplemental hand pollination from plants receiving open pollination. There was directional selection for earlier flowering start at population where the dominant pollinators were syrphid flies, and flowering phenology was subjected to stabilize quadratic selection, too. However, later flowering start date was significant selected at population where the dominant pollinators were legitimate bumblebees and 'nectar robbers', and flowering phenology was subjected to disruptive quadratic selection. Wider tube entrance diameter was selected at both populations, but the strength of selection was stronger at population where the dominant pollinators were syrphid flies. Pollinator-mediated selection explained most of the among-population variations in the strength of directional selection on flowering phenology and tube entrance diameter. Our results suggested the important influence of pollinator-mediated selection on floral evolution. Variations in pollinator assemblages not only resulted in variation in the direction of selection, but also the strength of selection on floral traits.

Biomass allocation ratios in temperate lianas: A test of the Darwin's hypothesis

Tomasz P. Wyka
Adam Mickiewicz University in Poznań, Faculty of Biology, ul. Umultowska 89,61-614 Poznań, Poland

Climbers are a diverse group of plants that are incapable of autonomuos vertical growth and therefore must rely on external support. For this reason they have been nicked "structural parasites". According to Darwin, the evolution of this growth form from self-supporting plants has been driven by the benefits of increasing biomass investment in leaves. Such shift in allocation was made possible by reduced investment of biomass in the construction of stems leading to lower cost of support. Although available studies indeed show higher leaf to stem biomass ratios in climbing vs. self-supporting plants, they often fail to account for the effect of plant size on biomass allocation patterns. Moreover, there is a shortage of studies that would account for biomass of the entire plant, including the root system. To test the Darwin's hypothesis on a whole-plant basis, we cultivated 5 species of temperate lianas and 5 species of shrubs belonging to the same families in large 120 L containers. Entire plants were harvested over three growth seasons and separated into principal organ fractions. Our analysis, strenghten by literature data, confirmed that climbers often achieve larger leaf mass fraction in comparison with self-supporting species. Combined with lower leaf-mass-per area (LMA; g m^{-2}) index of individual leaves in climbers, this leads to a greater ratio of plant leaf area to whole-plant biomass (leaf-area-ratio, LAR; m^{-2} g). Such biomass allocation pattern, together with the high foliar nitrogen content is conducive to high biomass productivity and fast growth, and facilitates the dominance of climbers in sufficiently productive habitats.

Sequence polymorphisms at the pseudophosphatase *RDO5* underlie natural variation in dormancy caused by the *DOG18* QTL in *Arabidopsis*

Yong Xiang

Shenzhen agricultural Genomic Research Institute, CAAS

Seed dormancy controls the timing of germination, which regulates the adaptation of plants to their environment and influences agricultural production. The time of germination is under strong natural selection and shows variation within species due to local adaptation. The identification of genes underlying dormancy quantitative trait loci (QTL) is a major scientific challenge, which is relevant for agricultural and ecological goals. In this study, we describe the identification of the *DELAY OF GERMINATION 18* (*DOG18*) QTL, which was identified as a factor in natural variation for seed dormancy in *Arabidopsis thaliana*. *DOG18* encodes a member of the PP2C gene family, which we previously identified as the *REDUCED DORMANCY 5* (*RDO5*) gene. RDO5 alters the seed phosphoproteome but does not have detectable phosphatase activity, suggesting that it functions as a pseudophosphatase. *DOG18*/*RDO5* shows a relatively high frequency of loss-of-function alleles in natural accessions restricted to Western Europe. The loss of dormancy in these loss-of-function alleles can be compensated by genetic factors like *DOG1* and *DOG6*, and by environmental factors such as low temperature.

Reconstructing the vegetation succession and climatic change in Beijing since Holocene

Gan Xie

State Key Laboratory of Systematic and Evolutionary Botany Institute of Botany, Chinese Academy of Sciences

Beijing, the ancient and modern capital of China, is a hot spot for studying the oriental human evolution and development of civilization. Undoubtedly, Holocene climatic fluctuations and vegetation successions played a key role in the survival and advancement of humans lived there. However, lack of quantitative climatic data inhibits us to understand the degree of progress on climate change and its ecological impacts in Beijing during Holocene. Here we have reviewed and reconstructed the vegetation succession and climate change, and illustrated ecology landscapes in plain and montane parts of Beijing during the Holocene by applying published pollen data. New climatic data portray that the mean annual temperature in Beijing decreased from the beginning of Holocene, then increased after reached its nadir at 8,000-5,500 cal yr B. P.; while mean annual precipitation increased from the earliest Holocene, and decreased after reached its peak at 9,500-8,000 cal yr B. P.. Quantitatively comparison with other units in China, MAP in Beijing, East Asian Monsoon Region, was 400-600 mm comparatively lower than Haligu and Xingyun Lake, Yunnan Provence, South Asian Monson Region, and was 200-400 mm higher than Tianchi Lake, Gansu Province, Gonghai Lake, Shanxi Provence and Daihai Lake, Inner Mongolia which falls in the Semi-arid Region in China. The increment of mean maximum monthly precipitation (about 25% higher in the current than in the late Holocene) indicated, the rainfalls in Beijing is strengthening in summer and suggested the Beijing government to prevent geological disasters in the montane region of Beijing in summer. These findings not only promote the comparing and understanding of the differences in climate changes between Beijing and other units in China and even in global since Holocene, but have potential for guiding the Beijing government to deal with the climatic and environmental changes in the future.

Large- and fine-scale population structure of ectimycorrhizal fungal *Floccularia luteo-virens* in Qinghai-Tibet Plateau

Rui Xing

Northwest Institute of Plateau Biology, Chinese Academy of Sciences

Ectomycorrhizal fungi (ECM fungi) plays a key role in the terrestrial ecosystem. Currently, the population genetic structure study of ECM focuses on the number of genotypes and their spatial distribution. The underlying mechanisms that lead to the generation and maintenance of these genotypes remain unclear. The ECM fungal life cycle is generally composed of two processes: sexual reproduction and vegetative mycelial extension. The balance between those two processes is one of the most important factor that influence the distribution pattern of ECM. The most effective way to dissect the secret of ECM reproduction is to examine the genets. In this proposed grant, we developed new SSR markers for *Floccularia luteo-virens*, a wildly distributed ECM fungi on the meadow of Qinghai-Tibet Plateau to reveals the distribution pattern among large- and fine-scale. For large-scale study 404 individuals of *F. luteo-virens* from 23 geographically separate populations were analyzed using eight pairs of SSR markers. The average number of alleles among nine populations was 28.65 with a range from 20 to 38. The mean observed (H_O) and expected (H_E) heterozygosity ranged from 0.446 to 0.501 and from 0.499 to 0.554, respectively. An analysis of molecular variance (AMOVA) showed that most genetic variation occurred within populations (83.32%). The mean value of F_{ST} (0.176) suggested low genetic differentiation among populations. The 23 studied populations were divided into two main clusters based on the NJ dendrogram, which was also confirmed by STRUCTURE analysis. For fine-scale research more 200 individuals were collected in two years from three plots. The relative between above- and blow-ground genets, the reproductive characteristic, genets dynamics and gene flow of this species were invested. This research will shed light on the ecological function, reproductive strategy and conservation. Furthermore, the knowledge gained from this study can be useful for understanding the function and diversity of the ECMs under the grassland ecosystem.

Lead tolerance mechanism in roots of *Typha orientalis* presl:

subcellular distribution, oxidative effects and nutrients

Xiaoying Xu, *Yikun Xu, Yingen Jin*
Yangzhou University

In order to investigate the phytoremediation potential of *Typha orientalis* to remove Pb^{2+} from contaminated water, the laboratory experiments were designed to evaluate the responses induced by Pb^{2+} (0.25-2 mM) in *T. orientalis* roots over a period of 10 days. The accumulation of Pb in subcellular fractions decreased in the order of cell wall > organelle > soluble fraction. Most of Pb in cells was located in cell wall and membrane system. The contents of K and Ca declined in *T. orientalis* roots under Pb^{2+} stress, but there was an opposite effect for some mineral elements (Mg, Cu, Zn and Fe). Meanwhile, the level of H_2O_2 increased in a concentration dependent manner, which induced oxidative stress. However, significant reduction in the levels of $O_2^{\cdot -}$ and MDA were observed for all Pb^{2+} concentrations. These results indicated that Pb^{2+} was toxic to *T. orientalis* in consideration of inducing oxidative stress and breaking the balance of mineral elements. But *T. orientalis* was also able to resist Pb^{2+} caused damage through the immobilization mechanism, which involved in the cell wall and membrane system.

Ecological stoichiometry and habitat heterogeneity of different land use types in a subtropical karst trough valley of Guizhou Province, southwestern China

Xin Xu, *Yue Xu, Jian Ni*
State Key Laboratory of Environmental Geochemistry, Insitute of Geochemistry, Chinese Academy of Sciences

A 30 m × 200 m plot was established on both sides of the karst trough valley along an altitudinal gradient in Langxi small watershed, Yinjiang county, Guizhou province. Five land use types were chosen from the top to the bottom of the valley: the evergreen and deciduous broadleaved mixed forest, *Pinus massoniana* plantation, throne shrubland and tussock, orchard garden and rice crop field. Key characteristics of plant community, soil property, topography and micro-habitat were chosen to study the relationship between the spatial variability of soil nutrients and plant ecological stoichiometry by using the Kriging interpolation, principal component analysis (PCA), cluster analysis and canonical correspondence analysis (CCA). Results showed that the contents and spatial distribution of nutrients were different in different land use patterns and different types of micro-topography. The C, N and P contents of both plant and soil had significant differences among different vegetation types. With the degradation of vegetation, the pool and spatial distribution of soil nutrients changed correspondingly. High correlation existed between vegetation types, soil physicochemical properties and micro-topography, indicating that spatial distributions and variability of soil nutrients were mainly affected by topographic factors and habitat heterogeneities. In addition, the spatial distribution of soil nutrients has an important impact on plant ecological stoichiometry and tree species distribution.

Early Pleistocene floral connection between Japan and Taiwan across the Ryukyu Islands—Plant fossils from the Katanoyama site in Tanegashima Island

Atsushi Yabe[1], *Toshiyuki Fujiki*[2], *Eunkyoung Jeong*[3]
1. Department of Geology and Paleontology, National Museum of Nature and Science
2. Faculty of Science, Okayama University of Science
3. Division of Biological Sciences, Chonbuk National University

The Ryukyu Islands, comprising approximately 190 islands, are a chain of islands stretching from southwest Kyushu to Taiwan along the Okinawa Trough to the north-west and the Ryukyu Trench to the south-east. These islands are known to be connected to Eurasian continents, Taiwan, as well as Japanese mainland before the rifting of the Okinawa Trough during the Pliocene–Pleistocene and have played important roles in the dispersal of land animals and plants. Based on molecular phylogeographic studies, extant faunas and floras of these islands are assumed to be created by a mixture of several different origins with different dispersal routes during different times. However, fossil records of these islands are still limited and do not contribute much to the discussion on the origin of their faunal and floral compositions. We investigated the Early Pleistocene plant fossil assemblage from the Katanoyama Member of the Masuda Formation in Tanegashima Island, which is located at the northern end of the archipelago, to understand the floristic connection between Japan and Taiwan across the Ryukyu Islands. The age of the plant-bearing deposits are assumed to be 1.3 Ma, a time period slightly after the opening of the Okinawa Trough. The Katanoyama Member has been well known to yield fishes (fresh water and marine), land mammals, reptiles, crabs, shells, as well as land and freshwater plants, which were transported to the coastal shallow marine environment. Reinvestigation of previously and newly collected materials revealed various plant mega- and microfossils (pollen and spores). A preliminary study of these materials revealed the presence of three different components in this assemblage: 1) those common to the modern day Tanegashima; 2) those common to mountain vegetation in Kyushu and Yakushima Islands; and 3) those common to mountain vegetation in Taiwan. The first component includes evergreen species belonging to the family Fagaceae (*Quercus* (*Cyclobalanopsis*) spp.) and Lauraceae (*Machilus thunbergii*), which together with deciduous oaks (*Quercus phillyraeoides*) and two-needle pine (*Pinus* cf. *thunbergii*), comprise the modern day coastal vegetation. The second component contains several conifer species such as *Abies firma*, *Tsuga sieboldii*, *Picea* sp. (Pinaceae), *Cryptomeria japonica*, *Thuja* sp. (Cupressaceae), and *Torreya nucifera* (Taxaceae), which are not present in this island nowadays. Most of these species or genera occur in cooler temperate forests in the mainland of Japan and their southern distribution limit is located at higher altitudes (over 1,000 m) of Yakushima Island. The third component includes *Fagus* cf. *hayatae*, *Liquidambar* cf. *formosana*, *Taiwania* sp. and *Cunninghamia konishii*. Some of these are known as relict species from the Neogene period in Japanese islands. The co-occurrence of the first and second components implies a similar or slightly cooler climate conditions than today; moreover, the presence of a mountain area with high altitude behind the basin, which is completely absent today (current highest point, ca. 280 m a.s.l.), is suggested. The third component can be derived either from the south or the north. More detailed systematic studies are needed to understand their origin.

Current re-vegetation patterns and restoration issues of degraded geological phosphorus-rich mountain: A synthetic analysis of Central Yunnan, SW China

Kai Yan, *Jianchu Xu*
Kunming Institute of Botany, Chinese Academy of Sciences

China has the largest inland geological phosphorus-rich (GPR) mountain, where vegetation restorationis significant for China's environmental safety.We reviewed the published literature and collected raw data to analyze the re-vegetation patterns and plant communities status in central Yunnan, where have the most studies around China. The aim of the study is to suggest future improvements in restoration in GPR mountain. The results showed that spontaneous recovery is the majorrestoration type. N-fixation species, e.g., *Coriaria nepalensis*, *Alnus nepalensis*, play a vital role in the succession. Monoculture tree plantation was the primary mode of afforestation practices in the past. In the recent years, several methods of restoration have experimented including agroforestry system. For practical restoration, the spontaneous recovery could have the best results. However, restoration results are affected by high erosion risk in the early stage, and the origin of propagates and environmental variation. In contrast, human-made communities were better in the early stage, but higher cost and vulnerable to degradation and erosion were constraints. Moreover, N-fixation species e.g., *Alnus nepalensis*, *Acacia mearnsii*, used for plantations reported less success. Thus there are fundamental restoration issues as follows. (1) Understanding merit and demerit of current natural and human engineered restoration, and their respective advantages. (2) The feedback mechanism between phosphorus-rich soil and species selected for restoration, especially N-fixating species. (3) The introduction of market incentives to vegetation restoration, e.g. specific agroforestry model, and improving the industry value chain.

The paleovegetation and paleonvironment reconstruction during the quaternary of the Khorat Plateau based on the palynological records

Feng-Chun Yang[1,2,3]*, Paul Grote*[1,3]
1. Suranaree University of Technology
2. Honghe University
3. Northeastern Research Institute of Petrified Wood and Mineral Resources Nakhon Ratchasima Rajabhat University

The Khorat Plateau is located at the center of mainland Southeast Asia. It is a relatively high altitude tableland. The local flora is closely related to the Indo-Himalayan-Chinese region in the north and the Malesian region in the south. This plateau is an important bridge connecting the biotas of the two large regions. However, it is still unclear how the Khorat Plateau has been affected by global changes including climate change. An exposed sand pit along the ancient fluvial terrace at the village Ban Som, Tha Chang Subdistrict, Chaloem Phra Kiat District, Nakhon Ratchasima Province, Thailand was selected for palynological research. A 14 m depth exposed section was analysed based on the stratigraphy and sedimentology. According to the results, three different stratigraphic groups were classified from the bottom to the upper layers, shallow lake and flood basin, developed river channel, and dry land with and an abandoned river terrace. Abundant pollen grains were discovered from the sediments, from which approximately 100 fossil palynomorphs were recognized and classified. Most of the pollen grains were concentrated in the channel river stage. The main paleovegetation varied from forest to the savannah. Mangrove components such as *Acrostichum, Barringtonia, Ceratopteris, Nypa, Oncosperma*, and Rhizophoraceae were recognized in a continuous deposit in layers 11, 10B, and 10A. These three layers contained pollen indicating deciduous and mixed forest in the ages from 52,296 ± 6,800 yr BP to 28,150 ± 7,860 yr BP. A period with a relatively high sea level was suggested. Temperate and subtropical savannahs were prevalent in cooler periods 16A (172,739 ± 22,400 yr BP), 13B (88,661 ± 10,600 yr BP), and 9B (27,332 ± 3,000 yr BP). These three periods corresponded well with cold events occurring elsewhere. The cold winter monsoon had influenced the Khorat Plateau even though it was far from the ice sheets presented during glacial periods. The pollen grains of confiners were not regarded as local deposits, but were probably transported from the north by wind.

P0942
The special floral traits and pollination adaptation of psammophytes ephemeral plant *Hypecoum erectum* L.

Shanlin Yang, *Xiang Shi, Jiashu Liu, Fanxiang Meng*
Shihezi University

In order to donate pollen to recipient stigmas efficiently, animal-pollinated plants have evolved a variety of floral characteristics. To adapt to the pollination is the fundamental power to floral traits. The evolution of floral characteristics and pollination adaptation is always one of the core problems in the field of evolutionary ecology. The study was carried out in the natural population of *H.erectum* found on the edge of the Gurbantunggut Desert. The floral traits and pollination adaptation were investigated both in the field and laboratory. The results show that: According to the external petal opening situation, the typical single flowering process for a flower can be divided into four stage, we observed the four stage of single flower including external petal color changes, the relative position of the median lobe and anthers, the pollen quantity changes in median lobe, the relative position of the stigma and anthers, the relative position of the median lobe and stigma, stigma dehiscence, and the situation of anther dehiscence. *H.erectum* has elaborate floral characteristics. Two outer petals white or yellow with obovate and 3 low crack, and the two inner petals were composed of lateral lobe and middle lobe. The middle lobe is specialized as a yellow cucullate structure. The middle lobe will reflexively wrap the anther as soon as the anther dehiscence, obtaining pollen and growing upward. The cucullate structure is the key functional organ in attracting pollinators secondary pollen presentation. “Intrafloral stamen differentiations” is a kind of significant differentiation phenomenon that between stamens and stamens. There are intrafloral stamen differentiations exist in *H.erectum*. The pollen viability of the two lateral stamen is more higher than the two middle stamen in all the flowering stage. And the seeds setting of cut the middle anther and bagged is significant higher than the operation on the lateral anther. The number of the pollen in the middle stamen is higher than lateral pollen. *Colletes vestitus* is the only effecity pollinators of *H.erectum*, the visiting frequency showed double-climax: 12: 00-13: 00 and 19: 00-20: 00. To analyze the breeding system type and the mating system under the desert habitat through artificial pollination experiment to explore the adaptation and the evolution significance. The duration of stigma receptivity about 48 h, the stigma always have receptivity along the flower phase. The breeding system type of *H.erectum* is mixed mating system. A part of floral shows self-compatible and another shows outcross. The pollen of geitonogamy is contribute to their reproductive success. Under the selection pressure for a long time, the *H.erectum* tend to mixed mating system, could be a response to adapt the adverse the environment conditions in desert.

Meet the balance of forest conservation and land use productivity - Case study from nature reserve in China

Xueqing Yang[1,2, 3], *Hongxi Liu*[1], *Sergey Blagodatsky*[1], *Carsten Marohn*[1], *Reza Golbon*[1], *Jianchu Xu*[2,3], *Georg Cadisch*[1]

1. University of Hohenheim, Germany

2. Kunming Institute of Botany, Chinese Academy of Sciences

3. World Agroforestry Centre (ICRAF)

In Mainland of South East Asia, land use change from natural forests to intensified economic plantations decreased biodiversity, led to habitat loss and increased carbon emission. In Southwestern China, the dramatic expansion of rubber monoculture plantations has been blamed for high rates of deforestation and forest degradation, and even for threatening food security if converted from swidden land. Against global warming background, some studies analyzed the possible future distribution of rubber plantations, while information about gradual rubber trees’ physiological response to climate change is still unclear. In order to better understand the dynamic process of biomass partitioning and latex production in rubber system, and various response of lowland rubber (located in suitable area) and highland rubber (located in marginal area) to future climate change, we combined empirical and process-based approaches by applying the Land Use Change Impact Assessment (LUCIA) model. Parameterization and validation of plant growth parameters in the model was completed using field dataset from destructively sampled thirty rubber trees, and non-destructively measured 882 rubber trees sampled from 27 plots in langdscape of Naban Watershed National Nature Reserve (NRWNNR), Xishuangbanna. The monthly measured leaf area index (LAI) and litterfall also used to calibrate model. In addition, for nature reserve carbon dynamic evaluation from 1989 to 2012, the RaCSA method (Rapid Carbon Stock Appraisal) was applied based on tree, plot, land use and landscape level. According to model simulation, lowland rubber plantation produced more total biomass (60 Mg ha^{-1}) and latex yield (18.3 Mg ha^{-1}) within 35-year rotation length if compared with highland rubber plantation. Lowland rubber plantations’ total biomass and cumulative latex yield decreased by 3.6% and 5.7%, respectively, if current CO_2 emission scenario is substituted by high CO_2 emission scenario (RCP 8.5, 2050). Highland rubber plantations, in opposite, had an increase of 23% and 27% accordingly due to climate change. Based on instinct nature of tree development, modeling results could guide future cultivation area of various rubber trees’ genotypes, and can be integrated with social-economic information to identify trade-offs between optimization of tree growth and maximization of economic benefit under climate change. Time series analysis of land-use and land-cover maps (1989, 2007, 2012) demonstrated that during 23 years, the whole landscape of the nature reserve (26,574 ha) gained 0.644 Tg C. The effective functional zoning and reforestation activities serve as practical strategies to cope with wide expansion of rubber plantations, most importantly, to balance forest conservation and land use productivity in landscape perspective.

Size-mediated interaction between cushion species and other plant species at high elevations of the Hengduan Mountains, SW China

Yang Yang, *Jian-Guo Chen, Hang Sun*

Kunming Institute of Botany, Chinese Academy of Sciences

Plant size or stage is an indicator of a wide range of ecological and evolutionary processes including responses to neighbours. Plants experience distinct differences in tolerance to extrinsic factors at different stages and therefore has evolved different physiological status. This then manifests itself as variations in morphological traits of plant, which in turn mediates plant-plant interactions by altering microhabitat conditions for other species. Within alpine habitat, species that have cushion morphology often acts as a ‘nurse’ and provide facilitation to other non-cushion species, size of which is easy to be measured. However, little is known about the mechanism link of size-dependent morphological and physiological variability of cushion species and the variation in balance between competition and facilitation so far. In this study, we assessed a series of functional traits in different size (i.e. 10 cm, 15 cm, 20 cm and 30 cm in diameter) of *Arenaria polytrichoides*, a common cushion plant occurs at high elevations of Himalayan Hengduan Mountains, SW China. Furthermore, we analysed how these size-dependent functional traits related to soil properties beneath cushions and the number of associated species and individuals compared with open areas. Large cushions showed good physiological; they were compact, had higher organic matter content and soil nutrient contents (N and P) compared with open areas and showed facilitation effects on other non-cushion species. By contrast, physiological data indicated stressful abiotic conditions for small size cushions of *A. polytrichoides* in the study site. These cushions showed less improved soil conditions and had reduced facilitation as compared with those larger ones. Our data, thus, offer a clear demonstration of a size-dependent mediates interactions occur among cushion species and other plant species, because the distinctive variations in morphology and vigour of this nurse plant at different size. This variability may affect the small-scale environmental created by cushion plant and finally have a relevant effect on its facilitative effects on other species.

Mangrove aerial plants and an update of the IUCN critically endangered and data-deficient mangroves

Jean Wan Hong Yong[1], *Wei San Wong*[2], *Jin Eong Ong*[3], *Chiou-Rong Sheue*[4]

1. School of Plant Biology, University of Western Australia, Department of Environment and Agriculture, Curtin University, Perth, Australia

2. Nanyang Environment and Water Research Institute, Nanyang Technological University, Singapore

3. School of Biological Sciences, Universiti Sains Malaysia, Penang, Malaysia

4. Department of Life Sciences & Center for Global Change Biology, National Chung Hsing University, Taichung, Taiwan

Little attention has been given to the aerial plants (epiphytes, mistletoes and climbers) in Old and New World mangrove forests globally. Epiphytes, mistletoes and climbers generally have a wide range of hosts, including both mangrove and non-mangrove host trees. In the mangroves, by using other host plants to perch high above the ground, mangrove epiphytes avoid the salt water sprays and attain favourable light conditions for growth in the dense canopy. Ferns, orchids and rubiaceous ant-plants constitute the majority of mangrove epiphytic plant life forms. Unlike the parasitic plants, epiphytes do not acquire water and mineral nutrients from the hosts. Hence, only the mistletoes appear to be more selective in colonizing and parasitize certain mangrove trees and shrubs. Conversely, epiphytes, and also climbers, are less ‘picky’ with their phorophyte host and several species of epiphytes and climbers can colonize a single host tree. Unlike epiphytes and mistletoes, climbers are plants that twine and curl round other plants, mainly trees while remaining rooted to the ground. Will the demise of mangrove aerial plants – both from the main and back mangroves, affect the pollination biology and dispersal of certain mangrove taxa? What will be the fate of aerial plants in the mangrove forests in view of increasing anthropogenic disturbances and climate change? An on-going effort is now in progress to compile the extant and extinct mangrove-linked aerial plants from past herbarium records, literature reviews and contemporary field surveys around Asia. Some salient observations of our current research is discussed using new data collected from the old (e.g., Myanmar, Malaysia, Indonesia, Singapore) and New World (Costa Rica, Panama) mangrove forests. of special concern are the two mangrove species that are listed as Critically Endangered (CR), the highest probability of extinction measured by the IUCN Red List. The rare *Sonneratia griffithii* (Perepat daun lebar) is distributed in parts of India and southeast Asia, where the loss of many mangrove areas have occurred within its patchy range over the past 60 years, with significant losses in Myanmar, Thailand and Malaysia, primarily due to agriculture, aquaculture and coastal development. New updates about *S. griffithii* and *Bruguiera hainesii* (Berus mata buaya) in Asia and especially from Myanmar and Malaysia will be discussed. Several rare Data Deficient (DD) *Brownlowia argentata* (Tiliaceae) trees was recently discovered at Sungai Kerian (along the Kedah-Penang state borders, Malaysia) and these new observations (field and herbarium records) suggested that this rare species has an unusual and specific preference for a certain mangrove habitat type: periodic and alternate freshwater and seawater inundation, and with certain periods of “drying out”. Sungai Kerian is a river with suitable geomorphic features that provided these set of hydrological conditions that supported the continual occurrence of *B. argentata*. Perhaps, these specific environmental and especially hydrological requirements may explain in part the rarity of *Brownlowia argentata* throughout its biogeographical range.

Breaking the rules of allometry allows host tracking in a plant insect community

Hui Yu[2], *Finn Kjellberg*[1]

1. South China Botanical Garden, the Chinese Academy of sciences

2. CEFE, CNRS - Université de Montpellier

While the communities constituted by phytophageous insects and their parasites and parasitoids may represent half of all terrestrial animal species, understanding how they have diversified remains a major challenge. Phylogeographic studies show numerous instances when parasites have failed to track their hosts when they colonised new habitats and also cases of delayed host tracking, but provide no mechanistic explanation of the observed patterns. Phytophages may escape from their parasites following variation in host plant morphology, by colonising new parts of plants or by producing differently shaped galls. In this study we investigate how parasitoids of a *Ficus*-pollinating wasp have responded to reduced accessibility of the larvae they feed on in part of the figs distribution. We show that an increase in ovipositor length from 1.7 to 2.8 times body size has allowed a single population of a species of parasitoid to invade the geographic area in which pollinators previously escaped parasitism. The shift in ovipositor length results from the evolution within a population of new allometric rules. Such strong modification of allometry has never been reported within any species but is frequent among species. It is a first step that could lead to ecological speciation following rapid morphological evolution. The results also evidence a period of latency before one species of parasitoid managed to track its host while another species has failed to evolve longer ovipositors. Our results support the idea that small incremental mutations are sometimes not sufficient to bridge adaptive valleys. Populations may have to wait for the chance appearance of rare large effect mutations to diversify by colonising a new dimension of their potential habitat (ref mimicry circles). We show that, in multitrophic interactions, phenotypic variation at one trophic level may often directly affect other trophic levels by generating new ecological opportunities, thus triggering diversification.

Transcriptome analysis of mangrove plants *Bruguiera gymnorrhiza* under drought stress

***Tianhui Yu**, Huaitong Si, Kunfang Cao, Alison K.S. Wee*
Guangxi university

The mangrove species, *Bruguiera gymnorrhiza*, is widely distributed throughout the Indo-West Pacific and is the dominant species of mangrove in China. Mangroves are a taxonomically diverse group of plants capable of thriving within tropical and subtropical intertidal zone, an area characterized by regular inundation by salt water and high temperatures due to sun exposure. To cope with the frequent physiological drought stress that occurs as a result of regular exposure to fluctuating salinity and high temperatures, mangrove plants have evolved unique physiological and morphological adaptations to survive. Abscisic acid (ABA) is a major response factor in the regulatory response to drought stress, through the initiation of leaf stomatal closing and other processes related to water conservation and retention. In this study, we performed transcriptomic analysis on *B. gymnorhiza* under drought stress, in conjunction with measurements of leaf ABA content. We subjected six one-year-old *B. gymnorhiza* seedlings to physiological drought stress for 14 days. We measured photosynthetic rate throughout the drought treatment and collected leaf samples for ABA content measurements and high-throughput RNA sequencing (RNA-seq). We performed RNA-Seq on Ilumina Hi-Seq platform, followed by transcriptome assembly, differential expression analysis and functional annotation, to identify the differentially expressed genes during drought stress. We identified 33,254 unique sequences annotated to 66 GO terms that were differentially expressed, including 466 up-regulated genes and 971 down regulated genes. The up-regulated genes were mostly functionally related to cytoplasm, response to pressure and abiotic stimulation. Our results showed that drought stress enhanced the expression of antioxidant genes and stress response in *B. gymnorhiza*. Following this, we tested candidate genes related to the ABA response pathway for expression validation. By understanding the drought stress regulation in mangroves, this study sheds light on the physiological adaptation of terrestrial plants to a coastal setting.

Multi-stage marginal impact of meteorological factors on rice productivity in China

***Wen Yu**[1], Shiwei Xu[1], Jiajia Liu[1], Jiayu Zhuang[1], Yu Wang[1], Yongen Zhang[1], Muhammad Luqman[2], Liwei Gao[1]*
1. Agricultural Information Institute, Chinese Academy of Agricultural Sciences, Beijing
2. University College of Agriculture, University of Sargodha

Climate changing have an important impact on crop yield in the world. Many researches have mentioned the possible impact of climate change on crop production using simulation models. In this research we use China provincial panel dataset for different season rice during 1979-2014, to estimate the meteorological impact on Chinese rice yield. We find that higher temperature in north is better for the yield, and in the filling stage, but it is not good for the planting stage; the sunshine duration and precipitation also have significant impact to the rice yield in different rice growth stage. In the yield-climate function, we also consider that material input including fertilizer, labor, so as to have an accurate estimation of meteorological impact on rice yields.

A meta-analysis of experimental warming effects on woody plant growth and photosynthesis in forests

Yongge Yuan
Shanghai Science and Technology Museum

Increasing field manipulation experiments have been conducted in forest to better understand the responses of woody plant growth and photosynthesis to climatic warming. However, it is still less known whether there is a general pattern in relation to how and to what extent warming impacts woody plants in forest ecosystems. Here, a meta-analysis was conducted with 522 observations from 52 studies in forests to investigate the direction and magnitude of warming effect on the traits of woody plant growth and photosynthesis. When the temperature increase was between 0.33 and 10°C, warming significantly increased specific leaf area (SLA) by 5.94%, plant height by 7.75%, plant biomass by 21.88%, foliar calcium (Ca) and manganese (Mn) concentrations by 20.67% and 39.62% and net photosynthetic rate (Pn) by 9.92%. Enhanced growth and Pn may have a relationship with the changing SLA, efficiency of PSII, photosynthetic pigment concentrations and foliar nutrient. Our results showed that warming was beneficial to woody plants, and the positive response magnitude to warming on forests was higher than the global average (12.3% for growth, 4.5% for Pn). Our findings will be useful to understand the underlying mechanisms of forests responding to global warming.

Landscape plant selection for green infrastructure (GI) response to climate change

Deshun Zhang
Tongji University

Green infrastructure is established by utilizing natural condition and natural law with the least changes to the nature. Urban GI which refers to an area covered by greenery in the city is a real flow of biological system. According to the dimension, the urban GI can be classified into three categories: place scale, built-up area scale and city area scale. The benefits of the urban GI are conducted through ecosystem service function including consensus establishments, exploitation of social public service of multiple values and assessment strategies building. In order to build urban GI with high ecology elasticity, the investigation and determination of stress-resistant physiological indexes of flood resistance, wind resistance and salt resistance of landscape plants are performed in Shanghai urban green space system as case study. Optimization matrix of future tree species selection was constructed based on plant resistance and scenarios of climatic change. Additionally, master planning strategies of thematic gardens for plant response climate change are introduced in several new Chinese botanical gardens.

Different foliar uptake of unsaturated water vapor under humidification conditions of desert plant *Tamarix ramosissima*

in different months

Huiwen Zhang[1], *Honglang Xiao*[2]
1. State Key Laboratory Breeding Base of Desertification and Aeolian Sand Disaster Combating, Gansu Desert Control Research Institute, Lanzhou
2. Key Laboratory of Ecohydrology of Inland River Basin, Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences, Lanzhou

Plant can absorb moisture from the atmosphere water vapor through the leaves. This process is called "reverse transpiration". It is difficult to form the dew and fog in extremely arid desert area because that wind is strong near the ground. But the atmospheric water vapor content increases a higher degree, or even close to saturation near the ground when temperature drops in the evening and morning. The unsaturated atmospheric water vapor is a special and precious source for desert plant when it is difficult to use precipitation and occult precipitation. Previous researches about foliar uptake of water have been reported for numerous species and almost focused on using saturated atmospheric water vapor (liquid water), but the researches about desert plants absorbing and utilizing unsaturated atmospheric water vapor (vapor water) have rarely not been reported, especially about differences in water vapor uptake by leaves in different months. This research taked *Tamarix ramosissima*, the key species of desert ecological system, as the research object and carried out humidification control field experiment with unsaturated ultrapure water vapor in different months. Stable isotope mixing models were used to quantify source contribution to a mixture of stem water and thus quantify the water vapor absorbed by leaves. We found that the amount of water vapor absorbed by leaves was different in different months. In the humidifying experiment from June to August, absorption of the ultrapure water in stem water accounted for the largest proportion of more than 50%, followed by soil water between 100 cm to 200 cm. Humidification of ultrapure water vapor was the main source of stem water, and might be involved in important physiological processes such as photosynthesis. In the humidifying experiment in September, absorption of the ultrapure water in stem water accounted for only around 20%, soil water between 50 cm to 80 cm was the main water source of stem water, followed by soil water between 100 cm to 200 cm. Humidification of ultrapure water vapor only eased the water shortage degree of plant, and could not be used as the main source of stem water. This research certified the phenomenon that the plant can absorb unsaturated water vapor through leaves. And humidifying experiments of three years at different months showed that changes of the climate conditions, water shortage degree, physiological structure and photosynthetic capacity of plant, soil profile water content in different months would have great impact on plant water use pattems. This research was supported by the National Natural Science Foundation of China (No. Y411381001) and the Major Research plan of National Natural Science Foundation of China (No. 91125025).

P0952
Hydrologically contrasting environments induce genetic but not phenotypic differentiation in *Solanum dulcamara*

Qian Zhang[1,2], *Janny Peters*[2], *Eric Visser*[2], *Hans De Kroon*[2], *Heidrun Huber*[2]
1. Taizhou University
2. Radboud University Nijmegen

In contrasting habitats, locally adapted populations are expected to evolve through directional selection. Hydrological gradients provide a scenario where strong selection forces have led to species segregation in communities along the hydrological niche axes due to specific adaptations to their ambient environment. However, much less is known about the processes enabling species with wide ecological amplitudes, such as *Solanum dulcamara* L., to occupy the contrasting niches at the far ends of the gradient. Here, we investigate the question whether local adaptation is indeed the driving mechanism enabling this species to inhabit contrasting wet and dry habitats. Using molecular analyses and performing a common garden experiment, we examined whether genetic and phenotypic differentiation had occurred between populations originating from flooding- and drought-prone habitat pairs from nine different locations. We also tested whether plants were better adapted to their home site stress. We found a significant genetic variation but hardly any phenotypic differentiation between populations from contrasting habitats for plants grown under optimal conditions. Surprisingly, comparison of the genetic differentiation in neutral markers with that in phenotypic traits using the QST-FST (estimated by ΦPT) approach revealed that the QST values were consistently and significantly smaller than the ΦPT values. This is in contrast to the hypothesis that directional selection is an important component enabling *S. dulcamara* to survive under contrasting habitat conditions. In addition, no home site effects were detected for responses to flooding and drought treatments. All plants were characterized by high levels of plasticity for traits associated with flooding and drought tolerance, such as rapid adventitious root formation upon flooding and increased root to shoot ratio in response to drought, irrespective of habitat of origin. Moreover, no trade-offs in such flooding and drought responses were found. Our results show that *S. dulcamara* has not evolved locally adapted populations in response to flooding and drought stress, despite genetic differentiation and despite the presumably strong selection gradient. The generally high levels of adaptive plasticity in traits increasing flooding and drought tolerance may be the main mechanism allowing *S. dulcamara* to occupy hydrologically contrasting habitats.

Response of physiological ecology characteristics to simulated climate change factors

Wei Zhang, *Li Zhuang*
Shihezi University

In recent years, with the greenhouse effect intensifying, global atmospheric temperature rising and nitrogen deposition and precipitation pattern changing, the relationship between global climate change and terrestrial ecosystems has become the important content and hot spot of global change research at home and abroad. As an important part of terrestrial ecosystem, plant photosynthesis is one of the most important biochemical reaction on earth and is the basis of terrestrial ecosystems of material circulation and energy flow, which is vulnerable to development state of plants

and changing exogenous environmental influences. Many recent studies demonstrated that atmospheric temperature rise both have promoted effect and inhibitory effect on photosynthetic physiological characteristics of plant, even no effect; Atmospheric nitrogen deposition has led to soil acidification, which will be helpful to the plants growth in a short-term, however, which will result in the decrease of plant species richness and ecosystem function in a long-term. In order to maintain their physiological ecological balance and adapt to global climate change, plants also have produced a series of feedbacks: they are mainly reflected in the instruction role of plant physiological traits (such as changes in stomatal regulation, photosynthetic structure adjustment and photosynthetic pathway and changes in plant photosynthesis, respiration rate, osmotic substance content or protective enzyme activity, *etc.*) and phenological characteristics to global climate changes. However, most researches on plant photosynthetic physiological characteristics under climate change are still limited in single or double factors coupling effect of raising temperature, add nitrogen and increasing precipitation. The purpose of this study is to discuss the photosynthetic physiological mechanism and adaptive strategy under the multi-factor coupling conditions of simulated raising temperature, add nitrogen and increasing precipitation, in order to provide more scientific and reasonable theoretical basis for further study on plants growth and distribution under the future global climate.

Impacts of alien black locust on species diversity: A comparison of native and alien plant communities in Shandong Province, China.

Wenxin Zhang, *Qiang Li, Xiao Liu, Ning Du, Renqing Wang*
Institute of Ecology and Biodiversity, Shandong University

The invasion of alien species is the main biological threats to biodiversity all over the world. Black locust (*Robinia pseudoacacia* L.) is a widespread alien species commonly thought to influence natural ecosystems. However, the effects of black locust on the species diversity of plant communities are still controversial. The main aim of this study was to compare the species richness, species composition, phylogenetic diversity and phylogenetic structure between black locust communities and native communities dominated by *Quercus acutissima* to study the possible impacts of black locust on native ecosystems. 17 black locust and 17 paired native communities were selected and all plant species were surveyed in the 20 m × 30 m plots in mountainous area of Shandong Province, China. In this study, there was no significant difference in the species richness between black locust communities and native communities. However, we found that alien plants in black locust communities are more diverse than in native communities. Black locust may increases soil nitrogen stores enhancing the establishment of alien plants. Black locust communities have relatively low level of phylogenetic diversity. We also found that plant assemblages tended to become more phylogenetically clustered in black locust communities. This result indicates that environmental filtering is the main driver of plant community assembly in black locust stands. Black locust could influence community structure, soil properties and nutrient cycling, which makes the habitats become more homogenous. Plant species surviving in black locust communities are from few lineages that have evolved the ability to tolerance these habitats.

Ammonia emissions are substantially underestimated in China

Xiuming Zhang[1]*, Yiyun Wu*[1]*, Baojing Gu*[1]*, Xuejun Liu*[2]*, Stefan Reis*[3]*, Jiaxin Jin*[4]*, Ulli Dragosits*[5]*, Martin Van Damme*[6]*, Lieven Clarisse*[6]*, Simon Whitburn*[6]*, Pierre François Coheur*[6]
1. Zhejiang University
2. China Agricultural University
3. NERC Centre for Ecology & Hydrology
4. Nanjing University
5. University of Exeter Medical School
6. Université libre de Bruxelles (ULB)

China is a global hotspot of atmospheric ammonia (NH_3) emissions and, as a consequence, very high nitrogen (N) deposition levels are documented in particular in areas of intensive agricultural production. However, previous estimates of total NH_3 emissions in China were much lower than inference from observed deposition values would suggest, highlighting the need for further investigation. We have reevaluated NH_3 emissions based on a mass balance approach, validated by N deposition monitoring and satellite observations, for China for the period of 2000 to 2015. Our results show that total NH_3 emissions in China increased from 12.1 Tg N yr^{-1} in 2000 to 15.5 Tg N yr^{-1} in 2015 at an annual rate of 1.9%, which is approximately 40% higher than existing studies suggested. This difference is due to more emission sources now having been included and NH_3 emission rates from mineral fertilizer application and livestock having been underestimated previously. Our estimated NH_3 emission levels are consistent with the measured deposition of NH_x (including NH_4^+ and NH_3) on land (11-14 Tg N yr^{-1}) and the substantial increases in NH_3 concentrations observed by satellite measurements over China. These findings provide a new perspective and substantially improve our understanding on NH_3 emissions in China, implying that future air pollution control strategies have to consider the challenges and potentials of reducing agricultural NH_3 emission to improve air quality in China overall.

Genome-wide transcriptome analysis revealed photosynthetic reaction responses to light variations in *Solidago canadensis*

Yang Zhang, *Yongge Yuan, Xiaojuan Wang, Liang Jin*
Shanghai Natural History Museum, Branch of Shanghai Science & Technology Museum

Solidago canadensis, the invasive plant in Central and East China seriously, was little known about its transcriptome of photosynthesis. In this research, we compared the transcriptome data of native species (*Solidago decurrens*) and invasive species (*S.canadensis*) with different illumination (shading 0%, 40%, 60% and 80%), to revealing the cause of the phenomenon of invasion from the molecule perspective. With the increase of shading intensity, the photosynthetic indexes (Fv/Fm, photosynthetic rate, α value and biomass) appeared a decreasing trend, both in the native species and invasive species. However, the light adaptation of invasive species was stronger than native species, except the one under the shading 80%. Coincidentally, the RNASeq results were similar to the photosynthetic data. In the process of photosystem I and within the same species, the genes which closely related to electron transfer (*PsaA*, *PsaD*, *PsaL*, *et al.,*) was negative regulation. In the photosystem II, LHCII gene family also had obvious decline. In addition, the expression level of partial LHCII gene family of invasive species was higher than local species' based on RT-PCR. We thought that the response to light might be an obvious strength of invasive species.

Curbing desertification development referenced to the determinants for plant distribution pattern

Zhi-Feng Xiong[1], *Ming-Hui Han*[1], *Lin Li*[1], ***Yi Zhang***[1], *Shuang-Xing Guo*[2]

1. College of paleontology, Shenyang Normal University;Key Laboratory for Evolution of Past Life in Northeast Asia, MLRC

2. Department of Palaeobotany and Palynology, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Traditionally, the determinants for plant distribution pattern are regarded as climate factors, especially temperature and humidity. But recently, based on the comparison between the distribution patterns of *Metasequoia* and *Populus*, we found that the distribution patterns of different plants have different determinants. *Metasequoia*, originated from the Late Cretaceous warm temperate zone in the Northern Hemisphere, was widely distributed in the Northern Hemisphere during the Early Cenozoic. But along with the global cooling and catastrophic climate changes during the Middle and Late Cenozoic, *Metasequoia* was forced to migrate southward. Due to migration routes in North America and middle Eurasia curbed by arid zones, only the route in East Asia was suitable for the *Metasequoia* migration. In Pleistocene, *Metasequoia* only survived in South China and Japan under the control of warm temperate climate. Extant monotypic *Metasequoia*, is only distributed in the area bordered by Chongqing, Hubei and Hunan. On the contrary, *Populus*, originated from the Eocene warm temperate zone in the Northern Hemisphere, experienced the similar changes during the Middle and Late Cenozoic, but today it is widely distributed in the warm and cool temperate zones, even colonized in cold and tropical zones, including 92 species. In this species, *Populus euphratica* is adapted to survive in the subtropical and temperate deserts. *Metasequoia* and *Populus*, both of them were originated from the similar warm temperate zones of the Northern Hemisphere, and experienced the same catastrophic climate changes, but their today's diversities and sizes of the distribution area are completely different, indicating their abilities in heritable variation very different. Plants, such as *Populus*, with very higher abilities in heritable variation to adapt to the environmental changes, are able to spread to the different climate zones; vice versa, such as *Metasequoia*, will be gradually eliminated. At the present time, it is an important strategic task for China to curb the desertification development in northern China, especially in Northwest and North China. Based on the above understanding, we think that although we have no way to change the fact that the ongoing desertification takes place in Northwest China resulted from the uplift of the Qinghai Tibet Plateau, it is possible for us to curb desertification development if we can take below measures: applying modern biological engineering to select drought-resistant, salt-tolerant, and fast-growing species, such as the *Populus* plants; introducing the drip irrigation technology to expand the area of shelter forests; establishing three-dimensional ecological farms; and taking efficient agricultural and forestry management.

The ecological divergence and projected the future suitable habitats for homoploid hybrid species *Picea purpurea*

Changming Zhao

Lanzhou University

Picea purpurea is the endemic and dominant tree species of alpine dark coniferous forest in the northeastern of Qinghai Tibet Plateau (QTP) in China. It is demonstrated that *P. purpurea* derived from the natural hybridization of *P. wilsonii* and *P. likiangensis* without the change of chromosomal number. The habitat of *P. purpurea* is characterized by higher latitude and altitude than *P. likiangensis* and *P. wilsonii*, respectively. In this study, we assessed the ecological divergence between *P. purpurea* and its progenitors via a series of statistical methods based on the current distribution information and ecological characters of three spruce species firstly. Then estimated the distribution patterns for three spruce species under different climate change scenarios using species distribution models (SDMs) for two future decades: the 2050s and 2080s. Additionally, we also compared the ecophysiological differences between *P. purpurea* and its progenitors in terms of leaf water relations and leaf photosynthetic apparatus frost tolerance via a common garden experiment. Our results indicated that *P. purpurea* occupied different niche from its parental species. Moreover, the low winter minimum temperature and high soil moisture were the key factors that contribute to this niche divergence. And the future suitable area of *P. purpurea* would increase by an average of 10% under all three scenarios in the 2050s, and increase by an average of 28% under medium stabilizing and very heavy emission scenarios (RCP 4.5 and RCP 8.5) in the 2080s. In contrast, the future suitable habitats of *P. wilsonii* were severe threated, whereas the *P. likiangensis* showed the slight shrinkage in 2050s (~6%) and had no difference between current stage and 2080s and exhibited the tendency of migrate from southeast to east of QTP. For the ecophysiological analysis, significant difference was detected in osmotic potential at full turgor (π_o), water potential at turgor loss point (Ψ_{TLP}) and the temperature causing a 50% reduction in initial Fv/Fm (FT_{50}) between the hybrid species and the progenitors. These results indicate that the ecological separation in *P. purpurea* from its progenitors was promoted by enhanced capacity of cell withstand desiccation and photosynthetic apparatus frost tolerance, thus facilitated its successful colonization and establishment in high altitude and latitude habitats.

The relationship between seed reserve compound contents and germination of six grassland species

Ming Zhao[1], Hongxiang Zhang[2]
1. College of Life Science, Northeast Normal University
2. Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences

Reserve compound and content of seeds is one of the inner factors that affect the germination characteristics. Previous studies on seed germination focused mainly on the effects of external environmental factors or the internal molecular mechanism. The aims of this study are to test the relationship between germination characteristic and seed reserve compound content, as well as the reserve dynamics during germination. We measured the contents of starch, protein and fat in dry seeds of six herbaceous species (*Kochia scoparia*, *Chloris virgata*, *Astragalus adsurgens*, *Lespedeza hedysaroides*, *Leonurus Artemisia*, *Dracocephalum moldavica*) with different seed size (thousand seed weight 0.454 - 2.069 g) in Songnen grassland. We also tested the contents of water, starch, fat, soluble protein and soluble sugar during different stages of germination, including imbibition, 1% germination, 50% germination, total germination, early seedling stage (with visible cotyledons). Results showed that seeds of *C. virgate* are high starch content type, seeds of *K. scoparia*, *L. hedysaroides,* and *A. adsurgens* are high protein types and seeds of *L. Artemisia, D. moldavica* are high fat content types. Except *D. moldavica*, the three reserves took more than 80 percent of the seed weight of other five species. Germination percentages of all the six species were higher than 80%. During germination periods, starch was first decomposed and utilized most for the high starch type *C. virgata* seeds. For the high protein type *K. scoparia*, *A. adsurgens* and *L. hedysaroides*, soluble protein was first decomposed and utilized most. Fat was first decomposed and soluble protein started to be used higher than fat from the mid-germination period for the high fat type *D. moldavica*. Soluble protein and starch were utilized during the whole germination periods for *L. Artemisia*. The soluble sugar increased during the germination periods for all species except *A. adsurgens*. No significant correlation was found between the seed reserve compounds content and germination characteristics. This study was funded by the National Natural Science Foundation of China (41571055).

Changes in germination responses of buried seeds in nature of the cold desert shrub *Zygophyllum xanthoxylon*

Xiaoying Zhao[1], Jiao Wang[1], Carol C. Baskin[2]
1. School of Life Science, Xinjiang Normal University
2. Department of Biology, University of Kentucky

Germination responses and dormancy of soil seed in nature can reveal dynamics of soil seed bank and predict trend of population regeneration, and thus information is needed on this aspect of the seed biology of a species before it is selected for use in habitat restoration projects. *Zygophyllum xanthoxylon* (Bunge) Maxim is a super-xerophilous shrub that is a potential pioneer species for use in revegetating highly disturbed areas of the cold deserts of northwest China. We study seasonal changes of germination and dormancy of buried seeds in nature of the species for two years in its cold desert habitat. Fresh fruits were put on surface and buried 2-5 cm in soil in August 2015 in Dabancheng of Xinjiang, China and exhumed and tested germination every 6 weeks in first year, every 2 months in second year over a range of temperature. Most seeds of *Z. xanthoxylon* exhibited an conditional dormancy in autumn in nature. Fruits exhumed in December (buried for 18 weeks) had a high germination percentage and become non-dormancy during winter in nature. A little fruit (about 20%) undergo high temperature of summer in June and July re-enter into secondary conditional dormancy which they can’t germinate at summer temperature in nature. Fruit exhumed at 23 December 2016 (buried for 70 weeks) undergo second cold winter germinated over 90%, and there are still more than 93% of the seed had vitality both on surface and in soil. Fruit on surface had higher germination percentage than in soil. These results maybe result from seasonal temperation changes, rainfall and special pericarp.

Dormancy breaking of buried seeds in nature of the cold desert shrub *Calligonum junceum*

Juma Aypaxia[1], Xiaoying Zhao[1], Ying Hai[2]
1. College of Life Science, Xinjiang Normal University
2. College of Geography Science, Xinjiang Normal University

Changes of dormancy statuaton of buried seed contributes to a better understanding how the timing of dormancy breaking is controlled in nature, and thus information is needed on this aspect of the seed biology of a species before it is selected for use in habitat restoration projects. *Calligonum junceum* (Fisch. et Mey.) is a super-xerophilous shrub that is a potential pioneer species for use in revegetating highly disturbed areas of the cold deserts of northwest China. We study seasonal changes of germination and dormancy of buried seeds in nature of the species for about two years in its cold desert habitat. Fresh fruits put on surface and buried 2-5 cm in soil in August 2015 in Dabancheng of Xinjiang, China and exhumed and tested germination every 6 weeks in first year, every 2 months in second year over a range of temperature. Over 95% freshly seeds of *C. junceum* exhibited an primary dormancy in autumn in nature. Fruits exhumed in March (buried for 29 weeks) had a high germination percentage and become non-dormancy during winter and Spring in nature. A Most of fruit (about 60%) undergo high temperature of summer in June and July re-enter in to secondary dormancy which they can’t germinate at summer temperature in nature. Fruit exhumed at 23 December 2016 (buried for 70 weeks) undergo second cold winter germinated over 80%, breaking the secondary dormancy; thus, the species exhibited an dormancy/non-dormancy cycle and there are still more than 93% of the seed had vitality both on surface and in soil. When the snow in the Field Fruit on surface had higher germination percentage than in soil. When it rains in the field Fruit in soil had higher germination percentage than on surface. These results maybe result from seasonal temperation changes, rainfall and special pericarp.

Atmospheric nitrogen deposition to China: A model analysis on nitrogen budget and critical load exceedance

Yuanhong Zhao[1], *Lin Zhang*[1], *Youfan Chen*[1], *Xuejun Liu*[2], *Wen Xu*[3], *Yuepeng Pan*[4], *Lei Duan*[5]
1. Laboratory for Climate and Ocean-Atmosphere Sciences, Department of Atmospheric and Oceanic Sciences, School of Physics, Peking University
2. College of Resources and Environmental Sciences, China Agricultural University
3. State Key Laboratory of Urban and Regional Ecology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences
4. State Key Laboratory of Atmospheric Boundary Layer Physics and Atmospheric Chemistry (LAPC), Institute of Atmospheric Physics, Chinese Academy of Sciences
5. State Key Joint Laboratory of Environmental Simulation and Pollution Control, School of Environment, Tsinghua University

We present a national-scale model analysis on the sources and processes of inorganic nitrogen deposition over China using the GEOS-Chem model at 1/2°×1/3° horizontal resolution. Model results for 2008-2012 are evaluated with an ensemble of surface measurements of wet deposition flux and gaseous ammonia (NH_3) concentration, and satellite measurements of tropospheric NO_2 columns. Annual total inorganic nitrogen deposition fluxes are simulated to be generally less than 10 kg N ha^{-1} a^{-1} in western China (less than 2 kg N ha^{-1} a^{-1} over Tibet), 15-50 kg N ha^{-1} a^{-1} in eastern China, and 16.4 kg N ha^{-1} a^{-1} averaged over China. Annual total deposition to China is 16.4 Tg N, with 10.2 Tg N (62%) from reduced nitrogen (NH_x) and 6.2 Tg N from oxidized nitrogen (NO_y). Domestic anthropogenic sources contribute 86% of the total deposition; foreign anthropogenic sources 7% and natural sources 7%. Annually 23% of domestically emitted NH_3 and 36% for NO_x are exported outside the terrestrial land of China. We find that atmospheric nitrogen deposition is about half of the nitrogen input from fertilizer application (29.6 Tg N a^{-1}), and is much higher than that from natural biological fixation (7.3 Tg N a^{-1}) over China. A comparison of nitrogen deposition with critical load estimates for eutrophication indicates that about 15% of the land over China experiences critical load exceedances, demonstrating the necessity of nitrogen emission controls to avoid potential negative ecological effects.

Functional traits of dominant tree species in a karst forest of southwestern China

Qiaolian Zhong, *Xin Xu*, *Jian Ni*
State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences

Plant functional traits are attributes of plant adaptation to the environment. In order to study ecological strategies of dominant tree species in adapting the harsh Karst habitats, a comprehensive survey of functional traits was conducted in a 30 m × 100 m plot of the Tianlongshan Mountains in Puding county, Guizhou province, southwestern China in the summer 2016. Choosing five dominant tree species (*Carpinus pubescens, Machilus cavaleriei, Itea yunnanensis, Platycarya strobilacea, Lithocarpus confinis*), three shrubs (*Zanthoxylum ovalifolium, Stachyurus obovatus, Rhamnus heterophylla)* and two vines (*Rosa cymosa, Dalbergia hancei*) in this evergreen and deciduous broad leaved mixed forest, all above ground and below ground traits from leaf, stem, branch and root, as well as habitat heterogeneity of soil and rock were investigated and measured. Relationships between above ground and below ground plant traits, and between traits and environmental factors were analyzed. The preliminary results showed that: 1) the specific root length (SRL) between trees, shrubs and vines have no significant differences, but significant differences in the specific leaf area (SLA) and root tissue density were found; 2) there are significant positive relationships between tree SRL and twig dry matter content, leaf dry matter content and fine root tissue density ($p < 0.05$). SRL is negatively related with SLA and leaf thickness (LT) ($p > 0.05$); 3) in contrast, SRL of shrubs and vines increases with increasing LT ($p < 0.01$), but decreases with increased SLA ($p < 0.01$), along with very weak relationships to other traits. These findings revealed that plants adopt different survival strategies to adapt to the karst environment.

Leaf morphology shift with climate change of 7 dicots in China

Dongting Zou, *Zhiheng Wang*, *Yaoqi Li*
Peking University

Leaf is a climate sensitive organ of plants. Leaf size and shape have been found to vary along geographical and climatic gradients and this phenomenon has been widely acknowledged. However, intraspecific variation of this pattern is largely lacking. Similarly, we do not know if leaf size and shape carry any signal of climate change. In the present study we investigated how leaf size and shape varies with geographical gradients and how they respond to climate change. We measured 6,063 specimens from Chinese Virtual Herbarium (CVH) of 7 dicots in China collected between 1910 and 2008. The measurements included leaf length and width, leaf size and leaf length – width ratio. We used loess regressions, linear models, ANOVA and redundancy analysis (RDA) models to investigate the geographical patterns of leaf size and shape and the relationship between leaf size and shape and climatic variables isolated from occurrence localities of the specimens. The results suggested that 1) for different species, leaf size and shape show similar patterns along geographical gradients, with leaf size and leaf length – width ratio usually increasing as latitude, longitude or elevation increases; 2) Spatially leaf size and leaf length – width ratio increases with temperature, precipitation and annual evaportranspiration for most species, and the relationship is consistent among different climatic variables; 3) Leaf size and shape have similar time trends for different species, and the trends of leaf length, leaf width and leaf area are similar; 4) the response of leaf size and shape to teperature and annual evaportranspiration change is various among species. Nevertheless, as precipitation increases, shrubs tend to grow larger leaves while leaves of trees and herbs do not change much; 5) For different species the same

leaf morphological trait may be controlled by different climatic variables; 6) for the same species, different leaf morphological trait may mainly be affected by varied climatic variables. We conclude that specimens collected at a larger temporal scale may carry useful signal of climate change and could be a good resource for future climate change studies.

Species richness and composition along microtopography and snow cover gradient in Hardangervidda National Park, Southern Norway.

***Prakash Bhattarai**, Kuber Prasad Bhatta, John-Arvid Grytnes, Ole Reidar Vetaas*
University of Bergen

The species richness and composition of vascular plants, bryophytes and lichens in alpine area are determined by local microtopography, snow cover gradient and strong winds. The aims of this study are to show the species richness pattern and species composition with respect to micro topography and snow cover gradient. We surveyed lichen and vascular plant species in 151 plots of size 4 m^2 within 23 transects. The transects ran from the top of the small hills (ridge) and ends on snowbeds. Weighted average snow indicator value (WASI) and relative distance (RD) from ridge to snowbeds of each plot were calculated. DCA analysis was performed to show the species composition with respect to microtopography. One way anova was performed to show the species richness with respect to micro topography and GLM was performed to show the pattern of species richness with WASI and RD. All together 69 species were recorded, of which 52 species were vascular plants and 17 species were lichens. Plant species associated with ridge (e.g., *Alectoria ochroleuca*, *Alectoria nigricans*, *Sphaerophorus globosus* and *Vaccinium vitis-idaea*) were ordinated in the negative part of the DCA axis I whereas snow bed species (e.g., *Anthoxanthum odoratum*, *Bistorta vivipara*, *Festuca spicata*, *Pyrola alpine* and *Rumex acetosa*) were ordinated on the positive side of the same axis. The species richness of total plant species, vascular plant species and herbaceous plant species followed the same pattern, highest in snow bed and least in ridge whereas, dwarf shrub followed the different trend in species richness in comparison to other life forms. Species richness of dwarf shrub remain almost constant with micro topographical change, while lichens species richness was least in snowbeds than ridge and mid. Regressionanalysis (GLM) revealed a linear relationship in species richness for total plant species and all other life forms except for dwarf shrub species when regressed against WASI and RD, while dwarf shrub showed unimodal pattern. We conclude that the microtopography is an important environmental gradient that shaped the pattern and composition of plant species in space.

Did grassland extensively migrate southward into the present-day forested eastern China during the Last Ice Age? - A new pollen record

Junwu Shu
Key Laboratory of Economic Stratigraphy and Palaeogeography, LPS, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Very little is known about the vegetation pattern covered the widespread low plain in east China during the Last Glacial Maximum (LGM) mainly to due to the loess-related sediment archive unfavorable for pollen preservation in this area. Fortunately, a LGM alluvial sediment sequence (23-16 ka) was occasionally newly recovered. Pollen results show first that herbaceous taxa are surprisingly abundant dominated by *Artemisia* and Poaceae (about 70% in average percentage) which are characteristic taxa in grassland in northern China. In addition, grassland taxa such as *Aster*-type, *Echinops*-type, *Taraxcum*-type, Apiaceae and *Thalictrum* are also common in low abundance. Arboreal taxa are poorly present such as *Quercus*, *Pinus,* and *Alnus.* The pollen flora suggests grassland or grassland with sparse trees distributed in the lowland under a dry and cold continental climate during LGM in sharp contrast to the present-day warm-humid broadleaved forest in the study area. The extensive migration of grassland (now in northern China) more than 1,000 km southward into SW China is probably attributed to the strengthening winter monsoon during the glacial period. Furthermore, the spread of loess into the south China support the grassland migration. The study will put insight into climate modeling and loess south-limit during LGM.

A new compound identified in smoke promotes seed germi-

nation of fire-chaser plants

Dechang Cao, *Matthias Schöttner, Lan T Baldwin*
Max-Planck Institute for Chemical Ecology, Jena, Germany

Smoke-stimulated seed germination is an adaptive trait for plants to colonize post-fire habitats. Regardless that karrikins have been reported as active compounds responsible for smoke-stimulated seed germination, some smoke-sensitive seeds do not respond to karrikins. Thus, the mechanisms underlying smoke-stimulated seed germination remains illusive. Here, we used a bioassay-guided fractionation on HPLC and UPLC to separate liquid smoke which can promote seed germination of a fire chaser, *Nicotiana attenuata*. An active fraction was obtained and a new germination cue identified in the active fraction. The new germination cue differs from karrikins in chemical characteristics and involves differential mechanisms in promoting seed germination. The new findings may open a new window to our understanding of plant adaptation to smoke in fire-prone ecosystems.

Floral nectary morphology and proteomic analysis of nectar of *Liriodendron tulipifera* Linn. plant polyphenols and their dynamics during leaf development under nutrient limitation: A potential nutrient conservation strategy for mangrove plant

Haichao Zhou[1,3*], *Xue Song*[1,3], *Pingping Wei*[1,3], *Hualin Xu*[2], *Qijie Zan*[1,2]
1. College of Life Sciences and Oceanography, Shenzhen University, Shenzhen, China
2. Guangdong Neilingding Futian National Nature Reserve, Shenzhen, China
3. Futian-CityU Mangrove Research and Development Centre, City University of Hong Kong, Shenzhen, China

Mangroves are a group of shrub and tree species that live along shores, rivers, and estuaries in the tropical and subtropical areas. The diversity of plant polyphenols in mangrove plants was reported as an evolutionary advantage adapting to harsh environments. However, there is very limited research on the chemistry and dynimics plant polyphenols in mangroves. Nutrient availability, especially nitrogen (N) and phosphorus (P), is reported as an important factor responsible for mangrove growth. N:P ratios have been applied to identify thresholds of nutrient limitation in wetlands. Thresholds of leaf N:P ratios were found to be16 for P-limitation. Although a increasing knowledge of nutrient limitation for mangrove plants and their adaptation on low nutrient availability, there are many different species of mangrove plants and still litter information about the importance of N:P ratio and variety of leaf polyphenols in nutrient conservation. In this study, we fully investigated the related nutrients (N, P and N:P ratio) and plant polyphenols of mangroves in Dongzhai Harbor national nature reserve. It is the first systematic research on the dynamics of plant polyphenols and nutrients during leaf senescence of 22 mangrove species. Among these species, 12 (mainly Rhizophoraceae), 7 (mainly Sonneratiaceae) and 3 (*Avicennia marina*, *Xylocarpus granatum*, *Excoecaria agallocha*) are condensed tannin (CT), hydrolysable tannin (HT) and low molecular weight polyphenol (LMWP) as the main type of plant polyphenol, respectively. Most of species remained high level of plant polyphenols during leaf senescence, with an increase in the CT species, but a decrease in the HT and LMWP species. Leaf N and P concentrations decreased significantly during leaf senescence. Based on the theory of N:P ratio, most of the mangrove forests are more or less N-limited with $N:P < 16$ in China. High levels of CTs in mangrove leaf were not only significant in reduction of leaf litter decomposition rate, but also played an important role in N immobilization, which provided a vital nutrient conservation strategy for mangrove plants to survive in mangrove swamps with low nutrient availability. The results from this research will enhance our current understanding of potential nutrient conservation strategies used by mangrove plants and improve management of mangrove wetland ecosystem.

5. Bayesic Research
6. Department of Ecology and Evolution

Biological invasions that involved well-documented rapid adaptations to new environments provide unequalled opportunities for testing evolutionary hypotheses. *Mikania micrantha* Kunth (Asteraceae), a perennial herbaceous vine native to tropical Central and South America, successfully invaded tropical Asia in the early 20th century. It is regarded as one of the most aggressive weeds in the world. In an effort to elucidate the molecular and evolutionary processes underlying this invasion, we extensively sampled this weed throughout its invaded range in Southeast and South Asia, and surveyed its genetic structure using variants detected from population transcriptomics. Clustering results suggest that more than one source population contribute to this invasion, and the computer simulations using genome-wide genetic variation support a scenario of admixture and founder events during invasion. The genes differentially expressed between native and invasive populations were found to be involved in oxidative and high light intensity stress responses, pointing to a possible ecological mechanism of adaptation. Our results provide a foundation for further detailed mechanistic and population studies of this ecologically and economically important invasion. This line of research promises to provide new mitigation strategies for invasive species as well as insights into mechanisms of adaptation.

5. World Agroforestry Centre, East & Central Asia Regional Office, Kunming, CHina
6. World Agroforestry Centre, East & Southern Africa Region, Lusaka, Zambia

Disentangling specific factors effects on wood decomposition remains a challenge given the complexity and the interaction among factors affecting wood decomposition. However, one would better draw meaningful conclusions if one designs an experiment that controls for certain factors/variables but leaves others to vary. One way of realizing such event is to have litter bed experiment where the decomposing substrates are exposed to the same environmental factors but substrates would vary in their respective innate functional traits. Even so, there is still the during life environmental "imprint". Therefore, to push this constraint one step higher, one could collect substrates from species that had experienced similar environment. Doing so, this would greatly reduce the "during life environmental 'imprint'" among species. Botanical gardens provide an ideal institutional environment to conduct manipulative experiments on diverse living collections using a common garden approach. At Xishuangbanna Tropical Botanical Garden we conducted a three years long experiment on the role of phylogeny in the decomposition of woody debris (WD). WD is an important terrestrial carbon pool contributing an estimated 10-20% globally, and can over 50% of the carbon is some forests. Using the garden's plant collections we sampled fresh wood logs (5 cm diameter) from 25 species selected across the phylogeny of higher plants. In each major clade, we selected species with both high and low wood density to maximize the range of wood traits represented at this scale. These were incubated in a patch of secondary rain forest within the garden, monitored for mass loss periodically over three years. In addition to phylogeny we collected data on wood density, bark and wood chemistry, and analyzed the fungal communities development and dynamics in the decomposing wood using both traditional techniques and next generation sequencing. We are currently analyzing the preliminary results. Through the phylogenic approach, we hope to produce a predictive model that incorporates microbial diversity effect on wood decomposition and can be used to calibrate WD decomposition globally based on knowledge of forest tree species composition.

Coordination assessment of glutathione with other antioxidants in halophyte *Halimione portulacoides* L. exposed to nanoscale-copper

Anjum Naser, *Duarte Armando, Pereira Eduarda*
CESAM-Centre for Environmental and Marine Studies, University of Aveiro

As a major component of ascorbate (AsA)-glutahione (GSH) pathway, key soluble redox-compounds such as AsA and GSH significantly contribute to cellular redox homeostasis by metabolizing various reactive oxygen species (ROS), major cause of oxidative stress. This study evaluated the glutathione coordination with other antioxidants in halophyte *Halimione portulacoides L.* exposed to nanoscale-copper oxide (nano-CuO) (<50 nm) concentrations (0,20,40,80,160 and 320 mg L^{-1}) under hydroponic set-up. *H. portulacoides* exhibited its differential sensitivity to tissue-Cu-burdens in terms of cellular redox system violators (such as $O_2^{\bullet -}$ and H_2O_2) and its managers (such as ascorbate, AsA; glutathione, GSH; AsA/DHA; GSSG/GSSG; GSH reductase; GSH peroxidase; GSH-sulfo-transferase; ascorbate peroxidase, APX; catalase, CAT). A close relationship among Cu ion release, tissue-Cu-burdens and cellular redox homeostasis was noted. This presentation will discuss and interpret the previous results to get insights into the nano-CuO-accrued phytotoxicity, and adaptive responses of *H. portulacoides*, and potential use of this plant in nano-CuO remediation in estuarine system.

The periderm structure in the leaves of *Agathis* species (Araucariaceae)

Alisa Arbicheva, *Anatoly Pautov*
Saint Petersburg University

Periderm is a dermal tissue of secondary origin which replaces the epidermis and takes over the protective function. Periderm regularly develops along surfaces that are exposed after abscission of leaves and branches. Mechanical damage causes the formation of wound periderm. This tissue develops regularly in the scales of wintering buds of some species. Photosynthetic leaves do not normally produce periderm. Nonetheless, a number of species do form periderm in the leaves. We studied periderm of the leaves of *Agathis brownii* (Lem.) L. H. Bailey and *Agathis vitiensis* Benth. & Hook.f. ex Drake using methods of light and transmission electron microscopy, experimental wounding and histochemical staining. Additionally we studied the periderm initiation in the *Agathis* stems. *Agathis* leaves are long-lived and remain alive for more than 25 years. The species studied have leaves of a similar structure. Periderm occurs regularly and can be initiated in the epidermis, mesophyll, phloem parenchyma of the leaf veins and in the ground tissue of the petiole. Periderm structure is either typical, consisting of phellogen, multilayered phellem and phelloderm, or disordered. Periderm arrangement in the leaves is highly diverse. It can be initiated in the epidermis and cover a small area of the leaf. If numerous cells undergo intense divisions, a lenticel-like structure may form. Phellogen may form in a paradermal plane when initiated in the mesophyll. There are cases of simultaneous periderm formation both on the abaxial and adaxial surfaces of the lamina, when only the central cell layers remain alive. We have found rare cases of circular phellogen initiation in the leaves of *A. vitiensis*. At the junction of the petiole and the lamina the oldest leaves may form a large number of transverse planes of periderm initiation. It leads to the splitting of the base of lamina, some of the areas undergoing necrosis. *Agathis* leaves are able to form true wound periderm, which has been shown experimentally. We believe that at least some of the factors inducing periderm initiation are identical both in leaves and stems. Phellogen initiation in the thickening stem was found exactly in the regions of cuticle breaks. These breaks point to the presence of a significant mechanical tension or epidermis deformation which exceed cuticle hardness. Such deformations and mechanical tensions arise in petioles in the part near the lamina, which is usually curled to maintain the lamina in a horizontal position. Mechanical deformations in petioles are indirectly evidenced by changes in epidermal cell shape. These data support the point of view that mechanical forces play an essential role in morphogenesis processes. Periderm initiation deep in the mesophyll leads to the isolation of cell groups or dissection of leaf parts. Cells of isolated parts are filled with tannins. The cells of the leaf and petiole are the storage of crystals, the amount of crystals substantially increasing with age. Leaf tissues isolated due to the suberinization process may function as a storage site for the substances not involved in the plant metabolism or excluded from it.

MOD1 modulate cell and organ growth by regulating endore duplication in *Arabidopsis thaliana*

Usman Aslam*, Yunhai Li*

Institute of Genetics and Developmental Biology, University of Chinese Academy of Sciences

How plants modulate growth and definite size of their organs is a fundamental question in plant biology. In agronomic context, organ size provides ultimate forecast of yield and total biomass which are key determinants of food and biofuel crop production. Typically, organ growth is controlled by coordinated maneuver of cell proliferation, expansion and differentiation into particular tissues. Many studies have highlighted the role of endoreduplication in development and physiology, however, the underlying mechanisms linking endopolyploidy with cell growth and final organ size are still nature’s secrets. Previously, UBIQUITIN-SPECIFIC PROTEASE 14 (UBP14) encoded by *DA3* (“*DA”* means big in Chinese) was described to function with anaphase-promoting complex/cyclosome (APC/C) ubiquitin ligase through interacting its inhibitor ULTRAVIOLET-B INSENSITIVE 4 (UVI4) to modulate endoreduplication and organ growth in *Arabidopsis thaliana*. The *Arabidopsis da3-1* mutant possesses larger cotyledons, leaves and flowers with higher ploidy levels. Using Next Generation Mapping (NGM) approach, I genetically identify several modifier genes of *da3-1* from EMS mutagenized *Arabidopsis* populations that influence the ploidy and growth phenotypes of *da3-1*. I selected one of them for functional analysis and designated as *mod1-1*. The cellular and genetic studies suggested that *mod1-1* strongly represses the cellular ploidy and synergistically regulate the organ growth phenotypes of *da3-1*. The DNA and protein sequence analysis revealed that *MOD1* is a key players of splicing complex in higher eukaryotes, however, their role in endoreduplication or any organ growth related mechanisms has never been described. The expression pattern analysis of *MOD1* revealed that they are highly expressed in transcriptionally active and differentiating cells. Bimolecular fluorescence complementation (BiFC), co-immunoprecipitation and pull down experiments demonstrate that MOD1 physically interacts with UBP14 and CDKB1;1 *in vivo* and *in vitro*. Further studies proves that UBP14 influences the stability of MOD1. We already knew that *cdkb1;1-1* enhanced the ploidy phenotype of *ubp14-1* and *uvi4-1*, however, in contrast our results showed that *mod1-1* does not suppress the cellular ploidy of *uvi4-1* and *cdkb1;1-1* suggesting *MOD1* is a downstream components of UBP14 in endocycle pathway. Overall, these findings define a genetic and molecular mechanism of MOD1 function in endoreduplication and plant organ growth regulation.

The mechanism and molecular basis underlying salt secretion in *Reaumuria soongorica*

Tianhui Bai*, Shuyi Zhao, Suomin Wang, Aike Bao*

Lanzhou University

Reaumuria soongorica, a salt-secreting super xerophyte belonging to Tamaricaceae which is a perennial fodder semi shrub at desert steppe in the northwest of China. It lives in the semiarid regions that endows the plant with salt-resistant, drought-resisitant and sand trapping inhere character. *R. soongorica* is also significant for the ecology protection. Our previous studies showed that secreting salt via salt glands is an important strategy for *R. soongorica* adapting to high salinity environments. However, the mechanism underlying salt-secretion of *R. soongorica* is still unclear. In this study, we analyzed the real-time Na^+ secretion dynamics via salt gland of *R. soongorica* using Non-invasive microtest technology (NMT).The results showed that under either salt (100,300 mM NaCl) or osmotic stress (-1.0 MPa), the net Na^+ efflux via salt glands showed significantly higher than control, and interestingly, the net H^+ influx across the salt gland was correspondingly induced by salt and osmotic stress, suggesting that there is active Na^+/H^+ exchange in the process of salt secretion on the plasma membrane of the secretory cells (SeC) in salt gland of *R. soongorica*. To further investigate how Na^+ was accumulated into collecting cells (CoC) and then secreted from SeC, we cloned *RsSOS1* and *RsNHX1* genes, which encode plasma membrane and tonoplast Na^+/H^+ antiporters of *R. soongorica*, respectively. The expression pattern analysis indicated that both *RsSOS1* and *RsNHX1* genes predominantly expressed in shoots, and were significantly induced by salt (50,200 mM NaCl) or osmotic (-0.5, -1.0 MPa) stress treatments. These results suggest that *RsSOS1* and *RsNHX1* may be involved in salt-secretion of *R. soongorica*. We thus proposed a model in that Na^+ may be firstly sequestered into vacuole of CoC mediated by *RsNHX1*, then transported into SeC and finally excluded by *RsSOS1*.

Gemination and initial establishment of *Euterpe edulis* Martius (Arecaceae)

Hector Barros Gomes*, Bruno Takami Fujiwara, Eliana Akie Simabukuro*

University of São Carlos

The germination of *Euterpe edulis* Mart. (knowing as palm jussara) it's a key aspect for population maintenance process of the species. In this respect, understanding the conditions required to maintain viability of seeds and growth of seedlings is critical for a specie like *E. edulis* that presents recalcitrant seed and seedlings with slow and uneven growth. The aim of this study was to verify the seed germination of *E. edulis* at different stages of maturation and the development of their seedlings. The species presented four maturation stages: immature (green pericap); in maturation (dark green); mature (purple pericarp) and post-maturation (black pericarp). The dry biomass had increased during maturation (0.82 to 0.91 grams), and the lowest relative humidity was observed in mature diaspores, with 50.2%. Diaspores with purple pericarp (mature) showed higher germination percentage (84%) and germination rate index (0.96) when compared to other maturity stages. When stored for a week (5°C), the germination percentage (G.P.) for purple pericarp increased to 98%. The best diaspore germination was observed at temperatures of 20-30°C and 20°C with 90% of G.P., and better results for seeds that have been stored for a short period (5°C). Seedlings originating with green and purple pericarp showed better growth (stalk with 15 cm and root with 22 cm). We can claim that the environmental conditions of the parent plant can predict the needs of progeny for *E. edulis* and purple diaspores had higher survival at the end of the experiment indicating the best maturation stage.

Analysis of the protein domains of the major carpel developmental regulator CRABS CLAW

Thomas Gross, *Kai Pfannebecker, Annette Becker*
Justus-Liebig-University Gießen

One of the most crucial steps in the life cycle of angiosperms is the development of carpels. They are the most complex plant organs, harbor the seeds, and later develop into fruits and are thus an important ecological and economic trait. CRABS CLAW (CRC), a Yabby protein and putative transcription factor, is one of the major carpel developmental regulators in *A. thaliana.* It is involved in various processes during floral development, such as carpel fusion, floral meristem termination, and nectary formation. While its genetic interactions with other carpel development regulators are well described, its biochemical properties and molecular way of action remain unclear. Here, we reveal the molecular base of CRC function with e.g. protein interaction and localization assays to assign functions to the three domains of CRC (a zinc finger like domain, a serine-proline rich domain, and the protein family specific Yabby domain), in respect to subcellular localization, nuclear transport, protein-protein interactions, and DNA binding. We can show that CRC regulates carpel fusion and nectary formation by activating transcription and regulates floral meristem termination by repressing transcription of target genes. In addition, we present our recent progress in the elucidation of the regulation of CRC during carpel development.

Investigating the role of regulatory B" subunits of protein phosphatase 2A in responses to salinity stress

Mallesham Bulle[1,2,3], *Amr Ramzy Abass Kataya*[2], *Kirti Pulugurtha Bharadwaja*[1], *Sadanandam Abbagani*[3], *Lillo Cathrine*[2]
1. University of Hyderabad
2. University of Stavanger
3. Kakatiya University

Protein phosphatase 2A (PP2A) is a serine/threonine-specific protein phosphatase that plays an important roles in regulation of most cellular processes of eukaryotes. Canonical PP2As are heterotrimeric complexes consisting of a catalytic (C1-5), scaffolding (A1-3), and regulatory (B) subunits. The regulatory B subunits play an important role in conferring substrate specificity and determining subcellular localization to the holoenzyme complex and are classified into B55, B', and B'' non-related families. In *Arabidopsis*, 17 regulatory subunits are present that can lead to 255 possible combinations. At present, little is known about the functions and substrates of plant PP2As. In this study, we identified a new function for PP2A in salt stress tolerance. Interestingly, *AtPP2A B"α* is targeting to mitochondria and we fused all the remaining B'' subunits with a reporter protein, and their localizations are under investigation. Expression pattern analyses revealed that *AtPP2A B"α* is strongly expressed in roots, and responds to NaCl stress at the transcription level. From the preliminary data, transgenic Arabidopsis plants overexpressing *AtPP2A B"α* developed more lateral roots, whereas, the seedlings of these knockout mutants show sensitive to high salt concentrations. The results indicating that PP2A plays an important role in salt stress tolerance. However, to fully understand the role of PP2A and its regulatory subunits in salt stress, it is of uttermost importance to identify proteins that are substrates of PP2A complexes containing the various B-subunits.

Methodology for analysis of multiple phytohormones

Bao-Dong Cai
Wuhan Greensword Creation Technology Co., Ltd.

Phytohormones are special small molecules that play important role in plant growth and development at trace levels. Quantification of multiple interacting phytohormones will be great helpful for research about cross-talk that plant hormones regulate the responses of plants against both biotic and abiotic stresses by means of synergistic or antagonistic interaction. However, it is still a challenge for simultaneous analysis of multiple phytohormones in one small sample because of the structural and chemical diversity of phytohormones. It is difficult to simultaneously enrich them.
We have been committed to improve the methodology for analysis of multiple phytohormones. Based on UPLC-MS/MS, more than 60 plant hormones could been analyzed from plant tissues with improved smaple pretreatment procedure.

1. Brazilian Bioethanol Science and Technology Laboratory, Brazilian Center for Research in Energy and Materials
2. Max Planck Partner Group at Brazilian Bioethanol Science and Technology Laboratory

Plant growth is controlled by metabolic network regulation, development and carbon partitioning between sink and source organs. There are now considerable genetic and biochemical evidences that the target of rapamycin (TOR) kinase is one of the key pathways in sensing and transducing sugars to control growth. We used genetic and pharmacological approaches to further investigate the kinetics of TOR inhibition in plants under different photoperiods to identify the mode of action of this pathway in controlling C metabolism. By combining metabolic profile, biochemical assays and gene expression analyses, we showed that down-regulation of TORC leads to accumulation of starch in the light, but this was not linked neither to allosteric regulation nor for the redox regulation of ADPG pyrophosphorylase (APGase). Surprisingly, the levels of maltose, the main starch breakdown product, were lower in plants exposed to short-term inhibition of TORC when compared to the control, suggesting an impaired starch breakdown at dawn. In addition, massive changes in organic acids from the TCA cycle clearly show that TOR influences not only C metabolism related to storage and use of sugars but also affect the energetic status of the plants. Furthermore, massive changes in the levels of transcripts and proteins involved in starch metabolism and sugar transport revealed a role of this pathway in keeping sucrose homeostasis to sustain plant growth.

Effect of shoot-to-root abscisic acid (ABA) transport on xylem sap ABA concentration, water status and stomatal conductance of plants in drying soil.

Pedro Castro Valdecantos, *Ian C. Dodd*, *Jaime Puertolas*
Lancaster University

Apoplastic ABA concentration is critical to determine stomatal aperture. Experimental evidence suggests that root sourced ABA is not necessary to increase apoplastic ABA levels and trigger stomatal closure under drought conditions. Recent findings indicate substantial transport of ABA from the shoots to the roots, with root synthesized ABA of secondary importance compared to shoot ABA biosynthesis in response to water stress. Our study aimed to understand the impact of shoot-to-root ABA transport on ABA concentration in the xylem sap extracted from different parts of the plant, and ultimately its effect on stomatal conductance. Soybean (*Glycine max* cv. Siverka) were grown in special pots designed to fit in a pressure chamber and subjected to a factorial experiment with irrigation (WW: well-watered; DR: droughted) and girdling (NG: intact plants; G: Girdled plants) as factors Girdling was achieved surgically in 30 days old plants (after sowing) by excising the phloem tissue with a sharp razor blade. Four days after girdling and withholding water, stomatal conductance, root, shoot and leaf water potential were measured and ABA was determined in xylem sap extracted from the leaf, shoot and root. Soil drying decreased water potential in all plant tissues. Root and shoot water potential were not affected by girdling, but leaf water potential in DR was slightly higher (by -0.1 MPa) for girdled plants. For non-girdled plants, xylem sap ABA concentrations remained stable in WW plants and approximately doubled in DR plants. Girdling diminished the increase in leaf and shoot xylem ABA concentration, and completely prevented it in root xylem sap and tissue. On the contrary, girdling increased ABA concentration of WW plants but only in leaf xylem sap. Stomatal conductance was best related to leaf xylem sap ABA concentration, and approximately halved for all the treatments except for WW-NG The results support previous evidence indicating the predominant role of shoot-sourced ABA explaining root ABA accumulation in response to drought and suggest that shoot to root ABA transport might be a mechanism to avoid apoplastic ABA accumulation in the shoots in order to maintain stomatal opening under optimal soil water content.

Diversity and association of phenotypic and metabolomic traits in the close model grasses *Brachypodium distachyon*, *B. stacei* and *B. hybridum*

Diana Lopez-Alvarez[1], *Hassan Zubai*[2], *Manfred Beckmann*[2], *John Draper*[2], ***Pilar Catalan***[1]
1. Universidad de Zaragoza
2. Aberystwyth University

Morphological traits in combination with metabolite fingerprinting were used to investigate inter and intra species diversity within the model annual grasses *B. distachyon*, *B. stacei* and *B. hybridum*. Phenotypic variation of 15 morphological characters and 2,219 nominal mass (*m/z*) signals generated using Flow Infusion Electrospray ionisation - Mass Spectrometry (FIE-MS) were evaluated in individuals from 174 circumMediterranean wild populations and 6 inbred lines, and 12 Iberian lines of the three species, respectively. Basic statistics and multivariate Principal Component Analysis (PCA) and Discriminant Analysis (DA) were used to differentiate inter- and intraspecific variability of the two types of variables, and their association was assayed with *rcorr*. Basic statistics and ANOVA detected eight phenotypic characters [(stomata) leaf guard cell length, pollen grain length, (plant) height, second leaf width, inflorescence length, number of spikelets per inflorescence, lemma length, awn length] and 434 tentatively annotated metabolite signals that significantly discriminated the three species. Three phenotypic traits (pollen grain length, spikelet length, number of flowers per inflorescence) might be genetically fixed. The three species showed different metabolomic profiles. DA significantly discriminated the three taxa with both, morphometric and metabolome traits and the intraspecific phenotypic diversity within *B. distachyon* and *B. stacei*. The populations of *B. hybridum* were considerably less differentiated. Highly explanatory metabolite signals together with morphological characters revealed concordant patterns of differentiation of the three taxa. Intraspecific phenotypic diversity was observed between northern and southern Iberian populations of *B. distachyon* and between E Mediterranean – SW Asian and W Mediterranean populations of *B. stacei*. Significant association was found for pollen grain length and lemma length and 10 and 6 metabolomic signals, respectively.

These results would guide the selection of new germplasm lines of the three model grasses in on-going GWAS experiments.

Leaf life-span dynamics of woody species in tropical dry forests of India

Ravi Kant Chaturvedi[1], *As Raghubanshi*[2]

1. Xishuangbanna Tropical Botanical Garden
2. Banaras Hindu University

Phenology is sometimes, concurrently or at different times of the year, controlled by multiple factors, therefore, it is important to understand the factors influencing the foliar phenology in the tree species of tropical dry forests (TDFs). In the present study, we analyse the diversity of leaf life-span in the woody species of Vindhyan highlands and group the plant species according to their leaf flushing period, leaf life span and leaf fall period. We also study the factor influencing the foliar phenology of the woody species. The study was conducted on five sites (Hathinala, Gaighat, Harnakachar and Ranitali, listed in order of decreasing SMC) within the tropical dry deciduous forest in northern India. Fifteen individuals each, of the woody species were randomly selected from the three 4 ha plots at each site and were marked. Plant species which were not present at all the five sites were selected from only those sites where they were present. On each marked individual, one twig (currently growing shoots of last-order branches) on each of four major branches (one in each direction was marked with metal tags). On these twigs monthly count of leaf number was made from January 2005 to December 2006. Soil moisture content was measured at 10 locations, randomly in each plot, at each site, as percentage by volume every month, at a depth of 10 cm at 1-month intervals for 2 years. Site wise variations of soil moisture content in each month was analysed by multivariate ANOVA. Across the 12 months in a year, July and August showed higher soil moisture content. Lower soil moisture content was observed in November and December. Across the 12 months, site wise variations in soil moisture content were not significant only in July, August and September. Leaf life-spans of the woody species were also highly variable. About 67% species had peak of their leaf flush intiation during summer period (pre-rain leaf flushing) and rest species had their peak leaf initiation during rainy season (post-rain leaf flushing). The peak period of leaf flushing initiation at all the sites was May when 52% of the species initiated their leaf formation and the peak period of leaf flushing completion was August when 38% of the plant species completed their leaf formation. The peak period of leaf fall initiation in maximum species (54%) at all sites was November and the peak period of leaf fall completion at all the sites was February when 63% of the species shed their leaves. The peak period of leaf flush initiation as well as leaf fall initiation in most of the species at dry sites was one month before as compared to that of moist sites.

The structural types of secondary xylem of perennial herbs

Ksenia Chebotareva[1], *Anna Stepanova* [1], *Shagdar Tsooj*[2]

1. Komarov Botanical Institute RAS
2. Institute of general and experimental biology MAS

Anatomical studies of wood or secondary xylem of main root of perennial herbs show that distinct annual rings are characteristic for many species. Their boundaries can be marked by the different ways: row of flattened elements, marginal parenchyma, variances in vessel diameter *etc*. But the regularities of diversity of these characters still remain unclear. More other, some peculiarities of wood structure of herbs result in terminological difficulties. We have studied in detail wood anatomy of main root on 35 herbaceous plants, relating to 14 families. The material were collected in Mongolia in 2009-2010 and analyzed with methods and terminology commonly using in wood studies. Three structural types of secondary xylem were proposed. 1. Fibrous wood, similar to secondary xylem of majority of woody plants, consists from vessels, fibres and axial and ray parenchyma. 2. Parenchymatous wood, formed mainly by vessels and parenchyma cells. 3. Zonate wood, there combination of fibrous and parenchymatous zones have been observed. This typification seems to be useful for descriptions and analyses of wood of herbs. Also some suggestions about factors, correlating with those types are proposed.

P0978
Agronomic nitrogen-use efficiency of rice can be increased by driving *OsNAR2.1* or *OsNRT2.1* expression with the *OsNAR2.1* promoter

Jingguang Chen[1,2], *Xiaorong Fan*[1,2], *Guohua Xu*[1,2]

1. State Key Laboratory of Crop Genetics and Germplasm Enhancement, Nanjing Agricultural University
2. Key Laboratory of Plant Nutrition and Fertilization in Low-Middle Reaches of the Yangtze River, Ministry of Agriculture, Nanjing Agricultural University

The importance of the nitrate (NO_3^-) transporter for yield and nitrogen-use efficiency (NUE) in rice has been demonstrated previously using map-based cloning. First, we used the *OsNAR2.1* promoter to enhance *OsNAR2.1* gene expression in transgenic plants. Transgenic lines expressing *pOsNAR2.1:OsNAR2.1* constructs exhibited increased *OsNAR2.1* expression, and transcription of *OsNRT2.1*, *OsNRT2.2*, and *OsNRT2.3a* in transgenic plant roots was increased, respectively, by 117,121, and 129% in 0.2 mM NO_3^-; by 105,118, and 110%, in 2.5 mM NO_3^-; and by 76,68 and 73% in 1.25 mM NH_4NO_3, compared with WT. And ^{15}N influx in roots increased 21–32% in response to 0.2 mM and 2.5 mM $^{15}NO_3^-$ and 1.25 mM $^{15}NH_4{}^{15}NO_3$. Grain yield, agricultural NUE (ANUE), and dry matter transfer (DMT) of *pOsNAR2.1:OsNAR2.1* transgenic plants grown in the field increased 21,22, and 21%, respectively, relative to WT plants. So next we enhanced the expression of the *OsNRT2.1* gene, which encodes a high-affinity NO_3^- transporter, using a ubiquitin (*Ubi*) promoter and *OsNAR2.1* promoter to drive *OsNRT2.1* expression in transgenic rice plants. Transgenic lines expressing *pUbi:OsNRT2.1* or *pOsNAR2.1:OsNRT2.1* constructs exhibited increased total biomass including yields of approximately 21% and 38% compared with wild-type (WT) plants. The ANUE of the *pUbi:OsNRT2.1* lines decreased to 83% of that of WT plants, while the ANUE of the *pOsNAR2.1:OsNRT2.1* lines increased to 128% of that of WT plants. The DMT into grain decreased by 68% in the *pUbi:OsNRT2.1* lines and increased by 46%

in the *pOsNAR2.1:OsNRT2.1* lines relative to the WT. The expression of *OsNRT2.1* in shoot and grain showed that *Ubi* enhanced *OsNRT2.1* expression by 7.5-fold averagely and *OsNAR2.1* promoters increased by about 80% higher than the WT. Interestingly we found that the *OsNAR2.1* was expressed higher in all the organs of *pUbi:OsNRT2.1* lines, however for *pOsNAR2.1:OsNRT2.1* lines *OsNAR2.1* expression was only increased in leaf sheaths and inter nodes. The ratio of *OsNRT2.1* to *OsNAR2.1* expression was altered in the transgenic lines with ratios of approximately 11.3:1 and 4.7:1 in the *pUbi:OsNRT2.1* and *pOsNAR2.1:OsNRT2.1* lines, compared with a ratio of 7.2:1 in WT plants. We also compared the phenotypes of *pOsNAR2.1:OsNAR2.1* and *pOsNAR2.1:OsNRT2.1* transgenic lines in the field and found that post-anthesis N uptake differed significantly between them, and in comparison with the WT. PANU increased approximately 39% and 85%, in the *pOsNAR2.1:OsNAR2.1* and *pOsNAR2.1:OsNRT2.1* transgenic lines, respectively, possibly because *OsNRT2.1* expression was less in the *pOsNAR2.1:OsNAR2.1* lines than in the *pOsNAR2.1:OsNRT2.1* lines during the late growth stage. We show that increased expression of *OsNAR2.1* or *OsNRT2.1*, especially in combination with a relative lower expression ratio with its partner gene *OsNAR2.1*, can improve yield and NUE in rice.

MYB89 transcription factor represses seed oil accumulation in *Arabidopsis*

Mingxun Chen, *Dong Li, Changyu Jin*
Northwest A&F University

In many higher plants, seed oil accumulation is precisely controlled by intricate multi-level regulatory networks, among which transcriptional regulation mainly influences oil biosynthesis. In Arabidopsis, the master positive transcription factors for seed oil accumulation are *WRINKLED1* (*WRI1*), *LEAFY COTYLEDON1-LIKE* (*L1L*), and *LEC2*. We found that an R2R3-MYB transcription factor, MYB89, was predominantly expressed in developing seeds during maturation. Oil and major fatty acid biosynthesis in seeds was significantly promoted by *myb89-1* mutation and *MYB89* knockdown; MYB89 was thus an important repressor during seed oil accumulation. RNA sequencing revealed remarkable upregulation of numerous genes involved in seed oil accumulation in *myb89* seeds at 12 days after pollination. Posttranslational activation of a MYB89- glucocorticoid receptor fusion protein and chromatin immunoprecipitation assays demonstrated that MYB89 inhibited seed oil accumulation by directly repressing *WRI1* and five key genes and by indirectly suppressing *L1L* and 11 key genes involved in oil biosynthesis during seed maturation. These results help us to understand the novel function of MYB89 and provide new insights into the regulatory network of transcriptional factors controlling seed oil accumulation in *Arabidopsis*.

Arabidopsis remorins modify root gravitropism against plasmodesmata-mediated virus infection

Xu Chen[1], *Meiyu Ke*[1], *Yanbiao Sun*[1], *Dingquan Huang*[1], *Deyan Wang*[1], *Zichen Chen*[1], *Liwen Jiang*[2]
1. Haixia Institute of Science and Technology, Fujian Agriculture and Forestry University, Fuzhou, China
2. School of Life Sciences, Centre for Cell and Developmental Biology and State Key Laboratory of Agrobiotechnology, The Chinese University of Hong Kong

Plasmodesmata (PD) are nano-sized membrane-lined channels that connect neighboring cells for cell-to-cell communication in plants. PD are also essential passages for intercellular spread of plant viruses which move through leaf-root-leaf route, while the role of root in regulation of PD-mediated virus transportation is still unclear. So far, only a few PD proteins were characterized and the mechanisms in control of PD permeability are largely unknown. In our study, we used *Arabidopsis* root as study system, aiming to demonstrate the role of root-specific expressed Remorins (REMs) which are PD-located proteins involved in PD-mediated virus spread, and further influencing root gravitropic response. Our results showed that the four members of *AtREM1* subfamily are individually expressed in different cell layers of root. Single mutants and multiple mutants of *rems* are hypersensitive to Cytomegalo virus (CMV), and overexpressed *REMs* significantly block PD permeability. Sterol biosynthesis of overexpressed *REM* lines is overall reduced, suggesting that *REMs* maintain PD open/closure possibly through the regulation of sterol enrichment. *REM* overexpression impairs endomembrane trafficking of auxin transporter PIN2, and thus disrupting auxin gradient during gravitropic response. Based on the data presented here, we hypothesize that REM1 proteins are important regulators in control of PD permeability in the process of virus infection, meanwhile function essentially in auxin-dependent root gravitropism.

SKU5 and SKS1 function redundantly to regulate cellulose synthesis in *Arabidopsis*

Lihong Li, *Dandan Zheng, Chenjin Wen, Yuting Qiu, Dingquan Huang, Zengyu Liu, Tongda Xu, Xu Chen*
Haixia Institute of Science and Technology, Fujian Agriculture and Forestry University, Fuzhou, China

Cell wall is a fundamental plant constituent, composed of the polysaccharides cellulose, hemicellulose, pectin and lignin. Cellulose synthases (CESAs) complexes localize at plasma membrane, being the critical components for cellulose biosynthesis, while regulation of this process is poorly understood. In our study, we found a glycosylphosphatidylinositol (GPI)-anchored glyco protein SKU5 which is highly co-expressed with all CESAs at transcription level. Further study showed that *sku5 sks1* double mutant (SKS1 is a homolog of SKU5) decreases crystallized cellulose level and exhibits typical cell wall-related defects. CESA3 speeds and trajectories were severely altered in *sku5 sks1* double mutant, indicating SKU5 and SKS1 are important regulators of CESAs involved in cellulose synthesis. As GPI-anchored proteins, we hypothesize that SKU5 and SKS1 might affect phospholipid-mediated membrane stability which is required for CESAs embedding. Hence, we have uncovered a mechanism for how SKU5 and SKS1 modulate CESA-dependent cellulose synthesis, which helps us to better understand the signals upstream of CESA regulation.

Researches on some structural genes in flavonoid metabolic pathway of *Dryopteris erythrosora*

Xuefei Chen[1,2], *Jianguo Cao*[1], *Xiling Dai*[1], *Quanxi Wang*[1], *Youfang Wang*[2]
1. Shanghai Normal University
2. East China Normal University

Flavonoids are a kind of important secondary metabolites in plants. In recent years, the synthesis of flavonoids and their molecular mechanisms have been extensively studied in flowering plants. However, the molecular mechanism of flavonoid biosynthetic pathway in ferns are less characterized. In this study, the unigenes involved in flavonoid metabolic pathway were identified from the transcriptome database of *Dryopteris erythrosora*. These unigenes include chalcone synthase (28 unigenes), chalcone isomerase (6 unigenes), flavanone 3-hydroxylase (8 unigenes), flavonol synthase (64 unigenes) and flavanone 4-reductase (18 unigenes). We screened candidate genes for functional investigation by cluster analysis and redundancy deletion from the unigenes respectively. The expression of these genes has been detected by qPCR with different light intensity treatment. Changes in expression levels are inconsistent from different genes. Among them, *DeCHS1* and *DeCHI1* have high levels in buds. The expression levels of *DeF3H1* and *DeF3H2* were low and decreased under the bright light. *DeFLSs* were highly distributed in buds; *DeFLS4* and *DeFLS6* were mainly distributed in buds and affected by light, may involved in plant development. Only *DeDFR2* showed very high expression of *DeDFRs*. In addition, by using the prokaryotic expression and enzyme activity analysis, we found all of three DeCHI proteins can not only catalyze naringenin chalcone to naringenin, but also catalyze isoliquiritigenin to liquiritigenin. This function was only reported in CHI-type II genes of legume plants and some bryophytes. It was not fully consistent with the evolutionary relationship, and need to be further verified. The results of enzyme activity tests of DeDFR1, DeDFR2 and DeDFR4 in vitro show that different products can be obtained under different DeDFR. Ferns are extremely important groups in the process of plant evolution. The current research results also show that the ferns have their particularity in the process of flavonoid biosynthesis. This study provides scientific data for elucidating the flavonoid metabolic pathway of ferns and flavonoid gene evolution.

Effect of controlled deterioration on seed vigor of 4 oat (*Avena satuva L.*) cultivars

Hang Cheng, *Lingling Chen, Ye Zhang, Mingya Wang, Peisheng Mao*
China Agricultural University

Seed deterioration occurs during storage. This would lead to the decline of seed quality and ultimately the loss of seed vitality, which caused huge economic loss in the agricultural production. In order to explore the deterioration tolerance capacity of different oat (*Avena satuva L.*) cultivars of Qinghai Province, 4 main cultivars were studied in this research. All the oat seeds with 16% moisture content were deteriorated at 45°C for 0,1, 2,3, 4,5 d. Then the germination percentage, germination potential, germination index and the average germination time were determined. The results showed that the germination of all these cultivars were inhibited after seed deterioration. The germination percentage, germination potential, germination index were declined and the average germination time was increased. The germination percentage of Baiyan 7 and Linna shapely declined with deterioration and lost the vitality after deteriorated 4 d. However, at the same time, the germination percentage of Qinghaitianyanmai and Jiayan 2 were 38% and 3%, respectively. After 2 d deterioration, the germination potential and germination index were the maximum in Qinghaitianyanman and minimum in Baiyan 7. The average germination time of Qinghaitianyanmai was the lowest among all these cultivars during seed deterioration. As a conclusion, Qinghaitianyanmai had better deterioration tolerance than Baiyan 7, Linna and Jiayan 2 and could be prior to use in agricultural production.

Effect of waterlogging on the growth and photosynthetic characteristics of *Cynodon dactylon* in Three Gorges Reservoir area, China

Ruimei Cheng
Institute of Forest Ecology, Environment and Protection, Chinese Academy of Forestry, Beijing

To explore the effects of water levels in the Three Gorges Reservoir in the growth, physiological and chlorophyll fluorescence traits of *Cynodon dactylon,* four different water treatments were applied to the plants to study the responses of photosynthetic physiology to waterlogged regimes, including normal growth group, root submergence group, semi-plant submergence group and whole plant submergence group. Results indicated that: (1) The basal diameter, stem height and non-photochemical quenching tended to increase in different waterlogging treatments for 45 d, illustrating that *C. dactylon* had adaptive response to different waterlogged environments. (2) The responses of the leaf length, leaf width and aboveground biomass in different waterlogged environment were different. Compared with the normal growth group, the semi-plant submergence group had an increase in the leaf length, leaf width and aboveground biomass, whereas the root submergence group and the whole plant submergence group had a decrease in those parameters. (3) The specific leaf area, net photosynthetic rate, stomatal conductance, transpiration rate, maximal photochemical efficiency, electron transfer rate and photochemical quenching of all waterlogged groups were significantly lower than the normal growth group. The above-mentioned parameters in the root submergence group and the semi-plant submergence group were able to maintain at a relatively high level, while that the whole plant submergence group declined to extremely lower. This study suggested that *C. dactylon* can adapt to waterlogged environment well (especially in partial waterlogged environment), and thus it can be applied to the re-vegetation and landscape restoration of Hydro-Fluctuation Belt in Three Gorges reservoir area in future, especially in the low altitude region (145-160 m) which suffers from the long-term water level fluctuation. Meanwhile, those tolerate-submergence characteristics of *C. dactylon* also provide a basis for screening riparian plants of Three Gorges Reservoir, China.

Elucidation of mechanism of formation of amino acids in dark-treated tea (*Camellia sinensis*) leaves

Sihua Cheng[1], *Yiyong Chen*[1], *Xiumin Fu*[2], *Ziyin Yang*[2]
1. South China Botanical Garden, University of Chinese Academy of Sciences
2. South China Botanical Garden, Chinese Academy of Sciences

Effect of dark on crop growth has been widely studied, while less attention has been paid to effect of dark on quality-related metabolites in crops. Shade management (dark treatment) on tea (*Camellia sinensis*) plants is a common approach to improve free amino acids in raw materials of tea leaves. However, the reason for accumulation of free amino acids in dark-treated tea leaves is still unknown. In the present study, dark treatment significantly increased content of free amino acids and reduced content of soluble proteins in tea leaves. Quantitative proteomics analysis showed that most enzymes involved in biosyntheses of amino acids were downregulated by dark treatment. Chloroplast numbers reduced in dark-treated leaves and the content of soluble proteins reduced in the chloroplasts isolated from dark-treated leaves compared to control. These suggest that proteolysis of chloroplast proteins contributed to amino acid accumulation in dark-treated leaves. Two chloroplasts proteases, ATP-dependent Clp protease proteolytic subunit 3 and protease Do-like 2, were upregulated in dark-treated leaves. This study firstly elucidated the mechanism of accumulation of amino acids in dark-treated tea leaves.

In vivo calcium dynamics in plant cells: A holistic view

Alex Costa
University of Milan, Department of Biosciences

In plants, increases in cytosolic Ca^{2+} concentration ($[Ca^{2+}]_{cyt}$), occuring in response to both biotic and abiotic stimuli, work as a key components of different signal transduction pathways. Depending on the stimulus, Ca^{2+} rises can display the form of a single transient or repetitive Ca^{2+} oscillations and are commonly designated as "Ca^{2+} signatures". Generation and shaping of Ca^{2+} signatures depends on fine-tuning of Ca^{2+} influxes and effluxes occurring at both the plasma membrane (PM) and membranes of the different subcellular compartments. The opening of PM Ca^{2+}-permeable influx channels (e.g GLRs, CNGCs, OSCAs….) in response to different stimuli will release Ca^{2+} into the cytosol and cause the generation of a Ca^{2+} spike, while activity of active Ca^{2+} efflux transporters (e.g H^+-Ca^{2+} antiporters, Ca^{2+}-ATPases…) will return the $[Ca^{2+}]_{cyt}$ to resting concentrations. Not only cytosol but also organelles and other subcellular compartments (e.g. chloroplasts, mitochondria, endoplasmic reticulum…) experience Ca^{2+} transients, hence putatively participating in the cellular Ca^{2+} homeostasis and potentially in the Ca^{2+} signature shaping process. In order to precisely define how cytosolic and organellar Ca^{2+} dynamics are generated and shaped in different plant cell types, we have followed two complementary strategies: i) the development of new molecular tools for the *in vivo* study of the Ca^{2+} transport through plasma and organelle membrane/s; ii) the analyses of Ca^{2+} transients in cells of complex tissues and organs, in natural context and in close-to physiological conditions. To fulfil the above requirements, the following evidence will be presented: a) *in planta* use of the genetically encoded FRET (Förster Resonance Energy Transfer)-based Ca^{2+} Cameleon sensors. Attention will be given to the developed Cameleon probes for the analyses of Ca^{2+} dynamics in several subcellular compartments resulting in the identification of organellar Ca^{2+} transport mechanisms; b) development of a new microscopy solution, based on Light Sheet Fluorescence Microscopy (LSFM), for FRET-based Ca^{2+} imaging in root; c) use of the presented technologies for the study of mutants impaired in the generation and regulation of cytosolic Ca^{2+} dynamics involved in development processes. Our approach has allowed to identify and study components of PM, mitochondria and ER localized Ca^{2+} transporters which are effective in regulating Ca^{2+} dynamics in the different compartments in response to external stimuli or developmental processe.

Suppression of *OsIBR*, encoding an E3 ubiquitin ligase, results in the enhanced Brassinosteroid responses in rice (*Oryza sativa* L.)

Hye Jo Min, ***Li Hua Cui***, *Woo Taek Kim*
Yonsei University

Ubiquitination is a critical post-translational modification of diverse cellular proteins. In sequential steps of ubiquitination, E3 ubiquitin ligase provides substrate specificity by transfer ubiquitin (Ub) to target proteins. In higher plants, E3 ubiquitin ligases are involved in various cellular processes, including hormonal and environmental stress responses. In this study, we elucidated possible role of a novel rice E3 Ub ligase IBR in brassinosteroid (BR) signaling. We identified a T-DNA inserted rice mutant, *osibr (increased brassinosteroid response)*. The *osibr* mutant plant showed increased BR responses in terms of leaf morphology, vegetative growth, and BR-related gene expressions. *osibr* displayed an increased lamina joint bending phenotype at both seedling and vegetative stages. When *osibr* was grown in the presence of BR or propiconazole (Pcz), an inhibitor of BR synthesis, it exhibited BR-sensitive and Pcz-insensitive phenotypes, respectively. In addition, the expression levels of BR biosynthesis genes were lower in the mutant plants than those of wild-type rice plants, suggesting an increased level of BR signaling in the mutant plant. Bacterially expressed OsIBR contained an E3 ubiquitin ligase activity and displayed dual-localization patterns to nucleus and cytoplasm. OsIBR directly interacts with OsBZR1, a positive regulator of BR signal transduction pathway, as evidenced by the results of yeast two-hybrid and in vitro pull-down assays. A higher amount of OsBZR1 was detected in the protoplasts prepared from *osibr* as compared to the wild-type protoplasts. Consistent with these results, OsBZR1 was poly-ubiquitinated by OsIBR and degraded by the 26S proteasome system. Collectively, our results suggested that OsIBR participates in the BR response as a negative factor by down-regulating OsBZR1 in rice plant.

Optimization of regeneration and transformation in *Sesamum indicum* L. cultivar JK-1 for studying tissue specific promoters

Anirban Jyoti Debnath, *Debabata Basu, Samir Ranjan Sikdar*
Bose Institute

For the crop improvement of *Sesamum indicum*, heterosis breeding can be an approach in which a male sterile/restorer line of sesame is necessary. Male sterility can be achieved by silencing of anther specific genes. For this approach, study of tapetum specific promoter is a perquisite phenomenon. Since sesame is an extremely recalcitrant plant, regeneration protocol of this plant was standardised at first for this study. Various combinations of 6-benzylaminopurin, thidiazuron, α-napthalinic acetic acid, indole acetic acid, indole butyric acid and gibberellic acid were used to standardise each step of organogenesis, shoot elongation and root induction. Among the different types of tried explants, best regeneration frequency (94.82±1.34%) was obtained from 4 days old cotyledon. To find an anther specific gene, sesame anther specific cDNA-subtracted library was created and screened thoroughly. One EST having homology with β-1,3 glucanase was isolated. Upstream element of the gene was identified by promoter walking, cloned in pPZPY112 vector and was fused with GUS reporter gene. TA29 is a known anther specific gene of *Nicotiana tabacum*. Promoter of TA29 served as control in this study. The promoter region of TA29 was amplified from *Nicotiana* genomic DNA and cloned in pCAMBIA2301 and was fused with GUS reporter gene. *Agrobacterium tumefaciencs* A4404 was transformed by both the constructs. Both constructs were used for *Agrobacterium*-mediated transformation of sesame, taking *Nicotiana* as control. Transgenic lines of sesame and *Nicotiana* were raised and confirmed by PCR and southern hybridisation. Anther-specific GUS expression of the both promoters were visualised by sectioning of anther.

How does fast or slow drought affect the drought-induced woody seedling mortality?

Honglang Duan[1], *Yue Xu*[2], *Houbao Fan*[1], *Juxiu Liu*[2]
1. Jiangxi Key Laboratory for Restoration of Degraded Ecosystems & Watershed Ecohydrology, Nanchang Institute of Technology
2. Key Laboratory of Vegetation Restoration and Management of Degraded Ecosystems, South China Botanical Garden, Chinese Academy of Sciences

The worldwide forest mortality has been attributed to severe droughts and increasing temperatures. Despite substantial progress in unravelling physiological mechanisms underlying drought-induced tree mortality, details about carbon and water relations towards tree mortality remain still unresolved. In particular, it is currently poorly understood how the intensity and duration of drought would impact the relative contributions of hydraulic failure and carbon depletion to mortality of subtropical woody species. In the context of global climate change characterizing with changing precipitation patterns, bridging this knowledge gap will help to improve the predictions in forest responses to future climates in the subtropical regions of China. In this study, one year old potted seedlings of three native woody species in south China, i.e. *Schima superb* (a tree species), *Castanopsis chinensis* (a tree species) *and Syzygium rehderianum* (a shrub species), were well watered and fertilized until the commencement of soil drought treatments (i.e. fast drought and slow drought). Water was completely withheld in the fast drought treatment, while 80-90% of the whole plant water loss was rewatered to seedlings in the slow drought treatment. We measured leaf gas exchange, growth, plant hydraulics, non-structural carbohydrates (NSC) as well as rate of mortality regularly until the death of seedlings, enabling to distinguish the responses of carbon and water relations to fast or slow drought. We are also able to compare drought strategies among the three species. Results showed that leaf gas exchange, water potential and xylem hydraulic conductance of the three species exhibited more profoundly declines in the fast drought treatment than slow drought treatment, indicating that fast drought had greater impacts on physiological responses than slow drought. *Syzygium rehderianum* had greater drought sensitivities in leaf gas exchange, leaf water potential and xylem embolism, associated with less negative P50 (i.e. the xylem potential at which 50% of xylem hydraulic conductance was lost) and turgor loss point, while *Schima superb* had higher drought tolerance. Organ NSC will also be reported. In combination with NSC data, we are able to determine the relative contribution of hydraulic failure and carbon depletion to seedling mortality and generate a better understanding of effects of drought intensity and duration on carbon and water relations. Furthermore, implications of shifts in forest composition and functioning in subtropical China will be obtained.

Genes sufficient for synthesizing peptidoglycan are retained in gymnosperm genomes, and MurE from *Larix gmelinii* can rescue the albino phenotype of *Arabidopsis MurE* mutations

Yilan E[1], *Ningning Li*[1], *Kudo Hiromi*[2], ***Xiaofei Lin***[1], *Zhang Zhe*[3], *Takano Hiroyoshi*[2]
1. College of Life Sciences, Inner Mongolia University
2. Graduate School of Science and Technology, Kumamoto University
3. College of Biological Science, China Agriculture University

The endosymbiotic theory states that plastids are derived from a single cyanobacterial ancestor that possessed a cell wall. Peptidoglycan (PG), the main component of the bacteria cell wall, gradually degraded during plastid evolution. PG-synthesizing *Mur* genes have been found to be retained in the genomes of basal streptophyte plants, although many of them have been lost from the genomes of angiosperms. The enzyme encoded by bacterial *MurE* genes catalyzes the formation of the uridine diphosphate-N-acetylmuramic acid (UDP-MurNAc) tripeptide in bacterial PG biosynthesis. Knockout of the *MurE* gene in the moss *Physcomitrella patens* resulted in defects of chloroplast division, whereas T-DNA-tagged mutants of *Arabidopsis thaliana* for *MurE* revealed inhibition of chloroplast development but not of plastid division, suggesting that AtMurE is functionally divergent from the bacterial and moss MurE proteins. Here, we could identify 10 homologs of bacterial *Mur* genes, including *MurE*, in the recently sequenced genomes of *Picea abies* and *Pinus taeda*, suggesting the retention of the plastid PG system in gymnosperms. To investigate the function of gymnosperm MurE, we isolated an ortholog of *MurE* from the larch, *Larix gmelinii* (*LgMurE*) and confirmed its presence as a single copy per genome, as well as its abundant expression in the leaves of larch seedlings. Analysis with a fusion protein combining GFP and LgMurE suggested that it localizes in chloroplasts. Cross-species complementation assay with MurE mutants of *A. thaliana* and *P. patens* showed that the expression of *LgMurE* cDNA completely rescued the albefaction defects in *A. thaliana* but did not rescue the macrochloroplast phenotype in *P. patens*. The evolution of plastid PG and the mechanism behind the functional divergence of *MurE* genes were discussed in the context of information about plant genomes at different evolutionary stages.

Genetic mechanisms underlying the evolutionary switches between pigments in *Caryophyllales*

Tao Feng[1,2], *Samuel Brockington*[1]
1. University of Cambridge
2. Wuhan Botanical Garden, CAS

Three groups of pigments, carotenoids, flavonoids including anthocyanins, and betalains are responsible for the colouration of flower, fruit, seed and vegetarian organ. Whereas anthocyanins are the most common pigments and broadly distributed across flowering plant, betalains replaced anthocyanins in the order of the Caryophyllales. However, along with the diversification of Caryophyllales, betalains have been lost and the pigment type reversed back to anthocyanin in at least three lineages. Intriguingly, these two kinds of pigments are mutually exclusive and have never been found in one single species. In betalain pigmented species, it is known that the structural enzymes within anthocyanin pathway are evolutionarily maintained but downregulated at the regulatory level. However, the fate of the betalain synthesis pathway, when the pigment type reverses to anthocyanic pigmentation is not known. Here we examine evolutionary fate of the betalain synthesis pathway across multiple reversions to the anthocyanic condition, and show that invariably the betalain pathway, is in various stages of degeneration and pseudogenisation, suggesting that mutual exclusion of the two pigment types is in part the result of wholesale loss of the betalain pathway.

Secondary woodiness in African representatives of Tordylieae (Apioideae, Apiaceae): Paedomorphic traits are confined to rosette shoots

Kamil Frankiewicz[1], *Alexei Oskolski*[2,3], *Anthony Magee*[4], *Łukasz Banasiak*[1], *Krzysztof Spalik*[1]
1. Department of Molecular Phylogenetics & Evolution, Institute of Botany, Faculty of Biology, University of Warsaw, Biological & Chemical Research Centre, ul. Żwirki i Wigury 101, 02-089 Warszawa
2. Department of Botany and Plant Biotechnology, University of Johannesburg, PO Box 524 Auckland Park 2006, Johannesburg, South Africa
3. Botanical Museum, Komarov Botanical Institute, Prof. Popov 2, 197376 St.Petersburg, Russia
4. Compton Herbarium, Biosystematics and Collections, South African National Biodiversity Institute (SANBI), Compton Herbarium, Kirstenbosch Research Centre, Kirstenbosch National Botanical Garden, P/Bag

Tordylieae is mostly herbaceous clade of Apiaceae subfamily Apioideae. However, several species of its African lineage have stems with woody base while the genus *Notobubon* is shrubby. Character mapping on molecular tree suggests that this genus is secondarily woody, i.e. wood habit was derived from herbaceous ancestor. According to Carlquist's theory of paedomorphosis such plants should demonstrate juvenile wood traits prolonged into secondary xylem. To verify if the theory is applicable to woody Tordylieae, we have examined secondary xylem in shrubby *Notobubon capense* and herbaceous representatives of closely related genera: perennial *Afrosciadium magalismontanum*, annual *Capnophyllum macrocarpum* and perennial *Dasispermum suffruticosum*.

We found that the wood of *N. capense* as well as the outer regions of secondary xylem in *D. suffruticosum* and *C. macrocarpum* have the suite of characters that is common for other woody Apioideae (e.g. *Bupleurum*, *Heteromorpha* etc) without any paedomorphic traits. However, inner regions in two latter species are paedomorphic, as expressed by scalariform pitting on lateral vessel wall. Both species are similar in forming lateral plagiotropic polycarpic shoots branched off from the rosette shoot with compressed internodes topped with terminal umbel. *Afrosciadium magalismonta-*

num also forms rosette, but topped with orthotropic monocarpic shoot. Wood in this species resembles inner regions of wood in *D. suffruticosum* and *C. macrocarpum* and is completely paedomorphic. Our observations allow us to speculate that development of paedomorphic wood in these taxa is confined to rosette shoots with short internodes. Apparently, the onset of formation of lateral polycarpic shoots as in *Notobubon* can trigger the deposition of advanced wood lacking paedomorphic traits. The shrubby habit in *Notobubon* could be result of longer persistence of lateral polycarpic shoots in its perennial herbaceous ancestor.

Study on kin recognition and physiological strategies of adjacent *Pinus thunbergii*

Yuan Gao, *Jiahui Guan*

Linyi Scientific Exploration Laboratory

The kin recognition of plants is a plant that adjusts its own growth ecological strategy and promotes the survival and reproduction of the relatives by identifying the relationship between the surrounding individuals and their own. At present, there is still much controversy about whether the genetic identification of the plants is real. This study used Chinese typical gymnosperms and afforestation-*Pinus thunbergii*. High performance liquid chromatography (HPLC) was used to detect the content of chlorophyll (chlorophyll a and chlorophyll b) in the primary production capacity and phenolic acid (ferulic acid, vanillic acid and syringic acid) in the secondary metabolites, to try to reveal the existence of kin recognition of gymnosperms. The results of the study showed that pine needles of *Pinus thunbergii* of chlorophyll a, chlorophyll b, ferulic acid, vanillic acid, syringic acid and ferulic acid showed is a group of far-genetic relatedness was significantly higher than a group of near-genetic relatedness. This study reveals that under natural conditions, *Pinus thunbergii* can identify neighbor strains phylogenetic distance, and correspondingly adjust physiological strategy, such as primary production and secondary metabolite distribution differences. This is the first study to discover and validate kin recognition of *Pinus thunbergii* is a real existence, as the world's first reported in gymnosperms, global the second case reports of woody plants.

Dynamic localization of ROP2 GTPase in root hairs requires the trans-Golgi network/early endosome-mediated vesicle trafficking in parallel to GDI1

Fu-Rong Ge[1], *Sen Chai*[1], *Qiang-Nan Feng*[1], *En Li*[1], *Jian-Wei Pan*[2], *Sha Li*[1], *Yan Zhang*[1]

1. State Key Laboratory of Crop Biology, College of Life Sciences, Shandong Agricultural University

2. College of Chemistry and Life Sciences, Zhejiang Normal University, Zhejiang

Plant tip growth is regulated by spatiotemporally restricted localization of activated ROPs. Extensive studies suggested evolutionarily recurrent mechanisms on the dynamic localization of activated ROPs by guanine nucleotide exchange factors (RopGEFs) and GTPase activating proteins (RopGAPs). However, whether guanine nucleotide dissociation inhibitors (GDIs) and vesicular trafficking play roles in the dynamic localization of ROPs, like their counterparts in other phyla, was unclear. Here, we examined the roles of GDI1 and vesicle trafficking on the dynamic targeting of ROP2 during *Arabidopsis* root hair growth. We show that the dynamic targeting of ROP2 relies on brefeldin A (BFA)-sensitive, ADP-ribosylation factor1 (ARF1)-mediated post-Golgi trafficking. Specifically, ROP2 recycling depends on Adaptin Protein 1 (AP1)-regulated protein sorting at the trans-Golgi network/early endosomes (TGN/EE), but not on RabA4b-mediated post-Golgi secretion or RAB5-mediated vacuolar trafficking. Functional loss of GDI1 significantly reduced ROP2 recycling at the apical plasma membrane while genetic interference of vesicle trafficking significantly contributed to ROP2 recycling only at the absence of GDI1. Results presented here demonstrate a crucial role of GDI1 and TGN/EE-mediated protein sorting in ROP2 targeting during root hair growth and reveal an evolutionarily conserved regulatory mechanism underlying the establishment and maintenance of a single and unique polarization site during tip growth.

Functional analysis of kation transport proteins in salt-tolerance of the halophyte *Nitraria sibirica*

Xin Geng, Li Wang, Chaoran Li, Yukun Ma, ***Xiaofei Lin***

College of Life Sciences, Inner Mongolia University

The mechanism of that saline plants adapt to salt-stress environment, involves in complex factors, such as cell structure, physiological processes and metabolism regulation. Among these complicated processes, the kation transporters play important roles in plant salt-tolerance. Na^+/H^+ antiporters are integral proteins located in vacuolar membrane and cytomembrane. The cytomembrane Na^+/H^+ antiporter proteins (SOS1) can transport cytoplasmic Na^+ to the exocellular, and the vacuolar Na^+/H^+ antiporter proteins (NHX1) can deliver Na^+ into the vacuoles against the electrochemical gradient. The compartmentation of Na^+ provides an effective mechanism to avert the deleterious effects of Na^+ on cytosol, and maintain an osmotic potential by Na^+ in vacuoles. On the other hand, high-affinity potassium transport protein (*HKT1*) located on the plasma membrane, uninstalls excessive Na^+ from the xylemby to the phloem by the way of symplasmic, then transports back to the roots, to prevent the excessive accumulation of Na^+ in aboveground tissues. *Nitraria* L. is a genus of flowering plants in Zygophyllaceae family, which grows primarily in deserts and semideserts, and exhibits strong salt-resistance. Therefore, to elucidate the molecular mechanism of salt-tolerance and to exploit salt-tolerant genes in *Nitraria* is very necessary. In the study, we isolated orthologs of *NHX1*, *SOS1* and *HKT1* genes from *Nitraria sibirica Pall* using homology-based cloning methods, and analyzed the molecular features and expression characteristics of the *NsHX1*, *NsSOS1* and *NsHKT1*.These results showed that the expression of *NsHX1*, *NsSOS1* and *NsHKT1* were induced by abiotic factors, such as drought, cold and salt. On the other hand, the function and application value of these genes in improving salt tolerance of plants were investigated by transforming *Arabidoposis thiliana* and *Populus tomentosa*. The results indicated that over-expression of *NsHX1*, *NsSOS1* and *NsHKT1* enhanced salt-tolerance of transgenic plants, suggesting that these genes play important roles in adapting to salt-stress environment of *N. sibirica*, and will likely be useful for improving salt-tolerance of forage grass agricultural crops and forest trees.

Pectin modification and promotion of root elongation by Aluminum in *Camellia sinensis* L. seedlings

Masoumeh Safari
Tarbiat Modares University (TMU)

Aluminum (Al) toxicity is a major factor limiting crop productivity in acidic soils. The cell wall is the first point of contact when plant roots are exposed to Al, and serves as a major pool for the metal. In Al-sensitive plants, Al bound to the cell wall negatively affects wall structure and function by increasing its rigidity and reducing cell expansion and mechanical extensibility, thus inhibits root elongation. The major Al binding site in cell walls are pectic polysaccharides. Demethylated, negatively charged carboxylic groups of pectin, bring about from the activity of pectin methylesterase (PME), have a high affinity for Al. Different from most of terrestrial plants, tea (*camellia sinensis* L.) growth is stimulated by Al and especially its root elongation is promoted. In this study the effects of Al on root elongation, the mechanical extensibility of the cell wall, and the modification of pectin fractions in the roots of tea were examined.Ten day old tea seedlings were treated with 400 µM Al in an aerated modified ¼ strength Hoagland solution (without phosphate, pH 4.5), for 8 days. Mechanical change of root apex of seedlings was monitored by freeze–thawing method. monoclonal antibodies (JIM5 and JIM7), which are specific for cell wall pectin differing in the degree of methylation, were used for immunofluorescence localization of cell wall pectins. Uronic acid content and the activity of PME were measured. Exposure to Al significantly promoted root cells extensibility and increased cell elongation of tea seedlings. Using immunofluorescence localization of pectin with specific antibodies bright fluorescence of antibody JIM7 was observed in sections obtained from Al-treated root apices demostrating high-methyl-ester pectins, compared to the control root sections where the fluorescence intensity of JIM5 (stains low-methyl-ester pectins) was high. Moreover, in comparison with the control, Al treatment resulted in a significant decrease of PME activity. Analyses of pectin fractions showed elevation of the ratio of total sugars to uronic acids in Al-exposed roots up to twice of the control ones. The result suggest that structural modifications of pectin in elongation zone of tea roots prevent insertion and accumulation of Al and its inhibitory role. However the mechanism by which elongation is triggered is yet to be clarified.

Cell culture of *Acanthophyllum glandulosum* L. as an alternative source for saponin

Mitra Jamshidi
1. Research and Development Section, Sehat Industrial and Commercial CO., Tehran, Iran,
2. Department of Plant Biology, Faculty of Biological Science, Tarbiat Modares University (TMU), Tehran, Iran

Saponins are a large family of secondary metabolites which are structurally-related compounds of steroid or triterpenoid aglycone (sapogenin) linked by glycosidic linkage to one or more oligosaccharide moieties. Because of their surfactant and foaming properties, saponins are used in production of shampoos, liquid detergents, toothpastes. Due to critical function of foam in removal of oils and fats from surfaces, foaming characteristic of detergents has an important role in their acceptability. Saponins are also used as emulsifier and long-lasting foaming agents in beverages. *Acanthophyllum glandulosum* L. is one of the endemic species of the genus Acanthophyllum (Caryophyllaceae) in Iran, which because of the prevalence of saponin in its roots has been traditionally used as a detergent. Despite the wide use, the plant has never been cultivated, neither it's various properties e.g., seasonal variations of growth are well studied. Biotechnological approaches have been recently provided researchers with the opportunity to find alternatives for production of secondary metabolites, other than the intact and sometimes endangered plants. It is widely accepted that plant tissue cultures have potential to produce bioactive compounds, in the amounts comparable with the intact plant, with the great advantage of sustainability of the cell cultures. Moreover, there is no need for harsh methods for extraction. In the present study a rapid growthing cell line of *Acanthophyllum glandulosum* L. was established from the seeds in a modified LS medium, supplemented with 3 mg L^{-1} of NAA, 3 mg L^{-1} of IAA, and 1 mg L^{-1} 2,4-D. The latter was omitted as soon as callus was emerged. Saponins were extracted from callus as well as intact plants root with diethyl ether and n-butanol subsequently. Steroid saponins were assessed spectrophotometrically using anisaldehyde-ethyl acetate and triterpenoid saponins with vanillin-sulfuric methods. The contents of saponin in calli was evaluated as 3.25 mg g^{-1} DW, which was noticeable vs. of the intact roots, 0.4 mg g^{-1} DW. The results clearly introduce the callus of *Acanthophyllum glandulosum* L. as an appropriate natural source for saponins. It is also noteworthy that saponins can be easily and efficiently extracted from this source.

Crucial role of fructan in the maintenance of membranes of wheat seedlings during severe drought stress

Farnoosh Nemati
Tarbiat Modares University (TMU)

The plasma membrane is thought to be the major target for drought stress damage due to changes in composition and structures of water and phospholipids. Removal of water from the membrane disrupts the normal bilayer structure and results in the membrane becoming exceptionally porous when desiccated. Fructan has the capacity to stabilize membranes and prevent leakage during water cessation. In the present study the relationship between fructan content and membrane damages was evaluated in 4-day old seedlings of a drought-tolerant (Sirvan) and a drought-sensitive (Marvdasht) wheat cultivar exposed to 7 days water cessation and subsequent re-watering. In comparison with sensitive cultivar, the tolerant one accumulated more fructan (3.56 ± 0.3 μg/g FW) meanwhile decreased the level of membrane leakage and lipid peroxidation. Freeze–thawing experiment showed that drought stress remarkably increased freeze-disrupt coefficient of sensitive cultivar (4.5 fold higher than of tolerant one) and severely damaged the epidermal and outer cortex cells of their leaves. The results suggest fructan as a flexible soluble carbohydrate with a direct protective effect on membrane integrity which plays a crucial role in the tolerance of wheat seedling against drought stress conditions.

Generation of a Humidity-sensitive Male Sterility (HSMS) system for hybrid wheat breeding

Changfeng Guo, Song Bo, Yingchun Zhang, ***Xiaoquan Qi***
Institute of Botany, Chinese Academy of Sciences, Nanxincun 20, Fragrant Hill, Beijing

Heterosis has been widely used in crops such as rice and maize for production of higher grain yield. Wheat (*Triticum aestivum*) is one of the most important cereals in the world. But heterosis in wheat has not been extensively explored due to lack of easy-to-use conditional male-sterile germplasm. The commonly used photoperiod-sensitive male sterility (P SMS) suffers from unpredictable changes of temperatures, causing failure in hybrid production. Our previous study on rice showed that a gene (*OsOSC12*) encoding 2,3-oxidoapualene cyclase for biosynthesis of a triterpene poaceatapetol involves in pollen coat formation. Lost-function mutants of *OsOSC12* are male sterile at normal relative humidity (RH) and fertile when RH is higher than 80%. This humidity-sensitive male sterility (HSMS) has the advantage of using two-line hybrid breeding system for hybrid production. In this study we identified three conserved homologs of *OsOSC12* in the hexaploid wheat (*Triticum aestivum*) genome. Each wheat genome has one conserved gene, and the three annotated genes from the A, B and D genomes were named as *TaOSC12A*, *TaOSC12B*, and *TaOSC12D*, respectively. By using TILLING (Targeting Induced Local Lesions IN Genomes) technology and Sanger sequencing, 9 mutations in *TaOSC12A,* 5 mutations in *TaOSC12B*, and 14 mutations in *TaOSC12D* were identified. GC-MS analysis of *Nicotiana benthamiana* heterologous expressing the three wheat genes revealed that *TaOSC12B* and *TaOSC12D* produced poaceatapetol, while *TaOSC12A* failure to product this triterpene. We expect that crosses between loss-of-function mutants of *TaOSC12B* and *TaOSC12D* will generate HSMS plants for hybrid seed production in wheat.

NaCl alleviates the impact of drought stress in the halophyte *Atriplex canescens*

Huan Guo*, Ya-Qing Pan, Yan-Nong Cui, Suo-Min Wang, Ai-Ke Bao*
State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University

Drought and salinity are the major abiotic factors threatening to agricultural productivity and ecological environment all over the world. Halophytes have evolved multifarious adaptation strategies to deal with saline surroundings. One of those is capable of secreting great quantities of salt in epidermal bladder cells, which sequester excess of Na^+ deviate from the photosynthetic tissue and allow plants survive and grow well in a low water potential environment. *Atriplex canescens* is a C_4 perennial fodder shrub with excellent tolerance to salinity and drought. Our previous study showed that moderate salinity (100 mM NaCl) has a positive effect on the growth of *A. canescens* seedlings, and especially, Na^+ exhibits high contribution to the leaf osmotic potential (Ψs) by increasing accumulation in tissues and salt bladders under salinity treatments, implying that Na^+ accumulation might also facilitate the osmotic adjustment of *A. canescens* seedlings in response to drought conditions. To test this hypothesis, in the present study, five-week-old *A. canescens* seedlings were subjected to water deficit (30% of field water capacity) in the presence or absence of additional NaCl (100 mM) with pot experiments. The results showed that the biomass, leaf net photosynthetic rate and relative water content of *A. canescens* seedlings decreased significantly under drought stress. However, the addition of 100 mM NaCl enhanced photosynthesis capacity and increased Na^+ concentration in all tissues and Na^+ sequestration in salt bladders. The contribution of Na^+ to Ψs significantly increased by 72% in the presence of additional NaCl compared to drought stress alone, while the contribution of K^+ to Ψs maintained a stability. In addition, the concentrations of three compatible solutes (free proline, betaine and soluble sugar) in leaves exhibited a significant increase in the presence of 100 mM NaCl than that of the drought stress. As a result, *A. canescens* is able to accumulate a high concentration of Na^+ and osmocompatible solutes and use them directly for osmotic adjustment, which was coupled with an improvement in leaf hydration and photosynthetic activity. These findings suggest that, 100 mM NaCl resulted in optimal growth of *A. canescans* seedlings and alleviated the deleterious impacts on the growth of plants under arid environments.

Molecular characterization of floral left-right asymmetry

Wuxiu Guo
Sun Yat-sen University

Left-Right (LR) asymmetry widely manifests in nature. In animals, previous works reported LR asymmetry is regulated by factors including Myo31DF in *Drosophila* and Nodal in snails. However, it is poorly studied in plants. In legume subtribe Phaseolinae, species are diversified with flowers in symmetrical, sinistral (left-handed), and dextral (right-handed) patterns. Here, we selected mung bean (*Vigna radiata*) as a model, which bears sinistral flowers, to unveil the molecular basis regulating floral LR asymmetrical development. We identified and characterized mutated mung bean *sinistral flower* (*sif*) processing flowers inverted into dextral patterns by large-scale γ-ray mutagenesis together with map-based cloning. *SIF* encodes a microtube-associated protein and is specifically enriched in developing flowers. Interestingly, we found Phaseolinae floral patterns exhibiting geological-associated distributions, and closely related with unique *SIF* homologues statuses. Our study for the first time unveils a conserved factor SIF recruited in flower LR asymmetrical development, suggesting its function possibly gaining or losing in different areas during the evolutionary process of subtribe Phaseolinae.

Identification of nitrogen use efficiency genes in barley: Searching for QTLs controlling complex physiological traits

Mei Han[1,2]*, Julia Wong*[1,3]*, Tao Su*[1,2]*, Perrin Beatty*[1]*, Allen Good*[1]
1. Department of Biological Sciences, University of Alberta
2. Co-Innovation Center for Sustainable Forestry in Southern China, College of Biology and the Environment, Nanjing Forestry University
3. School of Biotechnology and Biomolecular Sciences

Over the past half century, the use of nitrogen (N) fertilizers has markedly increased crop yields, but with considerable negative effects on the environment and human health. Consequently, there has been a strong push to reduce the amount of N fertilizer used by maximizing the nitrogen use efficiency (NUE) of crops. One approach would be to use classical genetics to improve the NUE of a crop plant. This involves both conventional breeding and quantitative trait loci (QTL) mapping in combination with marker-assisted selection (MAS) to track key regions of the chromosome that segregate for NUE. To achieve this goal, one of initial steps is to characterize the NUE-associated genes, then use the profiles of specific genes to combine plant physiology and genetics to improve plant performance. In this study, on the basis of genetic homology and expression analysis, barley candidate genes from a variety of families that exhibited potential roles in enhancing NUE were identified and mapped. We then performed an analysis of QTLs associated with NUE in field trials and further analyzed their map-location data to narrow the search for these candidate genes. These results provide a novel insight on the identification of NUE genes and for the future prospects, will lead to a more thorough understanding of physiological significances of the diverse gene families that may be associated with NUE in barley.

A potential innovative technology for *in-situ* wood identification based on image processing and artificial intelligence

Tuo He*, Lichao Jiao, Min Yu, Xiaomei Jiang, Yafang Yin*
Wood Collection and Department of Wood Anatomy and Utilization, Research Institute of Wood Industry, Chinese Academy of Forestry

Illegal logging and timber trade is becoming serious problem domestically and internationally, threatening individual wood species, and even entire ecosystem. The need for accurate and rapid recognition of wood to combat illegal logging and illegal timber trade around the world is outpacing the ability to train personnel to perform this task. The traditional identification methods based on the wood anatomical characteristics rely on the experience and proficiency of inspectors, however, can only identify wood to the level of genus or category in general, despite of the non-anatomical methods (e.g. genetic, spectroscopic and chemical analysis). The recent rapid developing of computer technology and artificial intelligence suggests that it is high time to move towards automatic wood inspection systems and methods for *in-situ* wood identification. In this work, an automatic wood identification system based on image acquisition, image processing, feature extraction and artificial neural networks was proposed. The images based on wood macroscopic features were acquired from processed wood samples by an image acquisition system. The image processing including image binarization, medium filter, image enhancement and histogram equalization was then carried out. The wood anatomical structures, such as vessels, rays, axial parenchyma and fibers, were extracted using the discrete wavelet transform (DWT) and grey level co-occurrence matrix (GLCM) algorithms. Furthermore, a multi-layered network based on the support vector machine (SVM) was adopted for training to realize the classification of wood species. The result indicates that the application of this technique could provide an *in-situ* inspection for wood identification.

Molecular cloning and analysis of a novel gene encoding a KUP/HAK/KT potassium uptake transporter in *Cryptomeria japonica*

Yoshihiro Hosoo*, Hirokazu Nishiwaki*
Graduate School of Agriculture, Shinshu University

Potassium ion (K^+) is an essential nutrient for plants and plays crucial roles in various aspects of plant physiology, such as enzyme activation, osmotic regulation, and homeostasis maintenance. Many of the roles of K^+ are closely linked to K^+ transport across biological membranes, such as the plasma membrane and the tonoplast. Such K^+ transport is mediated by membrane proteins, which are classified as transporters and channels. The molecular mechanism of K^+ membrane transport has been studied in detail in herbaceous plants such as *Arabidopsis thaliana* and rice, whereas information on this mechanism in trees, especially in conifers, is limited. We have recently isolated and characterized several genes encoding K$^+$ transporters from *Cryptomeria japonica*, which is one of the most commercially important conifers in Japan. In this study, we isolated a novel gene encoding a K$^+$ transporter (CjKUP3) from *C. japonica*, and investigated its function and expression pattern. Samples of current-year needles, inner bark, differentiating xylem, male and female strobili, and roots were collected from *C. japonica* saplings and mature trees, and total RNA was extracted from these samples. Based on the sequences of *C. japonica* expressed sequence tags homologous to known K$^+$ transporters, primers were designed to amplify *C. japonica* cDNA containing the predicted full-length open reading frame (ORF) of a K$^+$ transporter gene. The target cDNA (*CjKUP3*) was amplified by RT-PCR and its sequence was analyzed. Subsequently, complementation tests using the *Escherichia coli* LB2003 strain, which is deficient in K$^+$ uptake and cannot grow on low-K$^+$ media, were conducted to examine the K$^+$ uptake function of the protein encoded by *CjKUP3*. A pPAB404 vector carrying the *CjKUP3* cDNA was transformed into the LB2003 cells and the transformants were tested for their ability to grow on solid media containing different K$^+$ concentrations. Additionally, expression levels of *CjKUP3* in various parts of *C. japonica* trees were quantified by real-time RT-PCR. The *CjKUP3* expression levels were quantified relative to actin gene expression levels as an endogenous control. The *CjKUP3* cDNA was predicted to contain an ORF of 2,358 base pairs encoding a protein of 786 amino acids. The translated sequence of *CjKUP3* was homologous to KUP/HAK/KT-type K$^+$ transporters derived from other plant species. The predicted membrane topology of CjKUP3 was similar to that of other plant KUP/HAK/KT transporters. The LB2003 cells expressing CjKUP3 were capable of growing in medium supplemented with a low level of K$^+$. This indicates that CjKUP3 is able to compensate for the defect in K$^+$ uptake in this mutant, and therefore that it plays a functional role in K$^+$ uptake. *CjKUP3* expression was detected in all samples examined in this study. *CjKUP3* expression levels in developing male strobili and female strobili were higher than those in other parts of *C. japonica*. These results indicate that CjKUP3 is involved in K$^+$ membrane transport in the cells of various parts of *C. japonica* trees, especially in the reproductive organs.

Dynamic change of HG methylesterification patterns in the procambium-cambium continuum

Jundi Liu[2], ***Jie Hou*** [1], *Xinqiang He*[1]
1. Gansu Agricultural University.
2. College of Life Sciences, Peking University.

Pectin is a major component of primary cell walls of all land plants and encompasses a range of galacturonic acid-rich polysaccharides. Homogalacturonan is one of the main components of pectin in cell walls in poplar. Homogalacturonan (HG) is known to be synthesized and secreted in a highly methylesterified form. The procambium and cambium is considered to represent sequential developmental stages of the same vascular meristem. The former has been further subdivided into procambium, initiating layer, and metacambium based on anatomical observations. In this work, dynamic change of HG methylesterification patterns in the procambium-cambium continuum was studied in *Populus tomentosa* by immunolocalization with monoclonal antibodies (JIM5 and JIM7) against HG with different methylesterification patterns. JIM5 optimally binds to at least four contiguous unesterified residues between or adjacent to a methyl-ester group while JIM7 binds to a relatively highly methyl-esterified epitope. As a result, JIM5 signal was most abundant in the differentiated phloem, but is faint in the cell walls of procambium, initiating layer, metacambium and cambium. While the JIM7 signal equally distributed in all the cell walls. Furthermore, we characterized the expression patterns of pectin methyl esterase (PME) genes which removed methyl ester groups from HG in this process and found that different PMEs had different expression patterns in the procambium-cambium continuum. In conclusion, pectin showed different methylesterification patterns in the procambium-cambium continuum, and further experiments need to be performed to characterize the different roles of PMEs in this process.

Variations in volatile oil yields of *Magnolia biondii* Pamp flower buds at different growth stages

Mingli Hu[1], *Mei Bai*[1], *Wei Ye*[2], *Hong Wu*[1]
1. State Key Laboratory for Conservation and Utilization of Subtropical Agro-bioresources, South China Agricultural University
2. Xi'an Botanical Garden of Shanxi Province

The dried flower bud of *Magnolia biondii* Pamp, commonly known as Xin-yi in China, is offcially listed in the Chinese Pharmacopoeia. To investigate the variations of the contents of volatile oil in *M. biondii* flower, biological characteristics observation, modified version of the tissue clearing method, semi-thin sections and volatile oil extraction were employed to detect the volatile yields of *M. biondii* flowers at various growth stages. The results indicated that the volatile oil yields in *M. biondii* flower at different growth stages had significant differences, which were closely related to the dry weight of flower, the oil cell densities and oil accumulation degree. The yields of volatile oil first increased and later decreased with the growth of flower buds. Flower buds of *M. biondii* were formed in June of 2015, the flower buds not only had the lowest dry weight (0.13 g) and the lowest density of oil cells (100.83 n/mm^2), but also had the maximum percentage of oil cells at the oil less stage, resulting in the lowest oil content (0.8%). In February of 2016, the flower buds had the highest dry weight (0.53 g), the maximum percentage of oil cells at the oil saturation stage and the highest density of oil cells (217.92 n/mm^2), which coincided with the highest oil yield (3.25%). In the full flowering stage in March of 2016, the flower buds had a lower dry weight and higher percentage of oil cells at the oil degrading stage and the lowest oil cell density (145.42 n/mm^2), resulting in the decrease of oil yield (1.45%). These results provided reference information for the economic value evaluation and rational utilization of the *M. biondii* flower.

Spatial and temporal regulation of petal growth by transcriptional networks

Hongyang Yu[1], *Jing Li*[1], *Wei Wang*[1], *Yanzhi Wang*[1], *Yongxia Zhang*[1], *Vivian Irish*[2], ***Tengbo Huang***[1,2]
1. Shenzhen University
2. Yale University

Plant organ growth entails the regulation of cell division, cell expansion, cell type differentiation, and patterning of the organ as a whole. Recent studies have uncovered a number of genes involved in controlling these critical processes during plant organ development, however, our understanding of the gene network regulating the temporal and spatial changes in organ growth is still limited. The *Arabidopsis* petal is an excellent model for dissecting the temporal and spatial regulation of plant organogenesis. In this study, we focus on investigating key transcription factors that conduct temporal and spatial-specific roles during petal growth. We characterized the interactions of the downstream genetic networks of these transcription factors by utilizing genomic, genetic, developmental biology approaches. We found that they coordinately regulate important genes involved in plant organ development, particularly those associated with plant hormonal pathways. We hope these results will help elucidate how these key genes function together in the temporal and spatial regulation of petal growth, and in the long term, further understand the general mechanisms that establish the patterns of plant organ development.

Optimization of the genetic transformation system for *Sinningia speciosa*

Yu-Ling Hung[1], *Chwan-Yang Hong*[2], *Chun-Neng Wang*[3]
1. Institute of Life Science, National Taiwan University
2. Department of Agricultural Chemistry, National Taiwan University
3. Institute of Ecology and Evolution Biology, National Taiwan University

Sinningia speciosa is a popular houseplant because of its big flower with a remarkable diversity in colors, patterns and shapes. *S. speciosa* has a small genome size (300 Mb), short life cycle, self-compatible, easily propagated in tissue culture. Therefore, it is emerging as a model plant for flower development studies. However, a reliable genetic transformation system is not available in *S. speciosa*. To this end, the *Agrobacterium*-mediated transformation and particle bombardment transformation were tested in this study. The overall transient transformation rate reached to 78.3% when three-weeks old seedlings were pre-cultured for 3 days on medium supplied with 1 ppm BA, followed by 5 days of co-culture with *Agrobacterium* strain EHA105. We further tested whether particle bombardment transformation can achieve better transformation rate. It was found that the transient GUS transformation rates under helium pressure 900 psi reach to 58.1% and 21.6% at distance 6 and 9 cm, respectively. Comparing the transformation efficiency of *Agrobacterium* and particle bombardment (78.3% vs. 58.1%), *Agrobacterium*-mediated transformation is chosen for further optimization. Under above pre-culture and co-culture conditions, the shoot regeneration rate is 17.2%, and the transformation rate is up to 2.1% after evaluating by Southern blotting. However, these seedlings take 8-12 months to regenerate. It is known callus grows rapidly with high regeneration rate, we also studied callus induction condition. Embryogenic callus was successfully induced with 0.1 ppm 2,4-D and 2 ppm BA plus 25 or 50 mM sorbitol in the medium. Callus transformation efficiency will be tested further. This study provided easy to follow and high efficiency *Agrobacterium*-mediated transformation protocol for studying gene regulation and functions in *S. speciosa*.

Photosynthesis, phototropins and myosin XI-i regulate mitochondrial behavior in *Arabidopsis thaliana* leaf palisade cells

Md. Sayeedul Islam[1], *Van Toan Nguyen*[1], *Shingo Takagi*[1], *Motoki Tominaga*[2], *Yusuke Kato*[3], *Wataru Sakamoto* [3]
1. Osaka University
2. Waseda University
3. Okayama University

Light-induced mitochondrial redistribution in *Arabidopsis thaliana* mesophyll cells occurs along with that of chloroplasts. Genetic approaches identified phototropin as the photoreceptor involved in blue light dependent chloroplasts photo-relocation movement. There are two phototropins in *A. thaliana*, termed *phototropin 1* (*phot1*) and (*phot2*). Our recent study proposed that the intimate association of mitochondria with chloroplasts is precisely regulated through photosynthesis- and phot2- dependent signals. To dissect how non-uniform distribution patterns of mitochondria are established, we analyzed movement of individual mitochondria on the outer periclinal cytoplasm under weak blue light by time-lapse fluorescence microscopy. In the dark-adapted wild-type (WT) leaves, mitochondria moved smoothly one time, suddenly paused, and resumed the movement. We examined two parameters; 1) the velocity of movement of each mitochondrion, and 2) the probability of stoppage of each mitochondrion. Results revealed that phot1 and phot2 function non-redundantly in the early acceleration of the velocity of mitochondrial movement, while phot2 predominantly controlled the late immobilization of mitochondria. We were further interested in factors involved in the regulation of mitochondrial behavior. Higher plants have two classes of myosin, VIII and XI. Myosin XI members have been suggested to play important roles in intracellular trafficking of Golgi stacks, peroxisomes, and mitochondria. In *myosin XI-i* disruptants, the early acceleration of mitochondrial movement was not observed after exposure to weak blue light, while mitochondrial movement in the dark appeared to be normal. The late immobilization of mitochondria also took place normally. On the other hand, using the photosynthetic inhibitors (DCMU and DBMIB) and the *yellow variegated 2* (*var2*) mutant showing leaf variegation, a requirement of intact photosynthesis for the immobilization of mitochondria was confirmed. To reveal the effects of abnormal mitochondria-chloroplasts co-localization on photosynthesis, chlorophyll fluorescence measurements were carried out. Photosystem II was more susceptible to high-intensity white light in *phot2* and *phot1phot2* mutants, and *myosin XI-i* disruptants than in WT plants. These results indicate that phot2 and myosin XI-i contribute to the optimization of photosynthesis through regulating the intracellular positioning and interaction of mitochondria and chloroplasts.

Post-storage peel colour development strategies for cultivar samar bahist chaunsa mango under reefer and controlled atmospheric (CA) condition

Hafiz Umer Javed[1], *Aman Ullah Malik*[2], *Muhammad Amin*[2], *Muhammad Fiaz*[2]
1. China Agriculture University, Beijing
2. University of Agriculture, Faisalabad

Mango fruit colour is one of the main criteria of consumer's choice. Post-storage peel colour development is a serious issue in our commercial mango cv. S.B. Chaunsa. This study was aimed at evaluating the effect of pre-cooling and ripening temperature on quality and peel colour development under reefer and controlled atmosphere storage conditions. The fruit were harvested from a commercial orchard at physiological mature stage. After harvesting, fruit were physically de-sapped and subjected to prochloraz (0.5ml/L) dip followed by air drying, packaging and transport to PRTC in a reefer van at 18°C. At PRTC, the fruit subjected to pre-cooling for 8 hrs. at 12°C or 17°C, subsequently stored at 17°C under reefer and CA condition (4% CO_2 & 6% O_2) for different storage periods (10 & 20 days under reefer) and (10,20,30 and 35 days under CA). At removal, fruit were artificially ripened at two different temperatures (24°C or 35°C). The fruit response was significantly different under different treatment regimes. The experiment was laid down under CRD along with factorial design. Under reefer storage conditions (without CA), the fruit removed after 10 days of storage had 4-5 days of shelf life and in CA storage condition, the fruit removed after 10 & 20 days had 5-6 days of shelf life (including ethylene treatment period) at both ripening temperatures; whereas, the fruit removed from reefer (20 days) and CA (30 & 35 days) were found ripe (eating soft) at the time of removal (with 0 days shelf life), thereby not requiring any ethylene treatment. The peel colour development increased significantly at ripening temperature 35°C than 24°C and after removal to final ripe stage while pre-cooling temperature had non-significant effect. Significant difference was found among pre-cooling and ripening temperature regarding to physiological weight loss and respiration rate of reefer and CA stored fruit. Chilling injury, side rot and stem end rot were increased as the storage duration extends in CA stored conditions. Under reefer, the physico-chemical and organoleptic quality of fruit were found meritorious than the CA condition. This paper provides detail about treatment impact on physico-chemical, physiological and organoleptic quality attributes.

Identification and functional analysis of microRNAs involved in the rice flower development

Hyojin Heo, ***Dong-Hoon Jeong***
Hallym Univeristy

MicroRNAs (miRNAs) are non-coding small RNAs that regulate target gene expression at the posttranscriptional level. Plant miRNAs have been identified that contribute to a variety of biological process, including flower development. Functional studies examining *Arabidopsis* miRNAs have identified several miRNAs that play crucial roles in flower development by repressing key regulatory genes in floral organ identity. Although these miRNAs are well conserved in rice, their role in rice flower development had not been well characterized. To better understand the role of rice miRNAs in flower development, small RNA libraries were constructed from rice floral organs including glume, palea/lemma, lodicule, anther, and pistil. We also constructed PARE (Parallel Analysis of RNA Ends) degradome libraries from anther and pistil. Both small RNA and PARE libraries were deeply sequenced by Illumina technology and analyzed to identify differentially regulated miRNAs and to investigate their target cleavage functions. From the small RNA libraries, we have identified the floral-organ preferentially expressed miRNAs. In addition, analysis of PARE data revealed the cleavages of target RNAs in the particular floral organ where these miRNAs are expressed. Of floral-organ preferentially expressed miRNAs, *miR5179*, which targets an *OsMADS16* that is involved in anther identity, was pistil-preferentially expressed. To determine the biological function of *miR5179*, transgenic rice plants over-expressing *miR5179* were generated. The transgenic plants exhibited the multiple-pistil phenotypes, which is due to down-regulation of *OsMADS16*. Additional studies are underway to investigate the association of floral-organ-preferential miRNAs with the expression of their target genes.

Genetic analysis of pseudopeloric mutation in *Habenaria radiata*

Akira Kanno, *Mai Mitoma, Yumi Kajino, Risa Hayashi*
Graduate School of Life Sciences, Tohoku University

Orchids are commercially important plants with flowers that are unique and very specialized in shape and color. The flowers consist mostly of sepals, lateral petals, lip (labellum) and column. *Habenaria radiata* grows in wet grasslands in both warm and cold temperate regions of Honshu, Shikoku and Kyushu in Japan. This species has greenish sepals in the first whorl and white lateral petals and lip in the second whorl. Among *H. radiata* cultivars, one pseudopeloric cultivar 'Hishou' is known. In the 'Hishou' cultivar, the greenish median sepal is homeotically altered to a white-petaloid structure and the two lateral sepals are modified to white lip-like organs. In order to investigate the inheritance of 'Hishou' flower character, we performed intraspecific crosses using wild-type and 'Hishou' cultivars of H. radiata. Since 'Hishou' is female sterile, crosses were made using three lines of wild-type (W1, W2 and W3) plants as the female parent and one line of the *H. radiata* 'Hishou' (H) as the male parent. We obtained 230 progenies by these crosses. Among these F_1 progeny, 204 plants had flowers and 108 had 'Hishou' type flowers (F_1[H]) and 96 had wild-type flowers (F_1[WT]). We obtained 268 progenies by self pollination of F_1[WT] plants. Among 268 F_2 plants, 100 plants had flowers and all of these flowers were wild type. F_1[H] was female sterile as 'Hishou' cultivar, crosses were made using wild-type as the female plants and F_1[H] as the male plants. We obtained 208 BC_1 progenies from this cross. Among 208 progenies, 138 plants had flowers and 70 had 'Hishou' type flowers and 68 had wild-type flowers. These results suggest that the characteristics of pseu-

dopeloric mutation found in the 'Hishou' cultivar were inherited dominantly and that the underlying mutation is a gain-of-function mutation. Since half of the intraspecific hybrids (F_1) and half of the back cross progenies (BC_1) had wild-type flowers, the locus of pseudopeloric mutation is likely be heterozygous in the 'Hishou' parent.

Temporal responses of two wheat cultivars under phosphate starvation

Mohammad Rezaul Karim, *Ping Lan*
State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences

Phosphorus (P) is an essential macronutrient and often acts as a limiting factor for plant growth and development due to its low solubility and fixation in soils. Wheat is one of the most important cereal crops worldwide and the production is seriously affected by P status. The present study was executed to analyze the comprehensive temporal traits of wheat plants to P-starvation. Two wheat cultivars, Atlas 66 and Scout 66, were grown hydroponically under P–sufficient (250 µM) and –deficient (0 µM) conditions. Morpho-physiological and molecular characterization were examined at early (6 h to 1 d), mid (1 d to 7 d) and long (7 d to 21 d) time periods. Root length and biomass of both cultivars were increased steadily while shoot biomass was decreased at long time periods under P-deficient conditions. Notably, the Scout 66 exhibited higher root biomass and root volume, and more root tip numbers under P-starvation as compared to the Atlas 66. Inorganic phosphate (Pi) concentrations were tended to reduce from early time periods in both roots and shoots while the total P contents of roots and shoots were reduced from 3 d and 7 d time periods, respectively. Overall, the Scout 66 had higher concentrations of Pi and total P over the Atlas 66. In addition, phosphate deficiencies significantly affected the contents of iron (Fe) and manganese (Mn) in roots and decreased Zinc (Zn) content in both roots and shoots. Likewise, the Scout 66 possessed significantly higher amount of Fe, Mn, and Zn content in its roots and Mn content in shoots in both P-levels. The marker genes for P stress, *TaIPS1*, *TaSQD2* and *TaSPX3,* were significantly induced in both roots and shoots from early time periods till 21 d of P-depletion. But the magnitude of induction of these Pi-responsive genes varied between two cultivars. Taken together, the wheat cultivar Scout 66 might be more P-efficient cultivar and maintained higher level of Pi homeostasis and trace metal elements by the increased root biomass, root volume and more root tip number. These results enlarged our knowledges regarding the time course related responses of wheat cultivars under phosphate starvation.

Flower morphology and development in *Polyscias* (Araliaceae: Apiales): Meristic variations, multiple gains of monomerous gynoecium and the nature of epicalyx

Polina P. Karpunina[1], *Maxim S. Nuraliev*[1], *Alexei A. Oskolski*[2,3], *Dmitry D. Sokoloff*[1]
1. Biological Faculty, M.V. Lomonosov Moscow State University
2. Botanical Museum, V.L. Komarov Botanical Institute
3. Department of Botany and Plant Biotechnology, University of Johannesburg

Most eudicots and all monocots have cyclic flowers. While some groups of angiosperms are characterized by isomerous flowers (with equal organ numbers in all whorls), anisomery is also a common pattern. In many cases, anisomery is expressed in gynoecium merism that differs from the merism of other floral whorls. However, counting carpel number in syncarpous gynoecia is sometimes problematic due to the congenital nature of intercarpellary fusion. A convenient group for studying evolution of flower merism is the genus *Polyscias* (Araliaceae) that comprises about 160 species distributed throughout the Indian and Pacific Ocean basins from Africa and Madagascar to Australia and Hawaii (Lowry, Plunkett, 2010; Plunkett, Lowry, 2010). Members of the genus vary considerably in floral merism, sometimes even within a given species, which is generally unusual for core asterids. Although pentamerous flowers with syncarpous bicarpellate gynoecium are the most common type in the genus, gynoecium merism shows a considerable variation. Both polymerization of gynoecium (e.g., 10 carpels in *P. duplicata* from Madagascar) and its oligomerization up to the unilocular condition occurred in several lineages of *Polyscias*. Shifts to unilocular gynoecium with single fertile ovule took place in four groups of this genus, i.e. in a biphyletic group of species from Madagascar previously segregated as *Cuphocarpus* and in two lineages within the Australo-Malesian clade (Karpunina *et al.,* 2016). In angiosperms, reduced gynoecia with single fertile ovule can appear via several evolutionary pathways, including monomery and pseudomonomery. In an evolutionary context, pseudomonomery can be understood as a result of gradual sterilization of all carpels but one in syncarpous gynoecium (or rarely in gynoecium with postgenitally united carpels). In contrast to pseudomonomery, monomery is viewed as a result of abrupt change in carpel number with no intermediate stages. Our examination of morphology, anatomy and development of unilocular gynoecia in different clades of *Polyscias* convincingly shows that these gynoecia are truly monomerous. Both unicarpellate and pluricapellate species of *Polyscias* have unstable orientation of flower organs relative to flower-subtending bract. In two examined Australo-Malesian species with monomerous gynoecia and pentamerous outer whorls, the median sepal is either adaxial or abaxial. In the flower of the Malagasy *P. compacta* with monomerous gynoecium, two sepals of tetramerous calyx can be in transverse position, or all sepals are in oblique positions. In all three species, orientation of ventral side of the carpel is not fixed (adaxial, abaxial, transversal or oblique). Another Malagasy species, *P. aubrevillei*, has 4-5-merous outer whorls and 2-3 carpels which also show unstable orientation. A feature of some Malagasy species is the presence of a distinctive rim at the flower base. This rim is commonly described as "epicalyx", but its nature remains obscure. The epicalyx of *P. compacta* and *P. schatzii* ined. is initiated at late stages of flower development by extension of the peduncle, and it is not innervated by vascular bundles. Some Malesian *Polyscias* species have a similar, but less pronounced extension at the base of the flower, which is covered with trichomes.

The study is supported by RFBR (project 15-04-05836).

Prediction physiological changes in *trigonella* (*in vivo* and *in vitro*) in response to physical mutagenesi (gamma rays)

Mahmoud Khater
National Research Centre (NRC)

This investigation was carried out during two successive seasons 2013/2014,2014/2015 at the Greenhouse and tissue culture laboratory, Botany Department, National Research Centre, Giza, Egypt. Molecular studies were carried out at Genetics Department, Faculty of Agriculture, Zagazig University, Egypt. to study the physiological and molecular changes in fenugreek (*Trigonella foenumgraecum* L.) *In vivo* and *In vitro* as a response to gamma rays with doses (0,100,150,200,250 and 300 Gy.). Results revealed that callus induction frequency increased in response to the increase of 2,4-D concentrations and varied from one gamma-ray dose to another. The best interaction between gammaray and 2,4-D concentrations was between 2.0 mg/l 2,4- D and all doses of γ-rays, especially 200 Gy, which recorded the highest percentage of callus (above 90%). On the other hand, in RAPD analysis there were 44 bands (total bands) divided to polymorphic bands (25), monomorphic bands (2) and unique bands (17) with an average percentage 88.00% polymorphism and numerous molecular sizes that ranging from 265.122 to 1911.225 bp, Moreover, results of ISSR analysis illustrated that there were 22 bands (total bands) divided to polymorphic bands (3), monomorphic bands (11) and unique bands (8) with an average percentage 76.00% polymorphism and different molecular weights that ranging from 260.582 to 1333.384 bp.

Developmental sources of variation in floral organ numbers: Floral phyllotaxis and organ fate determination

***Miho Kitazawa**, Koichi Fujimoto*
Osaka University

Floral organ number is one of the fundamental features that characterises floral morphology. It is largely conserved in the major clade of angiosperms: Core eudicots show pentamerous or tetramerous flowers with multiple of five or four floral organs, whereas monocots show trimerous flowers. On the other hand, the number has been changed multiple times during evolution, as indicated by the fact that the closely related species show flowers with different numbers of floral organs. The variation can be a key to address the question of what developmental mechanism underlies such co-existence of robustness and flexibility. Although the floral organ number is a hallmark of the species, it can distribute stochastically even within an individual plant. Especially in the family Ranunculaceae, which branched near the monocot-eudicot bifurcation, the flowers show remarkable variations in floral organ numbers.

Here we suggest two candidate sources for the variation in floral organ numbers, through field observation of Ranunculaceae flowers and theoretical models. One is the stochasticity in the boundary of floral organ fate, and the other is the changes in floral organ arrangement, i.e., floral phyllotaxis. The former is suggested by the probability distribution of the floral organ numbers within a population. The probability distributions of floral organ numbers of Ranunculaceae are usually asymmetric and steep, indicating that they cannot be explained by the normal distribution. We compared several statistical models, and found that the most plausible model to explain the distribution is the one assuming stochasticity of the expression boundary of organ fate determinants. In addition to such stochastic homeotic transformation of floral organs, we can find variation of floral organ arrangements that affect floral organ numbers in many species. To measure this, we observed perianth organ arrangements in the genus *Anemone* (Ranunculaceae), which contains species with various merosities, i.e., the basic number of floral organs. We observed three species, *A. flaccida*, *A. scabiosa*, and *A. nikoensis* that are normally pentamerous but stochastically show higher perianth organ numbers. Quincuncial arrangement stably appeared in the flowers with five perianth organs, whereas the arrangements were more variable in the flowers with more than five perianth organs. Especially, we found positional arrangement of the excessive sixth perianth organ indicating the possibility of a transition from pentamerous to trimerous arrangement. The phyllotaxis model for initiation of the sixth organ showed that the arrangements found in the *Anemone* occur at a divergence angle <144°, indicating the spiral nature of floral phyllotaxis rather than a perfect penta-radial symmetry of 144°. The model further showed that selective occurrence of trimerous arrangement is mainly regulated by the organ growth rate, which may play a central role in the transitions between pentamerous and trimerous flowers.

The tissue and cell specific expression characteristics of the key enzyme regulated chlorogenic acid biosynthesis in *Lonicera japonica* flower organ at different growth stages

***Dexin Kong**[1], Yanqun Li[1,3], Hanjun He[1], Mei Bai[1], Haiyang Wang[1], Hong Wu[1,2, 3]*
1. State Key Laboratory for Conservation and Utilization of Subtropical Agro-Bioresources, South China Agricultural University, Guangzhou 510642, China

3. Guangdong Key Laboratory for Innovative Development and Utilization of Forest Plant

Hydroxycinnamoyl-CoA quinate transferase (HQT) is one of the key enzymes in the biosynthesis of chlorogenic acid in *Lonicera japonica*. Although some researches have investigated *HQT* gene expression and regulation at the transcriptional level, how the tissue-and cell-specific patterns of protein synthesis and gene expression regulated chlorogenic acid (CGA) change during the different growth stages of *L. japonica* and how they correlate with the biosynthesis and distribution of CGA remain largely unknown. The expression of HQT and its tissue and subcellular localization at different growth stages of *L. japonica* ((young alabastrum (S1), green alabastrum (S2), slightlywhite alabastrum (S3), whole white alabastrum (S4), silvery flower (S5), and golden flower (S6)) were investigated by using the techniques of western blotting, histochemical localization, in situ hybridization and immune-electron microscopy in this study. Whilst, we systematically examined the dynamic accumulation of chlorogenic acid at six growth stages using an HPLC-DAD-base method. The results indicated that the variation of HQT protein accumulation level and the dynamic accumulation of CGA exhibited a positive correlation with the temporal accumulation patterns of *HQT* gene transcript at different growth stages in *L. japonica*, respectively. Interesting, the results of in situ hybridization and histochemical localization revealed that transcript expression of *HQT* in tissue specificity or cellar specificity significantly related to the distribution of CGA in *L. japonica* corolla tube cells at different growth stages. For example, in S1-S3, the *HQT* was presented in the inner and outer epidermal cells, and parenchyma cells and vascular bundle, the CGA was also found to occur in these tissues. *HQT* and CGA were only distributed in vascular bundle and inner epidermal cells at S5-S6. The results of the rabbit anti-HQT Immunogold (lgG) and the laccase colloidal gold demonstrated that anti-HQT-lgG and laccase-lgG were mainly located in chloroplasts, plastids and cytoplasm during S1-S2. In S3-S4, while the weakening of structure and function of chloroplast, anti-HQT-lgG particles were reduced and mainly distributed in degrading cytoplasm, the laccase-lgG particles were transferred from plastids or cytoplasm to vacuole, accompanied by the process of vacuolization. After the buds fully opened, the large central vacuole almost occupied the whole cell, only few anti-HQT-lgG particles were observed in cytoplasm. The vacuole and cell wall were not found with the anti-HQT-lgG particles throughout the all growth stages, laccase-lgG particles were mainly located in vacuole in the S5, S6. Therefore, we suggested that chlorogenic acid was mainly synthesized in chloroplasts, plastids and cytoplasm. In middle and later stages of *L. japonica*, the chlorogenic acid was mainly synthesized in cytoplasm, and stored in the vacuole. This research will give further insight for studying the biosynthesis and regulation of Cholorgenic acid in *L. japonica*.

Genome-wide analysis of *FWL* gene family in *Brassica* plants

Chen Kuang[1], *Jun Li*[1], *Hong Fang Liu*[1], *Zhe Dong*[1], *Wei Hua**[1], *Jing Chu Luo**[2]

1. Oilcrops research institute, chinese academy of agricultural sciences

2. College of Life Sciences, Center for Bioinformatics, National Laboratory of Protein Engineering and Plant Genetic Engineering, Peking University

Plant and organ size can vary in natural populations. The individual differences in plant and organ size result from changes in the expression level of the specific genes. After the successful pollination, fruit size depends mainly on cell number and cell size, which determines the final organ size and plant growth and, ultimately, crop yield. A lot of genes associated with fruit size traits have been isolated by molecular biology technology. In tomato, the *FW2.2* gene is hypothesized to control 30% of the variance in fruit weight by negatively regulating cell division. In maize, the *CNR* genes are identified, which affects the plant size by restricting the cell division duration to reduce cell number rather than cell size. To expand investigation of how related genes may impact other crop plant or organ size, we identified the Brassica plants gene family of putative *fw2.2* orthologs, naming them *Brassica Organ Size Regulator (BOSR)* genes. This family represents an ancient eukaryotic family of Cys-rich proteins containing the PLAC8 or DUF614 conserved motif. To date, no genome-wide overview of the *Brassica Organ Size Regulator (BOSR)* gene family has been performed. Therefore, as the first step and as a helpful strategy to expound the structure and function of *BOSR,* a genome-wide study for this gene family is necessary. In this study, we used some bioinformatical equipment, such as BLASTp, tBLASTn, and Hmmer to identify *BOSR* sequences in Brassica plant databases. Using TMHMM trans-membrane domain prediction tool, we identified trans-membrane structure of *BOSR*. The subcellular localization of *BOSR* was forecast by targetp and their gene sequence were analyzed by MEME and WEBLOG. We investigated the evolutionary relationship of the *BOSR* gene family by phylogenetic analysis and the 3D structure of *BOSR* was forecast by phyre2. To verify gene expression changes, we further used quantitative real-time reverse transcription-polymerase chain reaction. Additionally, *BOSR* may have functions similar to tomato *FW2.2* or maize *CNR*. The genome-wide identification, bioinformatic analysis and expression analysis of *BOSR* genes can facilitate research of this gene family and polyploidy evolution. As previously proposed in maize, this study may contribute to the potential application to Brassica breeding and crop improvement.

Cytokinins in the light of plant evolution. Are there any evolutionary links within the plant kingdom?

Lenka Zaveska Drabkova[1,2], *Vaclav Motyka*[1], *Eva Zizkova*[1], *Petre Dobrev*[1]

1. Institute of Experimental Botany, the Czech Academy of Sciences

2. Institute of Botany, the Czech Academy of Sciences

Evolutionary physiology represents an explicit fusion of two approaches, evolution and physiology. In our research, we address one of important questions regarding physiological evolution: What phylogenetic patterns are reflected in the metabolism of plant hormones cytokinins (CKs) during evolution of land plants? Bioactive CKs represent essential molecules regulating many aspects of plant growth and development but a wide spectrum of non-active and/or weakly active CK derivatives exists and proportionally differs among plant species. However, not all of CK forms have been examined yet in the vast majority of plant species, tissues or developmental stages, therefore it is difficult to state that CK regulatory pathways are similar throughout the whole plant kingdom. Available data demonstrate ubiquitous occurrence of numerous CK metabolites including *O*- and *N*-glucosides as well as *cis*-zeatin-type CKs in the plant kingdom. We analyzed the occurrence of endogenous CK derivatives in cyanobacteria, algae, mosses, gymnosperms and angiosperms in order to perform phylogenetic analyses with the aim to test two main hypotheses, that (1) *O*-glucosylation has originated as a regulatory step from preexisting elements of the primary metabolism already in evolutionarily older plants while *N*-glucosylation has been acquired independently in different plant families during further evolution and whether (2) *cis*- vs *trans*-derivates of zeatin are more prevalent in the evolutionarily older plants, and also more significant here with respect to CK biological pathways. Moreover, (3) we elucidated evolutionary processes of *N*- and *O*-glucosyltransferase pathways based on phylogenetic and molecular analyses of UGT and *cis*ZOG1 genes in selected groups of plants. In our comprehensive screening throughout the plant kingdom, CK-*N*7- and CK-*N*9-glucosides were found ubiquitous in vascular plants. In contrast, their only rather low levels or a total absence was shown in non-vascular plants such as algae and mosses. Surprisingly, fungi representatives showed similar spectra of CK derivates with a lack of CK-*N*-glucosides and a prevalence of *cis*-zeatin types as lower plants. It is possible that the absent or sparse *N*-glucosyltransferase pathway is substituted here by other down-regulating mechanisms, e.g. by enhanced formation of *cis*-zeatin derivatives, as considerably higher *cis*-zeatin/*trans*-zeatin ratios were revealed for most of non-vascular than vascular plants.

The function of phosphorylation sites of BvM14-STPK in response to salt stress

Haiying Li[1,2], *Bing Yu*[1,2], *Chunquan Ma*[1,2], *Duanmu Huizi*[1,2], *Li Hongli*[1,2], *Mengdi Yu*[1,2], *Xiang Liu*[1,2]

1. Key Laboratory of Molecular Biology of Heilongjiang Province, College of Life Sciences, Heilongjiang University, Harbin, P. R. China, 150080

2. Engineering Research Center of Agricultural Microbiology Technology, Ministry of Education, Heilongjiang University, Harbin, P. R. China, 150080

In our lab, Guo *et al.,* obtained the sugar beet monosomic addition line M14, which contains the *Beta vulgaris* L. genome with the addition of No.9 chromosome of *B. corolliflora* Zoss. Sugar beet M14 line is a unique germplasm that contains genetic materials from *Beta vulgaris* L. and *Beta corolliflora* Zoss, and it exhibits tolerance to salt stress. Comparative proteomics analyses in the leaves and roots of M14 line had been performed under 0, 200 and 400 mM NaCl treatment. 40 differentially expressed proteins in leaves and 36 differentially expressed proteins in roots were identified, in which one serine-threonine protein kinase designated as BvM14-STPK is involved in signal transduction. Under salt stress, the expression of BvM14-STPK protein in roots was increased 3.24 times. So, BvM14-STPK protein might respond to the salt stress in sugar beet M14 line. Here the function of phosphorylation sites of BvM14-STPK (one serine/threonine protein kinase in sugar beet M14) was introduced. Based on the transcriptome database of M14 under salt stress, the full-length cDNA named BvM14-STPK was obtained by PCR. Sequence analysis showed that BvM14-STPK had a ser/thr binding domain, which belonged to the family of Protein Kinase C Family. The Real-Time PCR result showed that *BvM14-STPK* gene was responsive to salt stress. BvM14-STPK fusion protein was expressed in prokaryotic expression system and identified by Western blot. After gel digestion, desalting, enrichment, the peptides of BvM14-STPK were identified by mass spectrometry. The phosphorylation sites of BvM14-STPK protein were analyzed. In order to reveal the function of phosphorylation sites in BvM14-STPK, 8 key serine phosphorylation sites were divided into five segments to research. By site-directed mutagenesis technology, each of five Ser phosphorylation sites were mutated into aspartic acid in BvM14-STPK, which meaned that each of five Ser phosphorylation sites became sustained phosphorylated. Simultaneously, each of five Ser phosphorylation sites were mutated into phenylalanine in BvM14-STPK, which meaned that each of five Ser phosphorylation sites became non-phosphorylated. Each cDNA full length of ten *BvM14-STPK* genes by site-directed mutagenesis technology was obtained. Ten plant expression vectors containing the above ten mutant genes were constructed and transformed into the tobacco separately. The function of phosphorylation sites of BvM14-STPK were further clarified in transgenic tobacco. The transgenic seedlings of T1 generation were transplanted on the MS medium containing different concentrations of NaCl (0,150mM). After 20 days salt treatment, the result showed that the fresh weight and root length of all transgenic plants were inhibited after salt treatment. In transgenic plants containing non-phosphorylated site, the effect of 230 Ser site on inhibition of transgenic plants was obviously higher than that of other sites. The possible reason is that 230 Ser site is in the active domain of this kinase BvM14-STPK. The expression of mutant *BvM14-STPK* gene of transgenic plants under salt stress was analyzed by the real-time PCR technique. The results showed that the expression level of *BvM14-STPK* gene of transgenic plants containing sustained phosphorylated site was significantly higher than that of wild-type tobacco and the expression level of *BvM14-STPK* gene of transgenic plants containing non-phosphorylated site was obviously decreased than that of wild-type tobacco. In transgenic plants containing non-phosphorylated site, the 230 Ser site and 216 Ser, 217 Ser site had a greater inhibition effect on the plant. Analysis of the function of phosphorylation sites of *BvM14-STPK* under salt stress has provided insight into specific response mechanisms underlying salt stress tolerance. The knowledge gained can be potentially applied to improving crop salt tolerance.

The *robin1* mutation increases the BRI1 abundance to enhance BR signaling in *Arabidopsis*

Shasha Ren, *Xiaolei Liu*, *Jianming Li*

Shanghai Center for Plant Stress Biology, Chinese Academy of Sciences

Brassinosteroids (BRs) are a unique class of plant polyhydroxylsteroids that play important roles throughout the plant life cycle. BR-deficient mutants or BR-insensitive mutants display a characteristic set of phenotypes that include dark green leaves, dwarfed stature, delayed flowering and senescence. To fully understand the BR signaling mechanism, we performed a large-scale forward genetic screening for extragenic suppressors for the *Arabidopsis* mutant *bin2-sf,* carrying a dominant single amino-acid change (Ser^{308}-Phe) in an *Arabidopsis* GSK3-like kinase BRASSINOSTEROID-INSENSITIVE2 (BIN2). Our genetic and biochemical studies have shown that *revertant of bin2-sf 1 (robin1)* partially recovers BR responsiveness. We have recently cloned *ROBIN1* gene and found that the ROBIN1 protein is mainly localized in the nucleus. The *robin1* mutations also partially rescue the growth phenotypes of *bri1-9* (a weak BR receptor mutant) and heterozygous *bin2-1*/+ (another gain-of-function *bin2* mutant). By contrast, overexpression of *ROBIN1* could enhance the dwarfism of another BR receptor mutant *bri1-5*. Our biochemical studies revealed that the *robin1* mutation increases the abundance of BRASSINOSTEROID INSENNSITIVE 1 (BRI1, the cell-surface localized BR receptor). Additional studies aiming to link the robin1-increased BRI1 abundance with enhanced BR signaling will be reported at the conference.

P1026

BBP1 and its homolog negatively regulate BIN2 to stimulate brassinosteroid signaling in *Arabidopsis thaliana*

Xiuwen Rao, *Xuan Du, Xiaolei Liu, Jiamu Du, Jianming Li*
Shanghai Center for Plant Stress Biology, Chinese Academy of Sciences

Brassinosteroid (BR) is one of the most important plant hormones that regulate many aspects of plant development and growth. Extensive studies in the past 20 years have revealed a protein phosphorylation-mediated signaling cascade to transmit the extracellular BR signal into the plant nucleus, which involves a key regulatory step of inactivating an *Arabidopsis* GSK3-like kinase BIN2. However, the biochemical mechanism for BIN2 regulation remains controversial. Using a biochemical approach, we have discovered a previously uncharacterized *Arabidopsis* protein BBP1 for BIN2-binding protein 1. We found that BBP1 interacts with BIN2 at the plasma membrane to prevent the BIN2's phosphorylation activity towards its substrates BES1 and BZR1. BBP1 overexpression inhibits the phosphorylation of BES1/BZR1 and leads to enhanced BR signaling in a dosage-dependent manner. More importantly, simultaneous elimination of BBP1 and its homolog reduces BR signaling and enhances the dwarf phenotypes of weak BR receptor mutants. Genetic and/or chemical manipulation of the plasma membrane and nuclear localization of BIN2 and/or BBP1 could enhance and reduce BR signaling, respectively. Based on these findings, we propose that BBP1 and its closest homolog positively regulate BR signaling by controlling the subcellular of BIN2 to inhibit its phosphorylation activity.

Assessment of drought tolerance in urban trees and planting site selection: An application of multiple correspondence analysis and association rules

Ke-Ke LI, *De-Shun ZHANG*
Tongji University

Urban trees will be exposed to severe drought stress due to climate change and therefore require a high tolerance facing the coming years and decades. It is known that good quality of sites increases probability of maintaining healthy trees and survival whereas low quality sites diminish tree's health and survival. In fact soil characteristics (such as soil water content, soil mechanical composition, drainage and aeration), site characteristics and location (for example site size, air pollution, streets, sidewalks, parks, utility lines) and environment (like wind speed, temperature, population stress) seem to be factors linked to tree survival. Not all trees adapt to any site and some are more adequate for a given site than others. This study shows the results of extensive research and evaluation of reactions, parameters and characteristics of urban trees linked with drought tolerance. Our research target is to use successive steps of multiple correspondence analysis and handling missing attribute values for some data about the drought of urban tree This resulted in 42 possible parameters including such as leaf morphology, stomatal densities, wilting symptoms, wood anatomy and physiology. The estimations values are validated with a clustering approach. By detailed counterchecking, seven parameters with the highest significance for urban trees could be selected, followed by a ranking according to the significance. This ranking also allows the evaluation of "new", i.e. uncommon tree species and native tree species considering their drought tolerance. In the second part, we present an exploration of association rules determine planting sites considering urban tree's characteristics. In first step item sets and rules are generated using the unsupervised algorithm Apriori. They are rapidly characterized in terms of tree planting sites. In a second step planting sites are fixed as target values to establish rules (a supervised version of the a priori algorithm). An original approach is also presented and validated for the prediction of the planting site of the species.

ER-localized SNAREs are involved in transport of seed storage proteins

Lixin Li, *Xiaonan Zhao, Hailong Zhang, Yun Kong, Xiufen Guo*
Northeast Forestry University

Plant seeds accumulate large amount of storage proteins as N resorce for plant inicial growth. Storage proteins are synthesized as large precursors on the ER. The precursors are delivered to the vacuole by vesicle transport and processed to smaller mature forms.In our previous study, we found that ER-localized tethers, MAG2, MIP1, MIP2 and MIP3, form a tethering complex-MAG2 compplex, function on ER-Golgi vesicle transport in Arabidopsis. When they are defective, transport of newly synthesized proteins out from the ER are affected. To further clarify mechanism underlying MAG2-relating protein transport pathway, we investigated function of predicted ER-localized SNAREs, including Qa-SNARE, Qb-SNARE and Qc-SNAREs. Our results indicated that these ER-localized SNAREs interact with each other to form a SNARE complex. This SNARE complex interacts with MAG2 complex.When these SNAREs are defective, efficiencyoftransport of seed storage protein precursors from the ER is decreased.On the other hand, plant growth and development is also affected.Our findings indicate that these ER-Localized SNAREs collaborate with MAG2 complex to regulate ER-Golgi vesicle transport.

Differential regulation of protochlorophyllide oxidoreductase abundances by VIRESCENT 5A (OsV$_{5A}$) and VIRESCENT 5B (OsV$_{5B}$) in rice seedlings

Qingzhu Li

Shanghai Academy of Agricultural Sciences

A low-temperature virescent mutant (*osv*$_{5a}$) was isolated from a ^{60}Co-irradiated rice (*Oryza sativa*) population. At early seedling stage, the mutant exhibits chlorosis phenotype with reduced pigment content at a low temperature (22°C), but it produces green leaves at normal growth temperature (28°C). Chlorophyll accumulation is gradually restored in the mutant at 22°C as it is developing into five-leaf stage. Map-based cloning revealed that OsV$_{5A}$ is a J-like protein with four transmembrane domains. A close homolog, OsV$_{5B}$, was also identified in the rice genome. Both OsV$_{5A}$ and OsV$_{5B}$ are localized in the chloroplast envelope and thylakoid membranes. We demonstrated that they function as chaperone proteins of protochlorophyllide oxidoreductase (POR), which catalyzes a light-dependent reaction in the chlorophyll biosynthesis pathway. OsV$_{5A}$ and OsV$_{5B}$interact with two rice PORs (OsPORA and OsPORB) inside chloroplasts and they stabilize OsPORB in vitro under oxidative stress. Differential protein abundances of OsV$_{5A}$ and OsV$_{5B}$ in rice seedlings at different leaf developmental stages were also revealed. OsV$_{5A}$ apparently developed a specialized role for regulating POR abundances at the leaf pre-emergence stage, while the same function is performed by OsV$_{5B}$ during leaf emergence and expansion. Deficiency of OsV$_{5A}$ and OsV$_{5B}$ occurred in pre-emerged and emerging leaves in *osv*$_{5a}$ seedlings at 22°C, leading to reduced POR accumulation and chlorophyll content. Duplication of V5, which is not common among dicots, may have allowed the diversification of their differential roles in regulating chlorophyll biosynthesis in rice and other grass species.

Identification and functional analysis of downstream targets of the MKK7-MPK6 cascade involved in shoot branching in *Arabidopsis*

Shujia Li[1], *Weiyan Jia*[1,2], *Baohua Li*[1,3], *Xiaowei Wu*[1], *Yan Liang*[1], *Mei Ma*[1], *Jiayang Li*[1], *Yonghong Wang*[1]

1. Institute of Genetics and Developmental Biology, Chinese Academy of Sciences, Beijing

2. University of Wisconsin, School of Medicine and Public Health, Madison

3. University of California, Davis, California

Mitogen-activated protein kinase (MAPK) cascades play an important role in transducing environmental and developmental signals into adaptive and programmed responses. In higher plants, MAPK cascades are involved in a broad spectrum of signals, which include biotic and abiotic stresses, and hormone-mediated development. The *Arabidopsis* genome encodes a large number of MAPK signaling components, with more than 60 members of MAPKKK, 10 members of MKK and 20 members of MAPK. The least number of MKKs suggests that MKKs serve as the convergence and divergence points in the MAPK signal transduction. The complexity of MAPK cascades raise challenges not only to identify the MAPK module *in planta* but also to define the specific role of an individual module. Our previous study have characterized an *Arabidopsis bushy* and *dwarf1* (*bud1*) mutant, in which the MKK7 was constitutively activated, resulting in multiple phenotypic alterations. It is indicated that MKK7-activated cascades involve in many developmental and hormone signaling pathways through phosphorylating different substrates. Recently, we demonstrated that MPK6 and MPK3 are two major downstream targets of MKK7, and most strikingly, polar auxin transport are transmitted by MKK7-MPK6 signalling pathway specially. To elucidate molecular mechanisms of polar auxin transport regulated by MKK7-MPK6 cascade, we further identified the MKK7-MPK6 downstream specific substrates and studied the function of them. So far, our data have provided evidence to explain how the MKK7-MPK6 signaling pathway regulates polar auxin transport through the specific substrate to determine shoot branching in *Arabidopsis*. Shoot branches develop from axillary meristems initiated in the boundary zone. We therefore wondered whether the MKK7-MPK6 cascade regulate shoot branching through affecting axillary meristem initiation. In-depth genetic and biochemistry verification are underway.

Overexpression of maize phosphoenolpyruvate carboxylase gene enhanced the catabolism of endogenous saccharide under drought conditions

Xia Li [1,2], *Xiaolong Liu*[1], *Yafei He*[1], *Jinfei Zhang*[1], *Ting Yan*[1], *Chen Zhang*[1,2]

1. Jiangsu Academy of Agricultural Sciences

2. Nanjing Agricultural University

We compared the drought tolerance of wild-type (WT) and transgenic rice plants (PC) over-expressing the maize C$_4$ *PEPC* gene, which encodes phosphoenolpyruvate carboxylase (PEPC, EC 4.1.1.31) gene, and evaluated the roles of saccharide and sugar-related enzymes in the drought response. Pot-grown seedlings were subjected to drought conditions outdoors, and the yield components were compared between PC and untransformed wild-type (WT) plants. The stable yield from PC plants was associated with higher net photosynthetic rate under the drought treatment. The physiological indices of WT and PC seedlings under a simulated drought treatment (25% (w/v) polyethylene glycol-6000 for 3 h; PEG 6000 treatment) were analyzed in detail for the early response of drought. The relative water content was higher in PC than in WT, and PEPC activity and the *C*$_4$*-PEPC* transcript level in PC were elevated under the simulated drought conditions. The endogenous saccharide responses also differed between PC and WT under simulated drought stress. The higher sugar decomposition rate in PC than in WT under drought stress was related to the increased activities of sucrose phosphate synthase, sucrose synthase, acid invertase, and neutral invertase, increased transcript levels of *VIN1*, *CIN1*, *NIN1*, *SUT2, SUT4,* and *SUT5*, and increased activities of superoxide dismutase and peroxidase in the leaves. The greater antioxidant defense capacity of PC and its relationship with saccharide metabolism was one of the reasons for the improved drought tolerance of PC. In conclusion, PEPC effectively alleviated oxidative damage and enhanced the drought tolerance of rice plants, which were more related to the the increase of the saccharide decomposition. These findings show that components of C$_4$ photosynthesis can be used to increase the yield of rice under drought conditions.

Seed germination in *Artemisia frigida* Wild. under the drought stress

Yang Li
Xi'an Botanical Garden of Shaanxi Province

Artemisia frigida is a dominant species in the typical steppe of northern China, and highly adapted to the local edaphic conditions. As water is the main limiting factor in arid and semi-arid regions, we hypothesis *A. frigida* could endure drought stress. However, little is known about the effects of drought stress on seed germination characteristics. In our study, PEG-6000 was applied to soak the seeds of *A. frigida* to simulate drought stress. We applied 4 level of PEG-6000: CK, 5%, 10%, 15%. The results showed that after soaking with PEG-6000, there were no significant change in seed germination rate, germination index and germination time among different treatments. Our results showed that *A. frigida* could endure drought stress according to seed germination characteristics. It is one of reasons that *A. frigida* could dominant in arid and semi-arid regions.

Identification and characterization of MYB-bHLH-WD40 regulatory complexes controlling anthocyanin biosynthesis in flowers of a monocot plant, *Freesia hybrida*

Yueqing Li, Xiaotong Shan, Ruifang Gao, Song Yang, Li Wang, ***Xiang Gao****
Key Laboratory of Molecular Epigenetics of MOE and Institute of Genetics & Cytology, Northeast Normal University, Changchun, China

The emergency of anthocyanin biosynthetic pathway has played vital roles in plant development. In the past several decades, an anthocyanin-promoting ternary protein complex (designated as MBW complex), composed of R2R3-MYB, basic helix-loop-helix (bHLH) and WD40 repeats (WDRs) has been well characterized in plants. However, divergent regulatory mechanisms were found in dicot and monocot plants represented by *Arabidopsis thaliana* and *Zea mays*, respectively. Presently, a whelming proportion of MBWs have been well elucidated in core dicot plants, whereas they were studied randomly in monocot plants, which are of crucial importance to decipher their functional diversities among angiosperms during evolution. *Freesia hybrida*, a monocotyledonous genus of herbaceous perennial flowering plants in the family Iridaceae, is grown universally as a cut flower plant with a wide range of flower colors including white, yellow, red, blue, purple and bicolors. In our previous studies, five kinds of anthocyanin aglycons, i. e. delphinidin, petunidin, malvinidin, peonidin, and cyanidin, were detected in *F. hybrida* "Red River®". A strategy combining transcriptomic data, expression profiles, gain-of-function experiments and transient protoplast transfection assays was undertaken to identify *F. hybrida* anthocyanin regulators. Among the candidate genes isolated, five were similar to *AtPAP1*, *AtTT8* and *AtTTG1* (*FhPAP1L1*/*FhPAP1L2*, *FhTT8L*/*FhGL3L* and FhTTG1L, respectively) and two encoded putative negative MYB regulators (FhMYB4L and FhCPCL). *FhPAP1L1*/*FhPAP1L2*, *FhTT8L*/*FhGL3L* and *FhTTG1L* were found to positively regulate anthocyanin biosynthesis when heterogeneously expressed in *Arabidopsis* or tobacco respectively. In addition, they interacted and activated the anthocyanin biosynthetic gene promoters when co-expressed in *Arabidopsis* leaf protoplasts. Further experiments revealed sets of the MBW complexes involved in anthocyanin biosynthesis were organized in a hierarchical and partially redundant manner in *F. hybrida*. Moreover, R2R3-MYB FhMYB4L and R3-MYB FhCPCL were deemed as negative regulators as both of them could inhibit anthocyanin biosynthesis. Genetic and molecular evidences showed that FhMYB4L functioned as part of the MBW complex by interacting with bHLH proteins and repressed transcription through its C-terminal EAR motif, which changed the positive MBW complex into negative one. Comparatively, FhCPCL functioned as negative regulators by competing bHLH regulators with anthocyanin-promoting MYBs, which titrated the formation of anthocyanin-promoting MBW complex. Actually, the precise regulatory cascade and feedback regulation in the control of anthocyanin biosynthesis in *Freesia* flowers were much similar like that in core eudicot plants, *Arabidopsis* and petunia. However, more and more evidences exhibited there supported the finds that divergent regulatory manners were evolved after the division of monocots and dicots. For example, FhPAP1L1 or FhPAP1L2 was sufficient to activate *EBGs* (early biosynthetic genes) as well as *AtTT8*, and further interacted with AtTT8 to regulate the expression of *LBGs* (late biosynthetic genes), whereas in *Arabidopsis*, the *EBGs* were activated by co-activator independent and functionally redundant R2R3-MYB regulatory genes (*MYB11*, *MYB12*, *MYB111*). Moreover, AtPAP1 could not activate *AtTT8* or *LBGs* independently. In conclusion, it can be deduced that the regulatory mechanisms between monocots and dicots were divergent in many aspects, and the finds will benefit for the understanding of the genetic basis of the regulatory mechanism accounting for flower pigmentation in monocot plant.

The effect of flooding on clonal growth and regeneration of *Populus pruinosa* Schrenk riparian forest

Yaqiong Zheng, Zhengshuai Zhao, ***Zhijun Li***
College of life science, Tarim University

This study explored the effect of flooding on the clonal growth and regeneration of *Populus pruinosa* Shrenk riparian forest along the upper reaches of the Tarim River in Xinjiang, China. In 2014 and 2015, from April to October in both years, we surveyed *P. pruinosa* Shrenk clonal growth as well as soil physical and chemical factors before and after flooding. The results showed that: (1) From April to June, before flooding, there was a gradual increase in adventitious buds, unearthed/earthed clonal ramets, the number of ramets in each cluster, the ramet height and the growth of their basal diameter; while from August to October, after flooding, the numbers of buds and ramets decreased and the growth rate gradually declined. (2) From April to June, before flooding, there was a gradual increase in soil moisture, field capacity, and soil porosity, while soil bulk density gradually decreased. During the same period, soil organic matter, available nitrogen, and available phosphorus, soil available potassium, total salt content, and pH value all increased gradually. From August to October, after flooding, these chemical factors (soil organic matter, available nitrogen, soil available phosphorus, available potassium, total salt content, and pH value) continued to increase gradually. (3) Flooding had an effect on soil moisture which in turn led to significant changes in field capacity, soil bulk density, total salt content, and pH value. Correlation analysis also showed that the variation of four physical factors and six chemical factors exerted positive or negative effects on adventitious buds, unearthed/earthed clonal ramets, number of ramets in each cluster, height of ramets, and growth rate of ramet basal diameter. Thus, we can conclude that flooding not only nourished clonal growth during the flooding period, but also sustained clonal growth from April to June of the following year by replenishing soil moisture through the freezing and thawing of soil water in winter. Variations in soil physical and chemical factors due to flooding also influenced *P. pruinosa* Schrenk clonal growth. Therefore, flooding played an important role in the clonal reproduction and regeneration of *P. pruinosa* Schrenk riparian forest.

The relationship between the spatial and temporal characteristics of flower occurrence and the heterophylly of *Populus euphratica*

Jiahao Li, Peipei Jiao, ***Zhijun Li***
College of life science, Tarim University

We choose the *Populus euphratica* with different diameters on the same site as the research object, focus on the occurrence of flowers and heterophyll, and their vertical distribution range as diameters classes increased and the relationship among them. The results showed: (1) linear leaves occupied the entire crown before diameter class 2, lanceolate leaf, ovate leaves and broad ovate leaves began to appear from the canopy top in order, lanceolate leaves and ovate leaves occurred from diameter class 2, broad ovate leaves began to emerge from diameter class 4. There is a dynamic change of their frequency and the proportion of vertical distribution region in crown height as the diameter increased, the proportion of linear and lanceolate leaves in crown was significantly negative correlated with diameter classes ($P < 0.01$); while the proportion of ovate leaves and broad ovate leaves in the crown were significantly ($P < 0.05$), and very significantly ($P < 0.01$) positive correlated with diameter classes. (2) As same as the appearance of broad ovate leaves, flowers occurred from the top of crown and diameters class 4; the maximum distribution region and the proportion of flower concentrated region in crown height showed a very significant correlation with diameter classes ($P < 0.01$). (3)The flower maximum distribution region and flower concentrated region overlapped with the distribution region of broad ovate leaves, the vertical spatial distribution range of flowers and broad ovate leaves widened as the diameters classes increasing from diameter class 4-18, and processed simultaneously, and the occurrence time and spatial distribution range of flowers also overlapped with that of broad ovate leaves. Correlation analysis showed, the flower maximum distribution region in vertical space, and the proportion of concentrated distribution region in crown height of flowers were very significant positive correlated with the proportion of concentrated distribution region in crown height of broad ovate leaves, the results illustrated that the appearance of broad ovate leaves is a morphological characteristic and sign for *Populus euphratica* to transfer from vegetative to reproductive development.

Functional characterizations of β-glucosidases involved in aroma compound formation in tea (*Camellia sinensis*)

Yinyin Liao[1]*, Ying Zhou*[1]*, Lanting Zeng*[1,2]*, Jiadong Gui*[1,2]*, Fang Dong*[3]*, Ziyin Yang*[1,2]
1. South China Botanical Garden, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences
3. Guangdong Food and Drug Vocational College

Tea (*Camellia sinensis*) aroma is an important factor affecting tea quality. Many tea aroma compounds are present as glycosidically conjugated forms in tea leaves for better storage, and the glycosidically conjugated aromas can be hydrolyzed by beta-glucosidase (b-Glu) and beta-primeverosidase to release free tea aromas. b-Primeverosidase has been identified and functionally characterized, while b-Glu has not been identified in tea leaves. In the present study, we established a yeast expression system to recombine CsGH1BG1, CsGH3BG1, and CsGH5BG1, which belonged to GH1, GH3, and GH5 families in plants, respectively. These three recombinant Csb-Glus hydrolyzed the b-glucosidically conjugated aromas to form free aromas, suggesting that Csb-Glus were not specific for the hydrolysis of b-glucosidically conjugated aromas *in vitro*. Furthermore, subcellular localization of the Csb-Glus indicated that CsGH1BG1 and CsGH3BG1 were located in the cytosol and vacuole, respectively, while CsGH5BG1 was located in the cell wall. As b-glucosidically conjugated aromas occurred in the vacuole, CsGH1BG1and CsGH3BG1 might be responsible for the hydrolysis of b-glucosidically conjugated aromas in tea leaves during the tea manufacturing process. This study provides the first evidence of Csb-Glus in tea leaves, and will advance understanding of tea aroma formation.

Physiological indice study of the resurrection plant *Boea Hygrometrica* using weighted gene co-expression network analysis at different hydrating stages.

Tao Xu, ***Chih-Ta Lin***
Institute of Botany, The Chinese Academy of Science

Resurrection plants are defined as the plants that rapidly restore their biological processes after severe water deficit. In this course, the physiological indices and gene expression of the plants are varied to adapt the desiccation. To study the differentiation in gene expressions of plants in dehydrated and rehydrated status systematically, co-expression networks of *Boea Hygrometrica* have been constructed using weighted gene co-expression network analysis (WGCNA) method. Through modular analysis and the correlation between modules and variation in physiological indices, the constructed networks were found high quality and aggregation. Seven networks were found specific and significant from GO enrichment and KEGG annotation in both biological functions and cellular components, as well as their high physiological correlation compare to others. Modular analysis showed the highest correlation of the hub genes from individual network is with the ubiquitin-related genes, and the next is the bZIP-like genes. The ubiquitination levels in *Boea Hygrometrica* at different hydrating stages was further investigated to verify its involvement and importance in desiccation tolerance.

Endocytic mechanisms of membrane proteins in *Arabidopsis*—a single molecule analysis approach

Jinxing Lin
1. Beijing Forestry University
2. Institute of Botany, Chinese Academy of Sciences

The plasma membrane (PM) is highly dynamic and PM proteins play important roles in regulating various transport processes. Measuring the mobility and interactions of proteins is key to understanding cellular signaling mechanisms. However, bulk approaches have been unable to unambiguously monitor the behaviors of the individual PM molecules without disrupting their membrane environment. Besides, transient molecular interactions cannot be identified by conventional fluorescence imaging-approaches. In the past few years, we have developed variable-angle total internal reflection fluorescence microscopy (VA-TIRFM) to image PM proteins in intact plant cells, applied single-particle techniques to protein tracking and subunit counting, provided new information on the spatiotemporal dynamics of specific molecules and their interactions. Endocytosis is an essential way for entry of membrane proteins, lipids, and extracellular molecules into the cell. Clathrin-mediated endocytosis plays an essential role in many cellular and developmentalprocesses. Based on single-molecule and genetic approaches, we demonstrated that *Arabidopsis* AP2σ is closely associated and physically interacts with the clathrin light chain (CLC), and AP2σ-mCherry fluorescence appears and disappears before CLC-EGFP fluorescence. In addition, the density and turnover rate of the CLC-EGFP spots are significantly reducedin the *ap2σ* mutant. These findings led us to conclude that AP2 is involved in the CCV initiation, assembly and maturation stages, which is required for clathrin-mediated endocytosis. In recent years, the structure, composition, and possible functions of plant plasma membrane raft-like domains have been described. Similar to animal cells, plant cells have additional endocytic pathways besides clathrin-mediated endocytosis. In our investigations, we found that *Arabidopsis* flotillin1 (AtFlot1) was associated with the membrane microdomains, and participated in clathrin-independent endocytosis. By using VA-TIRFM, we demonstrated that the dynamic behavior of GFP-Flot1 puncta was different from that of CLC-mOrange puncta. Analysis of amiRNA AtFlot1 transgenic *Arabidopsis* plant lines established that a reduction in AtFlot1 transcript levels gave rise to a reduction in shoot and root meristem size and a retardation in seedling growth. Colocalization analysis and immunogold labeling revealed that AtFlot1 was not colocalized with CLC. These findings suggested that AtFlot1 is involved in a clathrin-independent endocytic pathway and functions in seedling development. Further studies based on single-molecule approaches and other methods revealed that clathrin and AtFlot1-associated membrane microdomains cooperatively regulate membrane protein dynamics and endocytosis, such as PIP2;1 (plasma membraneintrinsic protein), AMT1;3 (ammonium transporter), RbohD (respiratory burst oxidase homolog D), and BRI1 (brassinosteroid receptor) and the membrane microdomain played a role in altering its activity of these proteins by positively or negatively affecting their clustering and signal transduction.

P1039

A regulatory cascade for auxin regulated root growth under aluminium stress

***Guangchao Liu**, Shan Gao, Zhaojun Ding*
Shandong University

Auxin acts synergistically with cytokinin to control the shoot stem-cell niche, while both hormones act antagonistically to maintain the root meristem. In aluminum (Al) stress-induced root growth inhibition, auxin plays an important role. However, the role of cytokinin in this process is not well understood. In this study, we show that cytokinin enhances root growth inhibition under stress by mediating Al-induced auxin signaling. Al stress triggers a local cytokinin response in the root-apex transition zone (TZ) that depends on IPTs, which encode adenosine phosphate isopentenyltransferases and regulate cytokinin biosynthesis. IPTs are up-regulated specifically in the root-apex TZ in response to Al stress and promote local cytokinin biosynthesis and inhibition of root growth. The process of root growth inhibition is also controlled by ethylene signaling which acts upstream of auxin. In summary, different from the situation in the root meristem, auxin acts with cytokinin in a synergistic way to mediate aluminum-induced root growth inhibition in *Arabidopsis*.

A study of drought tolerance of ectomycorrhizal *Acacia confusa* seedlings

***Fengming Song**[1], Jianhua Liu[1], Jiangli Lei[2]*
1. Shenzhen Techand Ecology & Environment Company Limited
2. Fairylake Botanical Garden, Shenzhen & Chinese Academy of Sciences

Soil improvement and drought tolerance improvement in plants are the keys to successful recovery and reconstruction of slope vegetation. In this study, seedlings of *Acacia confusa*, a tree commonly used to afforest slopes, were inoculated with different quantities of the ectomycorrhizal fungus *Pisolithus tinctorius* for the purpose of soil improvement and drought tolerance improvement. Half a year later, the seedlings' mass growth and mycorrhizal colonization rates were measured. After that, the ectomycorrhizal seedlings and the control seedlings (not inoculated with Pisolithus tinctorius) were both exposed to natural drought stress. Leaf photosynthesis and chlorophyll fluorescence in the two groups were measured before and after the treatment in order to observe changes in the two indexes. The results show that, compared to the control seedlings, the ectomycorrhizal seedlings had significantly higher mass growth, photosynthesis and chlorophyll fluorescence under drought stress and experienced much slower decreases in the three indexes. These indicate that the inoculation with *Pisolithus tinctorius* can increase photosynthetic efficiency and water use efficiency of *Acacia confusa* and thereby improve its drought tolerance. Moreover, both large and small quantities of *Pisolithus tinctorius* were found to be able to boost growth of *Acacia confusa* seedlings, but large quantities of the fungus can result in higher mycorrhizal colonization rates and are thus more effective in promoting growth and enhancing drought tolerance.

T4

P1041

Study on the effect of three arbuscular mycorrhizal fungi on the growth and drought resistance of *Zenia Insignis*

Jianhua Liu[1], *Fengming Song*[1], *Zhengjun Shi*[2]
1. Shenzhen Techand Ecology & Environment Company Limited
2. Fairylake Botanical Garden, Shenzhen & Chinese Academy of Sciences

In order to improve the growth of plants in the greening of soil spray sowing, the survival rate of the plants in the initial stage of planting as well as the drought-resistance in the state of low maintenance in the later stage, three arbuscular mycorrhizal fungi, namely *Glomus mosseae, Glomus etunicatum* and *Glomus intraradensis*, are selected to study the effect on the growth and drought resistance of *Zenia Insignis* through mycorrhizal inoculation and natural drought stress. The results show that the rate of infection from *Glomus mosseae* is the highest (96.7%). The inoculation of three species of arbuscular mycorrhizal fungi could all significantly increase the plant height, ground diameter and biomass accumulation. Through natural drought experiment, it is concluded that the relative water content of mycorrhizal seedlings is significantly higher than that of the control group, while the relative conductivity and MDA content of the mycorrhizal seedlings are significantly lower than that of the control group, and the soluble sugar content is significantly higher than that of the control group, indicating that there is relatively little dehydrated behaviors of leaves of mycorrhizal seedlings, and the degree of damage on the cytomembrane is less, and more osmotic adjustment substances is produced at the same time. In the process of drought resistance, the photosynthesis and chlorophyll fluorescence of the control and the mycorrhizal fungi were the same in terms of the index change, and the inoculation of arbuscular mycorrhizae could increase the photosynthetic capacity and water use efficiency, decrease the damage degree of ΦPSII reaction center, enhancing the efficiency of solar energy utilization and the drought-resistant ability of seedlings, among which the Glomus mossea has the best performance in drought resisting.

P1042

Formation and emission of linalool in tea (*Camellia sinensis*) infested by tea green leafhopper (*Empoasca* (*Matsumurasca*) *onukii* Matsuda)

Xiaoyu Liu[1,2], *Xin Mei*[1], *Ying Zhou*[1], *Xiumin Fu*[1], *Lanting Zeng Zeng*[1,2], *Fang Dong*[3], *Ziyin Yang*[1,2]
1. South China Botanical Garden, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences
3. Guangdong Food and Drug Vocational College

Herbivore-induced plant volatiles play important roles in defense against stresses, and also can be used as quality components of agricultural plants. As an example, the famous oolong tea (Oriental Beauty), which is manufactured by the tea (*Camellia sinensis*) leaves infected by tea green leafhoppers with piercing-sucking mouthpart, has characteristic volatile monoterpenes, which were derived from linalool. However, effect of tea green leafhopper attack on formation and emission of linalool is unknown. In the present study, tea green leafhoppers inducing production of characteristic volatiles was identified as *Empoasca* (*Matsumurasca*) *onukii* Matsuda. *E.* (*M.*) *onukii* attack did not significantly affect internal linalool content, but induced higher emission of linalool from tea leaves, which was due to accumulation of high levels of *linalool synthases* (*CsLIS1 and CsLIS2*) mRNA. *CsLIS1 and CsLIS2* recombinant proteins exhibited ability of transformation from geranyl diphosphate to (*S*)- linalool with high ratio. An automatic machine was employed to simulate continuous mechanical damages from *E.* (*M.*) onukii attack on tea leaves. In contrast to single mechanical damage, the continuous mechanical damages had similar patterns of changes in emitted linalool, precursors of linalool, expressions of genes involved in formation of linalool with those of *E.* (*M.*) *onukii* attack. These suggested that continuous mechanical damages from *E.* (*M.*) *onukii* attack was one key factor affecting formation and emission of linalool from tea leaves. The information can be essential for the future utilization of stress-responses of plant secondary metabolism for improvement of quality components of agricultural products.

Molecular genetic mechanism of hybrid male sterility by the *Sc* locus in rice

Yao-Guang Liu
College of Life Sciences, South China Agricultural University

Hybrid sterility is a major form of postzygotic reproductive isolation between the species and subspecies in *Oryza* genus. A number of gene loci are involved in hybrid sterility in rice. So far, several hybrid sterility genes in five loci (or locus pairs) have been cloned, including *S5* (Chen *et al.,* 2008, Yang *et al.,* 2012)*, Sa* (Long *et al.,* 2008), *S27/S28* (Yamagata *et al.,* 2010), *DPL1/DPL2* (Mizuta *et al.,* 2010), and *HSA1* (Kubo *et al.,* 2016). Our recent results reveal that a pollen-essential gene in the *Sc* locus in rice has evolved into a speciation gene between *indica* and *japonica* by allele divergence via genomic structural variation. The allelic interaction of this locus in *indica-japonica* hybrids results in epigenetic variation in the *japonica* allele, leading to its silencing thus pollen abortion. These researches demonstrate that diverse molecular mechanisms have been produced for reproductive barriers in rice speciation.

Galactinol Synthase (*AnGolS1*) of *A.nanus* can improve the seed germination ability in tomato under low-temperature

Yudong Liu

Shenyang Agricultural University

Galactinol synthase (GolS) is important in the physiology of plant stress resistance, photosynthate translocation and seed physiology. A galactinol synthase (*AnGolS1*) which was isolated from *Ammopiptanthus nanus* (*A.nanus*) seedlings was transformed into tomato. In previous studies, we found that *AnGolS1* could affect *SlGolS* genes expression in the *AnGolS1* overexpression tomato whether or not low-temperature treatment. In addition, *AnGolS1* can also improve the germination ability and rate of overexpression tomato seeds under room temperature and low-temperature. It explains that *AnGolS1* maybe anticipate in the growth and development of plant and helps plant to resist cold damage. Thus, it is important to define its metabolic functions that will help us to further understand the molecular mechanism of cold tolerance of tomato.

Phenotypes of 57 terrestrial tree species under waterlogging

Ling Ma

South China Agricultural University

Both hydroponic experiments and waterside ecological restoration need abundant information about plant species that adapted to waterlogging environment during the planning stage. In this study, we evaluated the growth conditions and phenotypes of 57 plant species from 22 families and 33 genus with several different provenances grown hydroponically. We found that most plant species could survive in hydroculture for more than 10 weeks with survival rate >60%, and showed new shoot growth in hydroculture. While there were very interesting phenotypes expressed by some species, such as all leaves withered rapidly then new leaves grew out gradually for *Anthocephalus chinensis*; leaves kept alive but stopped growth for *Phoebe sheareri*, and *Acacia falcata*; all leaves fell down rapidly and had kept naked branches for at least 2 weeks for *Cassia barkeriana*, *Pithecellobium clypearia* and *Mytilaria laosensis*, *etc.* In addition, the 57 plant species also showed different fresh biomass growth rate. The phenotypes and growth condition information of 57 plant species were addressed in this study, it would be very useful for planning hydroponic experiments or waterside ecological restoration, although the waterlogging condition in waterside would be quite different from hydroculture.

P1046

Role of calcium and nitric oxide in enhancement of therapeutic potential and oxidative stress management in *Trigonella foenum-graecum* L.

Palash Mandal*, Saran Kumar Gupta*

University of North Bengal

Trigonella foenum-graecum being rich source of various bioactive phytochemicals has been used for the treatment of wide spectrum of diseases and disorders since ancient times. Considering such diverse implication of fenugreek, the present study was designed aiming the enhancement in the phytochemicals especially associated with the antioxidant and antidiabetic activity as these two therapeutic properties are the major point of concern of the present research work. The elicitors of two important signalling molecules (nitric oxide and calcium) were implemented in the present research work, to investigate their role in the elicitation of therapeutic potential of fenugreek sprouts. The technique applied in the study was priming; this method has been reported to be one of the important strategies in enhancement of crop productivity. Accordingly, the seeds were pre-treated with various elicitors of nitric oxide and calcium namely, sodium nitroprusside (SNP) as an exogenous source of nitric oxide; c-PTIO (CP), a nitric oxide scavenger; calcium chloride (CC) as an exogenous source of calcium ion; EGTA (EG) a calcium chelator; and lanthanum chloride (LC): a calcium channel blocker. As a result, the present study revealed significant increase in free radical scavenging activity and *in vitro* anti-diabetic activity along with associated bioactive phytochemicals by elicited sprouting in fenugreek with exogenous sources of nitric oxide and calcium ion. Additionally, a significant correlated relationship between the therapeutic potential and the phytochemical contents was obtained, indicating these phytochemicals as efficient antioxidant and antidiabetic agents. Further, the negative effects of the antagonists of calcium and nitric oxide indicate that the flux of these signalling molecules within the cellular system is essential during germination phases to regulate the mechanisms responsible for the biosynthesis of these bioactive compounds. The presence of trigonelline as a major hypoglycemic component was further confirmed by IR and NMR analysis. After successful elicitation of bioactive phytochemicals and their related therapeutic properties, the exogenous sources of nitric oxide and calcium were applied for studying their effect on the alteration of various biochemical parameters along with their antioxidant defence system during germination stages. The pre-treated seeds were exposed to saline condition and their various morphological, physiological and biochemical attributes were determined. Our results suggest that priming of fenugreek seeds with exogenous source of nitric oxide and calcium enhanced the morphological and biochemical attributes along with the antioxidant defense system under saline condition, which was further substantiated by the occurrence of adverse effects of salinity on the seeds which were unprimed and also those primed with the antagonists of these signalling molecules. Therefore, the enhancement in the enzymatic as well as non-enzymatic components might be due to the involvement of calcium and nitric oxide leading to tolerance towards salinity accompanied with better growth and development. Additionally, an uninterrupted influx of these signal molecules is very much essential for the better nutraceutical quality and growth of fenugreek seedlings, which can be hypothesized on the basis of the tremendous deterioration of the therapeutic potential as well as oxidative stress management status of the fenugreek seedlings revealed in the present study.

Development of stay-green chickpea technology to benefit small-holder farmers in the semi-arid tropics

Edward Marques[1]*, Jana Kholova*[2]*, Ramachandra Varma Penmetsa*[3]*, Eric Von-Wettberg*[1]

1. Florida International Institution

2. International Crops Research Institute for the Semi-Arid Tropics

3. University of California, Davis

Chickpea is the second most grown pulse legume worldwide and is a primary source of plant protein for 15% of the world's population living in semi-arid tropical (SAT) regions. In these regions, fluctuations in chickpea production and consumption threatens the nutritional and economic status of the subsistent farming communities. In many of these SAT regions, chickpea crops are typically raised during the low-income post-rainy season in variable rain-fed conditions which largely affects its production. Thus, finding and introducing chickpea adapted to these conditions is a practical strategy to enhance chickpea production value chains of the semi-arid tropics. One viable option to overcome this post-rain season and limited irrigation environment is "cosmetic" stay-green chickpea technology. This stay-green chickpea type carries a deleterious mutation of the *StGR1* gene that inhibits enzymes of the chlorophyll catabolism pathway, which leads to extended chlorophyll retention in seeds and leaves. Consequently, elevated levels of chlorophyll may extend the lifespan of light harvesting antennae (and increases production of reactive oxygen species (ROS) in plant tissues, which in turn, requires additional maintenance in the form of higher carotenoid levels, the ROS scavengers. Higher levels of carotenoids involved in photo-oxidative protection are very likely to enhance the nutritional value of the crop since these are also precursors of vitamin A. Similar findings have been documented in other green-seeded legumes such as the garden pea (*Pisum sativum*), common bean (*Phaseolus vulgaris*), and Alfalfa (*Medicago sativa*) which have lead to development of commercial products. Since the stay-green technology has not been investigated in detail, the goal of this study is to investigate its effect on key agronomic parameters and response to growth in SAT (drought-prone) regions. Our previous study of *StGR1* germplasm confirmed that these genotypes, indeed, maintain approximately a 33% higher carotenoids content in the seeds compared to other varieties. Additionally, it was found that the *StGR1* gene product might be specific to chlorophyll b since these *StGR1* lines maintained chlorophyll b at significantly higher levels. High levels of chlorophyll b appear to affect leaf thickness and efficiency of water use. A drawback in this study involved the use of a very diverse gene-bank germplasm which didn't allow us to rigorously compare agronomically important parameters. Therefore, we aim to repeat the study with *StGR1* (from donor parent ICC16340) introgressed on the background of 2 cultivars (KAK2, JGK1) fixed for phenology and harvest index. We are currently assessing the *StGR1* mutation effect on basic agronomy traits, plant water use-related traits, responsiveness to soil and atmospheric drought, chlorophyll contents, and carotenoid concentrations using the imaging phenotyping platform, LeasyScan, and analytical scales for gravimetric transpiration measurements. This study is currently ongoing at the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT). Ultimately, the data gathered will allow us to determine the potential of stay-green technology to enhance crop nutrition and the main agronomic parameters important for small-hold farmers in the semi-arid tropics.

Allocation of resources in sweet potato plants (*Ipomoea batatas* (L.) Lam.) In the community of San Félix Hidalgo, Atlixco, Puebla, México

David Martínez-Moreno[1], *Francisco Basurto-Peña*[2], *Agustina Rosa Andrés-Hernández*[1], *Jenaro Reyes-Matamoros*[1], ***Sombra Patricia Rivas-Arancibia***[1]
1. Benemérita Universidad Autónoma de Puebla
2. Universidad Nacional Autónoma de México

At present there is a growing interest in traditional agricultural production systems, and the value of indigenous technology, developed over centuries and based on empirical practices and accumulated experiences has been recognized for decades. This is the case of sweet potato (*Ipomoea batatas*), which has been studied from the following points of view: origin and history, ethnobotanical, taxonomic, taxonomical characterization through morphological and isoenzimatic descriptors, industrial, processes post-harvest, chemical characterization, industry and genetic engineering. Therefore, the present research aimed to record the allocation of resources to the different organs of three sweet potato varieties (White, Purple and Yellow) through 10 destructive crops in the community of San Félix Hidalgo, Atlixco, Puebla. The differences of the dry weights in white and purple sweet potato inflorescences were in general very similar and the energy of these structures perhaps affected the allocation of energy to the anthropogenic organ that is sweet potato, a situation that was not present in the yellow sweet potato variety, since the dry weight percentage of the different structures shows this. Finally, there are no differences in the last harvest, this was due to the producer's strategy of not harvesting the crop in harvest nine, because the price of sweet potato was very low at that time, this shows that many times this type of decisions is not correct since leaving the crop for a longer time and not harvesting it at the right time can reduce its dry weight, as occurred in this work, and as a consequence the producer lost money, this decision many times causes the crop gets lost, since the risk that the sweet potato was decomposing or attacked by animals was enormous. In conclusion, the yellow sweet potato variety does not elaborate reproductive structures and the percentage of biomass allocation to sweet potato is high, compared to its vegetative structures. These three varieties do not develop seeds, which indicates that asexual reproduction probably accumulates unfavorable mutations or that pollinators specific to varieties may not be found. Keeping the sweet potato in the field for more time than programmed for its life cycle, results in a reduction of its dry weight and it gets decomposed or attacked by insects, and this situation would generate losses.

Centrin in *Marchantia polymorpha*: characterization, localization, and implications in the evolution of microtubule system in land plants

Kaori Nomura[1], *Kimitsune Ishizaki*[2], ***Masaki Shimamura***[1]
1. Department of Biological Science, Graduate School of Science, Hiroshima University
2. Department of Biology, Graduate School of Science, Kobe University

The intracellular localization of centrin, a centrosomal-associated protein, was investigated by immunofluorescence microscopy in a liverwort, *Marchantia polymorpha.* In vegetative tissue, mitotic spindles were initiated from the spherical "polar organizers" (POs) lacking the centrioles. Although gamma-tubulin, another typical centrosomal protein, clearly localized on the POs, centrin did not localized there. The typical centrosomes including centrioles arise *de novo* just before the production of spermatid mother cells. Centrin was clearly detected at the spherical MTOCs corresponding to the centrosomes in spermatid mother cells. Through the spermiogenesis, centrin was detected at basal bodies and multilayered structure (MLS) of sperm cells. Unexpectedly, centrin also localized on the developing cell plate in phragmoplasts. Phylogenetic analysis and genetic analyses using gene targeted mutagenesis indicated that the three homologous genes of centrin in *M. polymorpha* have specific function respectively. Although angiosperms have no centrosomes through the life cycle, they also have centrin homologs. Functional diversification of centrin through the evolution of land plants seems to be associated with evolutional changes of microtubule organizing system concerned with the formation of mitotic and cytokinetic apparatus.

A transcriptomic approach to explore fruit formation and maturation in *Arabidopsis thaliana*

Chiara Mizzotti[1], *Lisa Rotasperti*[1], *Bianca Galliani*[1], *Moretto Marco*[2], *Kristof Engelen*[2], ***Simona Masiero***[1]
1. Università degli studi di Milano
2. Fondazione Edmund Mach

Given the fundamental nature of both the dietary and biological significance of fruits, molecular dissection of fruit maturation has, certainly, considerable interest. The yield and quality factors associated with fruits are of key importance to agricultural production, and future improvements of fruit characteristics will rely on the comprehension of the mechanisms controlling fruit development and maturation. Here we report our efforts to shed light into the molecular networks controlling fruit development in the model plant *Arabidopsis thaliana*. In order to identify genes whose products control *Arabidopsis* fruit development and maturation, a transcriptome analysis by RNA-deep-sequencing has been performed, comparing wild-type (WT) siliques, devoid of seeds, at 3, 6, 9 and 12 DPA, thus covering all the phases of silique development and maturation. The bioinformatics and statistical analysis of the data led to the identification of about one thousand genes differentially expressed between early and late stages of silique development. Among all the different clusters, we are currently exploring the role of the NAC transcription factors.

Overexpression of UDP-glucose pyrophosphorylase from *Larix gmelinii* enhances vegetative growth in transgenic *Arabidopsis thaliana*

Lili Mei[1], *Ningning Li*[2], *Xiaofei Lin*[2], ***Wenbo Zhang***[1]
1. College of Forestry, Inner Mongolia Agricultural University
2. Inner Mongolia University College of Life Sciences

UDP-glucose pyrophosphorylase (UGPase) is an important regulatory enzyme in carbohydrate metabolism, that catalyzes the reversible production of glucose 1-phosphate (Glc-1-P) and the conversion of uridine triphosphate to uridine diphosphate glucose (UDPG) and pyrophosphate. UDPG, the substrate/product of UGPase, is the key precursor for synthesizing sucrose, mannose, cellulose, cutin, glucoprotein, glycolipid, and carbohydrate. Therefore, the expression of *UGPase* may affect the timber qualities of the forest trees by regulating the biosynthesis of plant cellulose. Dahurian larch, *Larix gmelinii* (Rupr.), one of three major timber conifers in northeast China, has high wood density, strong mechanical properties, and a clear wood texture. In addition, larch fiber cells are long and the nonfiber cell content is low, so *L. gmelinii* has important economic value in the construction, decoration, paper production, and chemical fiber industries. Therefore, investigating the role of *LgUGPase* in cellulose biosynthesis is important to improve growth and timber qualities by controlling *LgUGPase* gene expression. In this study, a larch UGPase (*LgUGPase*) gene was isolated from *L. gmelinii* using reverse transcription-polymerase chain reaction (RT-PCR). The 1443-bp open reading frame encodes a protein of 480 amino acids with a predicted molecular weight of 53.7 kDa and shows striking sequence similarity to UGPase proteins from *Pinus taeda* and *Picea sitchensis*. Semiquantitative reverse transcription-polymerase chain reaction showed that the *LgUGPase* gene was expressed primarily in the larch stem in addition to in root and leaf. Southern blot analysis indicated that *LgUGPase* is encoded by two genes in the *L. gmelinii* genome. Overexpression of *LgUGPase* enhanced vegetative growth in transgenic *Arabidopsis* and increased the contents of soluble sugars and cellulose, and thickened parenchyma cell walls. These results revealed that *L. gmelinii* UGPase participates in sucrose/polysaccharide metabolism and cell wall biosynthesis, suggesting that *LgUGPase* may be a good candidate gene for improvement of fiber cell development in plants.

P1052
Relationship between light habitat and functionality of the seedling bank of *Calophyllum mariae* Planch. & Triana, in tropical rainforests of the pacific coast of Colombia, South America.

Omar Melo, *Edgar Andrey Sosa, Leidy Carolina Mendez*
Universidad Del Tolima

The functional traits are morphological, physiological and phenological characteristics that directly or indirectly influence the fitness of the plant against the environment affecting its growth, reproduction and survival and generating phenotypic differences between species that play an important role in the maintenance of diversity within communities. The research was carried out in secondary forests located in the Bajo Calima region of the, Biogeographical Chocó of Colombia. Coordinates 3°57′2.11" N and. 76° 59′9.39" W. The average annual rainfall is 7467 mm. The average annual temperature is 26 °C. This region is one of the most humid places in the world and with high values of biodiversity. Twelve *Calophyllum mariae* seedlings banks were placed, which were classified into three light environments (100%, 60% and 40%). We using the photosynthetic active radiation (PAR). Populations were monitored for three years by conducting monthly assessments. In each bank, the following variables were recorded: leaf area index (LAI), light extinction coefficient (K), relative growth rate (RGR), root/shoot ratio (R/S), specific leaf area (SLA). The values of biomass were generated from the seedling harvest and determination of their dry weights. Likewise, a foliar analysis was generated at the end of the experiment and the contents of nitrogen, total proteins and total phenols were evaluated. The hypothesis of compromise between adaptation and competition was raised. When *C. mariae* seedlings bank are subjected to contrasting light environments, their stability in the differential distribution of biomass is altered, modifying both physiological and morphological components, in such a way that the seedlings prioritize the organs that facilitate the best adaptation and/or competition against them. By subjecting the seedlings to environments with light constraints, the relative growth rate accelerates and reaches its highest values, for which it must increase the SLA, to maximize the availability in the capture of photons. This is why biomass is prioritized towards aerial components. This strategy allows the natural regeneration of the species to be established in the undergrowth, under low radiation light environments, where their seedlings compete strongly for space and light mainly, to reach the canopy in the shortest possible time. In contrast, when *C. mariae* seedling banks are established under high illumination conditions, the seedling life strategy prioritizes the resources towards the growth components that guarantee their survival and that is why the underground biomass reaches the highest values in these. It also modifies its SLA, allowing it to reduce its growth rates and adapt better to an environment different from its natural regeneration. These results show the high plasticity of the juvenile populations of this species, which allows their adaptation to different types of growth environments.

L-drying preservation of cultured plant cells

Tomoyo Mikuni[1], ***Hiroto Kinoshita***[1], *Hideyuki Yamazaki*[2], *Akira Kuriyama*[1]

1. Graduate School of Science and Engineering, Tokyo Denki University

2. National Institute of Technology and Evaluation

Vacuum-drying is a popular method for preservation of microorganisms, because long-term viability excellent in most cases and the storage distribution requirements are simple. For example, strains of microorganisms enclosed in glass tubes can be in cold storage and transported easily. Liquid-drying is a useful method of vacuum-drying for the preservation of microorganisms that are particularly sensitive to the freezing stage of the normal lypholization process. Liquid-drying has several advantages over freeze-drying and effectively used for preserving fungi also.

Cultured plant cells become gene resources together with seeds, spores, pollens *etc.* Cultured cells and tissues are commonly cryopreserved for the long-term storage. Since Nag and Street (1973), Sugawara and Sakai (1974) successfully preserved cultured carrot cells and sycamore cells in liquid nitrogen respectively, cultured cells of various plant species have been preserved. However, there is no report of successful preservation of cultured plant cells by the vacuum-drying method. In this study, we tried to preserve actively growing cultured cells by liquid-drying (L-drying) method.

A suspension culture of Pogonatum inflexum was established and maintained in CI medium supplemented with 10 μM BA, 5 μM 2,4-D, and 3% sucrose. Cells were subcultured onto fresh medium for a period of 7 days and used for experimental materials. Actively growing cells were exposed to L-drying after washing with and resuspending in liquid culture medium with or without torehalose. L-drying itself decreased survival rapidly with little further effect from temperature of storage, although survival was markedly improved by addition of torehalose into suspension medium. Cells suspended in the torehalose containing medium survived L-drying at rates comparable to controls (>86%). Dropping the torehalose suspended cells on a piece of aluminum foil before L-drying was important for their subsequent survival through these procedures because the cells dropped on filter paper did not survived L-drying. Cells prepared by L-drying were successfully regrown after 4 weeks storage at 5°C.

L-drying method, widely used for preservation of microorganisms, appears to be a technique which could be used for the preservation of cultured plant cell.

Extremely low nucleotide diversity in the X-linked region of papaya

Robert Vanburen[1,2], *Ching Man Wai*[1,2], ***Ray Ming***[1,2]

1. FAFU and UIUC-SIB Joint Center for Genomics and Biotechnology, Fujian Agriculture and Forestry University

2. Department of Plant Biology, University of Illinois at Urbana-Champaign

The papaya Y-linked region showed clear population structure, resulting in the detection of the ancestral male population that domesticated hermaphrodite papayas were selected from. The same populations were used to study nucleotide diversity and population structure in X-linked region. Diversity is very low for all genes in the X-linked region in wild dioecious population, with nucleotide diversity $\pi_{syn} = 0.00017$, tenfold lower than the autosomal $\pi_{syn} = 0.0017$ and twelvefold lower than the Y-linked region $\pi_{syn} = 0.0021$. Analysis of the X-linked sequences shows an undivided population, suggesting a geographically wide diversity-reducing event, whereas two sub populations were observed in the autosomes separating gynodioecy and dioecy and three sub populations in the Y-linked region separating three male populations. The extremely low diversity in papaya X-linked region was probably caused by a recent, strong selective sweep before domestication, involving either the spread of a recessive mutation in an X-linked gene that is beneficial to males, or a partially dominant mutation that benefitted females or both sexes. Nucleotide diversity in the domesticated X samples is about half that in the wild Xs, probably due to the bottleneck when hermaphrodites were selected during domestication. The extreme low nucleotide diversity in papaya X-linked region is much greater than observed in humans, great apes, and the neo-X chromosome of *Drosophila miranda*, which show the expected pattern of Y-linked genes < X-linked genes < autosomal genes, whereas papaya shows an unprecedented pattern of X-linked genes < autosomal genes < Y-linked genes.

Pseudoperolic mutation is caused by the insertion of B-class gene in *Habenaria radiata*

Mitoma Mai, *Kajino Yumi, Kanno Akira*
Graduate School of Life Sciences, Tohoku University.

Habenaria radiata (Orchidaceae) has two whorls of perianth, consisted with three greenish sepals, two white petals and one lip (labellum). In contrast, pseudopeloric cultivar of *H. radiata*, whose name is 'Hishou', forms a white petaloid organ instead of dorsal sepal, and the two lateral sepals replaced to lip-like structures. According to the orchid code and P-code model, *DEFICIENS-like* and *AGL6-like genes* have important role for morphological difference of tepals in orchid. Therefore, we isolated and characterized these genes from H. radiata to clarify the molecular mechanism of pseudopeloric mutation in *H. radiata.* We isolated and characterized four *DEFICIENS*-like (*HrDEF-C1, HrDEF-C2, HrDEF-C3* and *HrDEF-C4*) and two *AGL6*-like genes (*HrAGL6-1* and *HrAGL6-2*) from this plant. Comparative expression analysis revealed that many of the genes showed similar expression patterns in wild type and 'Hishou' cultivar except *HrDEF-C3*. *HrDEF-C3* gene was expressed in petal and lip in wild type, but *HrDEF-C3* transcript was observed in the sepal, petal, lip, leaf, root and bulb in 'Hishou'. The genomic sequence of *HrDEF-C3* gene was compared in wild type and 'Hishou', we found retrotransposon-like insertion in the promoter region of one of the *HrDEF-C3* gene in 'Hishou'. We also investigated the genetic inheritance of pseudopeloric mutation by crossing 'Hishou' cultivar with wild-type plants, and found that the characteristic of pseudopeloric mutation was inherited dominantly and this character is linked to the insertion found at the promoter region of *HrDEF-C3* gene. These results demonstrated that pseudoperolic phenotype is caused by the mutation of *HrDEF-C3* gene and the expanded expression of *HrDEF-C3* gene due to the insertion of retrotransposon-like structure in the promoter region. The expression of *HrAGL6-2* gene, whose product has interaction with *DEF-C3* and related to lip development, is limited to dorsal sepals and lip. This differential dorsoventral expression of *HrAGL6-2* gene is correlated with the lateral-specific change of sepal to lip-like structure.

P1056
Transcriptome analysis of genes involved in sex determination of male and female in *Arisaema serratum*

Yuko Miyazaki, *Miyu Adachi, Tetsuya Matsumoto, Miwa Okada*
Okayama University

The genus *Arisaema* is a dioecious perennial plant belonging to the family Araceae, and its sexual expression varies with a year even if it is the same individual. There is a correlation with individual size in the sex change of *Arisaema*, and it tends to become a female when the size is large, and a male when it is small. Since the individual size can be thought of by replacing it with the amount of resources in the individual, it is possible that some resource may be involved in sex determination. However, the trends seen between the individual size and sex is only to detect the correlation, it does not refer to the mechanism and the mechanism of determining sex has not been clarified yet. In this study, we conducted comparative analysis of transcriptome data between male and female flowers of *Arisaema serratum* in order to clarify the genes that cause a difference in the sexual phenotype of *Arisaema*. Male and female inflorescences of *Arisaema serratum* growing on the forest floor were sampled from 3 individuals and used for analysis by the next generation sequencer, Hiseq 2500. As a result of comparison with the microarray results of each floral organ of *Arabidopsis thaliana*, male flowers of *A. serratum* contained a statistically significant number of genes highly specifically expressed in *A. thaliana* male organs (stamens, pollen). Similarly, in the female flowers of *A. serratum*, a statistically significant number of genes highly expressed in *A. thaliana* female organ (stamen) were included. These results suggest the validity of the results of this transcriptome analysis. The genes with high expression in male flowers of *A. serratum* contained a statistically large number of genes whose expression was high under the limitation of nitrogen and sucrose. On the other hand, the genes with low expression in male flowers of *A. serratum* contained a statistically large number of genes whose expression was low under the limitation of nitrogen and sucrose. As a result of this transcriptome analysis, male flowers of *A. serratum* may be deficient in the amount of nitrogen and sucrose, and it seems that resources such as nitrogen and sucrose are involved in the formation of male flowers and female flowers.

P1057
Ecological signals in the wood anatomy of the hemiparasite *Krameria lappacea* (Krameriaceae) in the high elevation cold desert of Peru

Samantha Moody[1], *Carole T. Gee*[1], *Maximilian Weigend*[2]
1. Steinmann Institute of Geology, Mineraology, and Paleontology, University of Bonn
2. Nees Institute for Biodiversity of Plants, University of Bonn

Although *Krameria lappacea*, commonly known as rhatany, is a medicinal shrub of global economic importance, little is known of its ecological wood anatomy. The antiseptic properties of the species' roots have led to overharvesting and pertinent questions of future sustainability, while basic questions about its role as a keystone species in the cold deserts of Peru remain unknown. Previous studies have shown that *K. lappacea* is hemiparasitic on multiple hosts of various species. Thus, the issue is if the ecological signals inherent in the wood of *K. lappacea* reflects its dependence on host plants or are instead tied to abiotic factors. Here we show that the growth dynamics in the wood of *K. lappacea* are clearly not affected by temperature and precipitation, but by hemiparasitism. Measurement of cell dimensions and densities in the thin sectioned wood of eight individual shrubs were taken, and calculations of standard wood indices were done. The wood of *K. lappacea* has short vessel elements (mean of 117 µm) and narrow vessels (mean of 20.25 µm), like most woody xeric plants. It also has a low vulnerability index (VI=0.25) and mesomorphic ratio (MR=15.3) based upon the vessels, which show the ability to withstand water stress. In addition, *K. lappacea* lacks the helical thickenings and grouped vessels that are found in other clearly xerophytic woods. Curiously, it has a non-complacent mean sensitivity (MS=0.39), which exhibits a degree of influence on growth from outside influences. Comparisons of growth ring widths with mean annual temperature and precipitation for 25 years (1985-2010) showed no significant correlation, meaning the steady rates of growth observed in the growth rings of *K. lappacea* are not due directly to climate. Another species of hemiparasite, *Santalum album* (Santalaceae) of dry deciduous forests in the paleotropics, has many xeromorphic wood characteristics, such as helical thickenings, narrow vessels, and shorter vessel element lengths. Apart from the helical thickenings, the wood anatomy of *S. album* is like that of *K. lappacea*, i.e., they both possess tracheids and have indistinct growth rings, which means ecological signals do occur in the wood anatomy. Because *K. lappacea* wood exhibits seasonally affected growth and presence of indistinct growth rings, it can be inferred that its growth is influenced by their parasitization of neighboring species for water and nutrients. The ecological signal of hemiparasitism is recognizable through the characteristics that support xeromorphy e.g., numerous vessels per millimeter squared, narrow vessels, shorter vessel element lengths, and the presence of vasicentric or vascular tracheids, and by growth that shows variance from year to year that is not influenced directly by climate.

How do plants age and die? – Some new insights

Hong Gil Nam[1,2], *Hyojung Kim*[1], *Junhyun Lim*[1], *Timilsina Rupak*[2], *Ji-Hwan Park*[3], *Sunghyun Hong*[1], *Sukjoon Jung*[2], *Jin Hee Kim*[1], *Hye Ryun Woo*[2], *Pyung Ok Lim*[2], *Daehee Hwang*[1,2]

1. Center for Plant Aging Research, Institute for Basic Science, Daegu
2. Department of New Biology, DGIST, Daegu
3. Department of Chemical Engineering, POSTECH, Pohang, Gyeongbuk

Aging followed by death is an inevitable fate in most organisms including human. Our group has been studying the molecular mechanisms of aging and death over two decades to solve the question ‘How does living organisms know when and how to die?’ We have been revealing that aging and death in plants are highly regulated at the chromatin, transcriptional, post-transcriptional, and epigenetic levels. In this presentation, we will report some new insights on the regulatory mechanisms of aging and death in plants with a comparative view on aging in animals.

Aging involves transitions of complex regulatory networks across lifespan. Yet, limited is understanding of causal relationship between age-associated networks and aging processes. Here, we built age-evolving causal regulatory networks of *Arabidopsis* NAC transcription factors across lifespan using mutants of 49 age-associated NACs. These age-evolving networks revealed a regulatory inversion at pre-senescent stage from activating to repressive regulatory modes, which was governed by three hub NACs that negatively regulated key pro-aging pathways, ROS and salicylic acid pathways. Knockout and overexpression of the three hub NACs (the NAC troika) delayed and advanced the regulatory inversion, respectively, rendering earlier and delayed aging. Thus, the network transition by the NAC troika at pre-senescent stage determines initiation and rate of the following aging process in *Arabidopsis*. Meristems are small population of pluripotent stem cells located at shoot and root tips of plants. They have remarkable ability to maintain themselves for a long period and serve as the constant source of cells for newly developing tissue and organs, allowing the long lifespan often observed in many tree species. We are striving to reveal the mechanisms behind the long lifespan stemmed from the long-time maintenance of meristem cells, employing the root apical meristem (RAM) as a model. *Arabidopsis* RAM consists of mitotically inactive quiescent cells (QC) and surrounding active stem-cells. While active stem-cells are susceptible to various stresses, QC cells are highly stress resistant. We have found that *ORE15* has important role in maintenance of RAM. We will report the underlying mechanisms. Light is one of the most important environmental factors which affect plants growth and development. The critical roles of red light through phytochrome-mediated light signaling has been reported recently. We examined the role of far-red light on leaf senescence and found that leaf senescence is modulated by red (R): far-red (FR) ratio (R/FR). We also found a strong correlation between FR-responsive leaf senescence of various ecotypes and latitudinal cline, suggesting that FR signal is used for latitudinal adaptation of *Arabidopsis* ecotypes. ‘Climatome’ analysis using climate information around ecotypes’ habitat revealed that temperature in winter and spring is strongly associated with FR-responsive leaf senescence. We will report a possible mechanism on how *Arabidopsis* adapted to latitude-dependent environmental changes. We are also comparing the regulatory mechanisms of aging between plants and animals. We will report the differential roles of tRNA fragments in regulating aging in *Arabidopsis*, *C. elegans* (worms), and mouse.

Elicitation of *Andrographis paniculata* (Burm. f.) Nees suspension culture for andrographolide and its derivatives production

Khoa Van Nguyen[1,2], *Benyakan Pongkitwitoon*[1], *Thanika Pathomwichaiwat*[1], *Sompop Prathanturarug*[1]

1. Department of Pharmaceutical Botany, Faculty of Pharmacy, Mahidol University, 447 Sri-Ayuthaya Road, Rajathevi, Bangkok
2. Department of Plant Science, Faculty of Science, Mahidol University, Rama VI Road, Rajathevi, Bangkok

Since *in vitro* plant cell culture is a platform for secondary metabolites production which can be enhanced by various elicitors. This biotechnology would offer sustainable and economically feasible alternative to propagated plants. In this present investigation, we aimed to establish callus and cell suspension cultures of *Andrographis paniculata* and elicit the cultures for andrographolide and its derivatives (e.g. neoandrographolide, 14-deoxy 11,14-didehydroandrographolide) production and analyze their secondary metabolites by HPLC. The first part of study was to induce callus and cell suspension culture from *A. paniculata* explants. Leaf, stem and root parts of *in vitro Andrographis paniculata* seedlings were used for callus induction. They were cultured on MS media supplemented with 6-benzylaminopurine (BA, 0.5 mg/L) and α-napthaleneacetic acid (NAA, 0.0 – 4.0 mg/L). The optimum combinations for callus induction from three different explant types were 0.5 mg/L BA and 4.0 mg/L NAA. Browning was observed, but could be reduced when NAA concentration increased. Leaf-derived callus was green, hard, and compact; callus derived from stem was greenish yellow, hard, and compact; whereas root-derived callus was soft and friable texture with creamy white color. Therefore, root-derived callus was the most suitable for cell suspension culture initiation. Suspension culture was established using 500 mg fresh weight of root-derived calli. They were grown in liquid MS media supplemented with 0.5 mg/L BA and 4.0 mg/L NAA. The suspension culture reached stationary phase at day 25th - 30th of culture. They were friable with creamy white color. No browning was observed during culture time. Abiotic elicitors were used to elicit *A. paniculata* cell suspension culture for andrographolide and its derivatives production. HPLC chemical analysis of *A. paniculata* cell suspension cultures will be discussed.

2. Federal University, Dutse

Tomatoes are consumed widely throughout the world. The edible part of the fruit is known as the power house of nutrition. Many forms of preserved tomato today are available in the market. They range from dried, paste and some other forms. These are to ensure nonstop supply of the fruit throughout the year and to prevent spoilage. A comparative evaluation of the Proximate, mineral and vitamin analysis conducted on five samples of tomato (Fresh, Mutilated, Paste, Sun dried and Oven dried) show that, the fresh tomato has high percentage composition of moisture and least percentage of ash, protein and carbohydrates than the other tomato samples. The Paste has the high percentage composition of pH, carbohydrate and protein, compared to samples of tomato with significant difference ($p < 0.05$). Phytochemical analysis was conducted and it indicate that lycopene (36.90 ± 0.00), saponin (3.26 ± 0.01), alkaloid (1.28 ± 0.00) and glycoside (4.12 ± 0.02) were significantly higher in sun dried tomato, while the tannin was found to be significantly higher in mutilate tomato. Beta-carotene content of fresh tomato is higher while that of vitamin C is higher in gino tomato paste. Five species of fungi were isolated and identified thus *Aspergillus niger, Rhizopus* spp., *Penicillium* spp., *Fusarium* spp. and *Mucor* spp. Mutilate tomato has the highest percentage occurrence with 36.59% and theTomato paste with the lowest percentage occurrence with 9.76%. This result revealed that Sun dried, Oven dried and paste tomato contain more nutrient than Fresh tomato.

Discovery of small molecules display ethylene activity through compound library screening

Keimei Oh
Akita Prefectural University

Ethylene is a gaseous plant hormone that plays key roles in plant growth and development. By now, great efforts have been made to develop chemicals with ethylene activity and one of the most successful example is ETHEPHON®, a prodrug of ethylene which degrades and subsequently releases ethylene in plant tissues. Because of the gaseous nature of ethylene restricted the extensive usefulness of ethylene, we conducted a triple response assay based chemical library screening for searching such chemicals which are non-gaseous at normal atmosphere but with ethylene activity. Among 9600 compounds, we found N-[(1,3, 5-trimethyl-1H-pyrazol-4-yl) methyl]-N-methyl-2-naphthalenesulfonamide (EH-1) displayed promising biological activity on inducing triple response in Arabidopsis seedlings. To determine the structure-activity relationships of this synthetic series, chemical synthesis of EH-1 and its analogues was carried out. Data obtained from the biological studies of synthesized compounds indicating that 3,4-dichloro-N-methyl-N- (1,3, 5-trimethyl-1H-pyrazol-4-ylmethyl) benzenesulfonamide (compound 8) exhibits the most potent biological activity on induce triple response morphological characteristics in *Arabidopsis* seedlings.

Wood structure as manifestation of climatic niche: A case study

Alexei Oskolski[1,2], *Pavel Alexeev*[2], *Anna Kostikova*[3]
1. University of Johannesburg
2. Komarov Botanical Institute
3. InsideDNA Ltd.

Wood structure of a particular species is rather uniform within its members: only few traits show considerable infra-specific variation influenced by local environmental fluctuations. Accordingly, adaptive or functional significance of many wood traits is linked to parameters of ecological niche of a species rather than to individual responses to local environments. Quantitative parameters of specific niches remain, however, beyond the scope of ecological wood anatomy: most studies are focused on correlations of wood traits with local ecological parameters. Open data sources on biodiversity and climates foster new opportunities for addressing this question. Georeferenced species occurrence records combined together with the corresponding climatic records allow to estimate climatic tolerances of their ecological niches. These data allow to assess correlations between wood structure and specific niche dimensions to reveal ecological patterns of the interspecific wood diversity. We used climatic niche modelling and analysis of wood structure to assess the relationships between interspecific variation of wood traits and climatic parameters within 30 species belonging to the Neotropical clade of *Schefflera* (Araliaceae). The species of this group occur in both rainforests and savanna-like habitats in more seasonal climates, such as the cerrados and campos rupestres. The coordinates of the species occurrences were obtained from the GBIF database. For each occurrence record, we extracted the values of 19 bioclimatic variables from the WorldClim climate layers. We used the wood anatomical data published by Kotina *et al.,* (2013). Relationships between the values of bioclimatic variables and quantitative wood features for each species were analysed by correlation analysis, also by PCA and CCA. Besides, we investigated the correlations between bioclimatic data for collecting localities of the wood samples and their anatomical traits. We found that the lengths of vessel elements, length of libriform fibers, number of bars on scalariform perforation plates and ray height within the species of Neotropical *Schefflera* show significant positive correlations with the precipitation parameters of climatic niches as well as negative correlations with the indicators of annual inequality of temperature and precipitations. Infraspecific variations in vessel diameter depend positively only on precipitation, whereas vessel frequency correlates negatively with temperature and its seasonality. Intervessel pits size, ray width and vulnerability index show positive correlation with seasonality and/or annual range of temperature. Fibre wall thickness correlates negatively with parameters of precipitation and annual inequality of temperature. Mesomorphy index depends negatively of diurnal range of temperature and precipitation seasonality. Similar, but weaker trends in variation of length of vessel elements and libriform fibers, bar number on scalariform perforation plates and intervessel pit size have been revealed in relation to the bioclimatic parameters for collecting localities of the wood samples. Proposed approach allows to distinguish between the effects of temperature, precipitations, and their temporal inequality on the wood structure occurred in the course of diversification of the Neotropical *Schefflera* species. Our results suggest that this methodology can be used for clarification and explanation of ecological patterns in diversity and evolution of secondary xylem. The study was supported by the Russian Foundation of Basic Research (grant 16-04-00725).

Molecular mechanism of Hd1 functional switch in rice photoperiod flowering

Xinhao Ouyang
Xiamen University

The molecular mechanism by which Hd1 reverses its activity in response to day length is largely unknown. Here, we demonstrate that the repression of flowering in LD mediated by Hd1 is dependent on *DAYS TO HEADING 8* (*DTH8*). Loss of function of *DTH8* results in the activation of *Hd3α* by *Hd1*, activate leading to early flowering. We also show that Hd1 directly interacts with DTH8 and the DTH8-Hd1 module is necessary for the inhibitory activity of Hd1 in LD. Further, we reveal that DTH8 associted with *Hd3a* promoter to modulate trimethylated H3K27 levels. our results showed the H3K27me3 levels are increased by the presence of the DTH8-Hd1 module in *Hd3a*. However, Hd1 attenuated the H3K27me3 levels in *Hd3a*, when DTH8 was absent. Therefore our data demonstrate that Hd1 represses flowering in LD by constituting the DTH8-Hd1 module which enhances the H3K27me3 levels within the *Hd3a* and in turn negatively regulates *Hd3a* expression. In contrast, Hd1 promotes flowering in LD through reduction of the H3K27me3 levels within the *Hd3a* and in turn positively regulates *Hd3a* expression, when DTH8 is absent in LD.

Cambial variants in Malpighiaceae: Diversity, evolution and their impact on diversification rates in the family

Marcelo Pace[1,2], *Pedro Acevedo*[1], *Veronica Angyalossy*[2]
1. Department of Botany, National Museum of Natural History, Smithsonian Institution
2. Departamento de Botanica, Instituto de Biociências, Universidade de São Paulo

Although Malpighiaceae contains numerous genera and species with cambial variants, the nature and diversity of these structures are still not well understood. Their ontogeny, common developmental stages, and their significance on the evolution and diversification of the family are among the many questions that remain to be answered. Working toward this end, we have sampled 99 species in 42 genera of Malpighiaceae where we are applying standard anatomical procedures to classify these structures according to their ontogenetic pathways and to map their distribution upon a well-supported phylogeny for the family using a maximum likelihood approach. Our preliminary results support the recognition of 8 different types of secondary growth as follows: 1) regular, 2) interxylary phloem, 3) interxylary cambia, 4) phloem wedges furrowing the xylem, 5) fissured stem without inner xylem partition, 6) fissured stem with inner xylem partition, 7) fissured stem without complete inner xylem partition, and 8) asymmetrical stems. Interxylary phloem is exclusive of *Dicella* and involves the periodical formation of phloem by the cambium toward the inside and outside, ultimately generating phloem islands embedded in secondary xylem; interxylary cambia result from the differentiation of new cambia deriving from non-lignified xylematic axial parenchyma, a novel, undescribed type of cambial variant; phloem wedges are very common and appear in several genera, including all species with fissured stems, and are derived from cambial portions that have differential production of phloem-and xylem. Fissured stems, which can develop in 3 different ways, are formed by the combination of phloem wedges and non-lignified xylematic axial parenchyma in bands that merge, either by the formation of new cambia and/or by intense proliferation of axial parenchyma. In *Alicia* and *Callaeum* it involved the complete partition of the inner xylem due to the proliferation of disruptive parenchyma from the pith, xylem, phloem, pericycle and cortex. In other genera, a partition may be partial or inexistent. From ancestors with regular secondary growth, these seven cambial variants evolved independently at least 8 times within Malpighiaceae and are conserved within genera or sometimes between sister genera. This study also shows how different ontogenies may result in almost identical mature anatomies and their importance in characterizing clades previously solely circumscribed by molecular sequence data. Our study shows wood anatomical characters to be conservative and essential in recognizing ancient phyletic relationships.

Environmental control of *de novo* root regeneration in *Arabidopsis*

Jing Pan, Jie Yu, ***Lin Xu***
Institute of Plant Physiology and Ecology, Shanghai Institutes for Biological Sciences, CAS

Plants have the ability to regenerate a new plant from many organs after detachment or wounding via *de novo* organogenesis. Adventitious roots formation can be induced by appropriate types and concentrations of plant hormones in the medium, but endogenous hormones contributes more to this progression in natural conditions. By culturing *Arabidopsis thaliana* leaf explants on medium without additive hormones, we imitate natural conditions for adventitious root formation, and find that the regeneration ability of the leaf explants depends on the developmental stage of the leaf. Our results showed that different nutrients can have obvious influences on adventitious root formation, and so does light condition. Our method could provide a simple procedure to investigate the regeneration of adventitious roots, and these results suggest that leaf developmental stage, together with sugar and plant hormones, should have complex and composite effects on adventitious root formation.

Mirroring establishment: molecular mechanisms governing zygomorphic flower development in *Sinningia*

***Zhao-Jun Pan**, Hao-Chun Hsu, Jen-Chih Chen, Chun-Neng Wang*
National Taiwan University

Multiple evolutionary transitions of symmetry in zygomorphic flowers contribute to the flowering plant diversification. This syndrome shift is hypothesized to associate with the co-evolutionary relationships between bilateral symmetry flowers and theirs pollinators. Most Gesneriaceae species possess zygomorphic flowers with dorsal-ventral asymmetric petals and stamens. In this study, we analyzed and compared the global gene expression profiles among dorsiventral petals of zygomorphic flowers and dorsal petals of actinomorphic flowers in *Sinningia* by RNA-seq. A total of 399 genes showed as differentially expressed genes (DEGs) from the dorsiventral petals of zygomorphic flower transcriptomes. Based on extensive data analysis, 151 genes were assigned to hormone or hormone-related genes and 57 transcripts were predicted as transcription factors (TFs). Of which, the *CYCLOIDEAE* (*CYC*)-clade class II *TCP* gene, *SsCYC*, was identified as a dorsal petal-specific gene, while a class I *TCP* gene showed ventral petal expression. In addition, other predicted TF genes belong to families of *B3*, *MYB*-related, *TIFY*, *TCP*, *ARF* and *ERF*. The dorsiventrally asymmetric transcripts of these newly identified candidates and the well-known floral symmetry genes were validated their spatial-temporal co-expression patterns. Sequence analysis revealed one or more predicted TCP binding sites within the promoter regions of candidate genes. This provided the first insight into the genetic regulation governing *Sinningia* flower symmetry and implied *SsCYC* and other DEGs may control distinct developmental pathways in dorsiventral petals.

Regulation of ethylene-responsive SlWRKYs in the color change during tomato fruit ripening

*Ling Wang[2], Yanan Tian[1], Xuelian Zhang[1], Zhaoqi Zhang[2], **Xuequn Pang**[1]*
1. College of Life Science, South China Agricultural University
2. college of Horticulture, South China Agricultural University

WRKY transcription factors are specifically and widely present *in planta*. They have been found playing important roles in plant responses to biotic and abiotic stresses as well as developmental regulation. Tomato is a typical climacteric fruit, where rapid respiration and ethylene production, chlorophyll degradation and lycopene accumulation occur during fruit ripening process. To study the role of *SlWRKY* family transcription factors in regulation of fruit ripening, tomato fruit ripening was manipulated by treatment with ethylene and 1-MCP, an ethylene receptor inhibitor. Based on the similarities to 24 ethylene responsive *WRKY* genes from *Arabidopsis*, rice, *Gossypium hirsutum* and *Brassica napus*, 23 *SlWRKY* genes were selected from the whole tomato *SlWRKY* gene family that includes 81 members. The expression profiling of these *SlWRKYs* was analyzed in the ripening system along with 8 fruit ripening related genes, including 5 color change related genes. Eight *SlWRKYs* genes displayed over-lapping up-regulation expression patterns as the ripening related genes and were detected to localize in nucleus, and showed potential transcriptional activation in yeasts. Yeast One-Hybrid and *in vivo* regulation assays in tobacco leaves showed that SlWRKY16, 17, 22, 25, 31, 33, 53, 54 were found to bind and activate the promoters of the color change related genes, *SlPPH* (*PHEOPHYTINASE*)*, SlPAO* (*PHEOPHORBIDE A OXYGENASE*)*, SlPSY1* (*PHYTOENE SYNTHASE1*) *and SlPDS* (*PHYTOENE DESATURASE*). Furthermore, yeast two-hybrid assay indicated that obvious interaction may occur between WRKY16, 17, 33, 53, 54 and with other ripening regulators including, SlRIN, SlERF2b and SlERF7. Our study provides for the first time direct evidence that the WRKY transcription factors may function in fruit ripening, particularly in color change, and may connect to the intricate regulatory network with other ripening key regulators.

Microsporogenesis and pollen formation in *Zingiber officinale* Roscoe

Shaik Sha Valli Khan Patan
Yogi Vemana University

The present study provides the first description on microsporogenesis and pollen formation in *Zingiber. Officinale* Roscoe (family Zingiberaceae). This species is one of the most important vegetable condiment with proven antioxidant activity. Ginger widely cultivated in the tropics and sub-tropics, in India particularly in North-east. This species produce very rarely seeds and it is very difficult to breed new genotypes of this species through sexual hybridization. Classical cytological squash technique, and staining protocols with acetocarmin, FDA, DAPI were employed for the study of microspore development as well as assessment of embryogenic window and microspore viability. The study revealed that the general pattern of microsporogenesis and pollen formation in this species starting from PMCs to binucleate mature pollen grain. The microspore development was divided into four basic stages viz. (1) pre-meiotic, (2) the tetrad stage, (3) free microspores and (4) the mature pollen grains. This information enriches the database of cytology, pollen viability estimations and can be useful for breeding program hybridization, also contributes with basic information that will hopefully allow the development of doubled haploid protocol for production of androgenic haploids to accelerate breeding and genetic improvement of ginger. Further research is continuing on evaluating several media and other cultural factors influencing microspore embryogenesis and plant regeneration in this valuable species.

Role of the outer stomatal ledges in the mechanics of guard cell movements

Anatoly Pautov[1], *Svetlana Bauer*[1], *Olga Ivanova*[1], *Elena Krylova*[1], *Yulia Sapach*[1], *Galina Gussarova*[2,1]

1. Saint Petersburg University

2. University of Oslo

Methods of light, scanning and transmission electron microscopy were used to study stomata of the leaf epidermis in evergreen *Carissa spectabilis* (Sond.) Pichon (Apocynaceae), *Acokanthera oblongifolia* (Hochst.) Codd (Apocynaceae), *A. oppositifolia* (Lam.) Codd (Apocynaceae), *Exbucklandia populnea* (R.Br. ex Griff.) R.W. Brown (Hamamelidaceae), *Trochodendron aralioides* Sieb. et Zucc. (Trochodendraceae). The stomata are located on subsidiary cells, have large outer ledges, and lack inner ledges. To elucidate the role of the ledges, we applied dynamic modelling using the finite-element method. In modelling, we took into account the shape of the guard cells, uneven thickness of their walls, positioning and size of the outer ledges. Obtained geometric data were used as parameters for the construction of the finite-element models. The turgor pressure was simulated by creating the load distributed on the inner surface of the guard cells. To estimate the effect of the outer ledges of the guard cells on stomatal mechanics, the following models were constructed: Model 1. The guard cells with the walls of uneven thickness without the outer ledges; Model 2. The guard cells with the walls of uneven thickness and the outer ledges. For stomata having no ledges, the modelling has demonstrated that the turgid guard cells, located on subsidiary cells, are bended above the leaf surface. The opening stomatal pore also moves above the leaf surface. The outer ledges prevent wide opening of the stomatal pore and its lifting above leaf epidermis. The more the stiffness of the ledges, the less the movements of the pore. The results of the modelling are supported by the observed deformations in the guard cells of the real stomata. The modern concepts of the stomatal mechanics do not consider the presence of the ledges on the guard cells (Aylor *et al.,* 1973; Cooke *et al.,* 1976, 2008; Sharpe *et al.,* 1987; Sitte *et al.,* 2008). In contrast, our modelling results showed decisive influence of the outer ledges on the guard cell movements. The discovered mechanics takes place in stomatal complexes with guard cells lying on subsidiary cells. We found such stomatal mechanics in the families, which according to APG III system (Bremer *et al.,* 2009), belong to several taxonomic groups occupying different positions in the flowering plant system. This means that discovered by us stomatal mechanics either has an ancient origin or has arisen in evolution repeatedly and independently in several taxa. All studied species show similar leaf anatomy. It has much in common with the leaf anatomy of species connected in their origin with subhumid Tertiary laurophyllous forests.

RTFL peptide family: How it regulates the morphogenesis in land plants

Pin Guo[1], *Tomoyuki Furuya*[1], *Takayuki Kohchi*[2], *Tomoko Abe*[3], *Hirokazu Tsukaya*[1,4]

1. Department of Biological Sciences, Graduate School of Science, The University of Tokyo

2. Graduate School of Biostudies, Kyoto University

3. RIKEN Nishina Center

4. Bio-Next Project, Okazaki Institute for Integrative Bioscience, National Institutes of Natural Scie

The land plant-specific RTFL family encodes small peptides functioning in the regulation of positional cues and polarized cell proliferation of multiple developmental processes in *Arabidopsis thaliana*. Up to now, our understanding of above biological function of *RTFL* family is mainly based on the pleiotropic phenotypes of the lateral organs among transgenic overexpressors in *A. thaliana*. The loss-of-function lines, however, provide little functional information of *RTFL* family, indicating a high level of its genetic redundancy in *A. thaliana*. In this study, a double *RTFL* overexpressor in *A. thaliana,* which was constructed with two *RTFL* members from *A. thaliana* and *Oryza sativa,* was mutated by heavy-ion beam irradiation. Up to now, two suppressors were obtained after screening of 18,680 M_2 populations. Meanwhile, we also used *Marchantia polymorpha* to study the function of *RTFL* family, regarding for the non-redundancy of *RTFL* (*MpRTFL*) in its genome and its important evolutionary position in land plants. We checked the transcriptional patterns of *MpRTFL* in the haploid generation of *M. polymorpha*. In the young gemmae and thallus, *MpRTFL* expression was found in apical notch areas and the epidermis. After the far red-light induction of reproductive organs, *MpRTFL* expression was found in archegoniophores and antheridiophores. The overexpression lines of *MpRTFL* driven by the promoter of *ELONGATION FACTOR-1* alpha showed discernible phenotypes compared with *MpRTFL*-knockout lines which were made by CRISPR-Cas9 in *M. polymorpha*.

Histochemical screening of terpenoid in secretory structures of *Pogostemon* (Lamiaceae)

Kanjana Pramali[1,2,3], *Bhanubong Bongcheewin* [2], *Paweena Traiperm*[1]

1. Department of Plant Science, Faculty of Science, Mahidol University

2. Department of Pharmaceutical Botany Faculty of Pharmacy, Mahidol University

3. Master of Science Program in Plant Science

Plants in the genus *Pogostemon* Desf. are the important source of commercial patchouli oil and perfume industry, especially *P. cablin* (Blanco.) Benth. The patchouli oil is mainly composed of sesquiterpenes, one type of terpenoids. Leaves are the main material for essential oil extraction since they possess various secretory structures involving in the accumulation of essential oil such as glandular trichome, internal gland and oil body. Therefore, leaves of twelve *Pogostemon* spp. i.e. *P. auricularius* (L.) Hassk., *P. cablin* (Blanco.) Benth., *P. glaber* Benth., *P. globulosus* Phuong ex S. Suddee & A.J. Paton, *P. helferi* (Hook.f.) Press, *P. hispidus* (Benth.) Prain, *P. menthoides* W.W. Smith, *P. myosuroides* W.W. Smith, *P. nudus* Bongcheewin & Pramali, *P. parviflorus* Benth., *P. trinervis* Chemsri. ex Press, and *Pogostemon* sp. were investigated by histochemical methods using NADI reaction in order to preliminarily screen for the presence of terpenoids. From this study, capitate glandular trichomes of the most of *Pogostemon* species, except *P. helferi* and *P. myosuroides,* showed positive results to NADI reaction, indicating that capitate glandular trichomes are the main site for storing the patchouli oil. Moreover, peltate glandular trichomes of five species such as *P. auricularius*, *P. helferi*, *P. menthoides*, *P. myosuroides*, and *P. trinervis* are also positive to NADI reaction revealing the presence of terpenoids in these structures. Furthermore, internal glands of *P. trinervis* and oil bodies of three species i.e. *P. auricularius, P. menthoides* and *P. trinervis*, present positive results with NADI reaction. Since, terpenoids have been known as the secondary metabolite in protecting plant from herbivores, the accumulation sites of terpenoids in *Pogostemon* from this study are allocated in both external and internal parts of leaves. Therefore, terpenoids inside those structures may be the first step of mechanisms in preventing plants from herbivores through irritated scent of terpenoids. In addition, it may also an indirect method of protection for the plants by affecting the alimentary system of herbivores.

Physiological and biochemical response of wheat (*Triticum aestivum* L.) genotypes to water stress environments

Abdul Qayyum[1], *Yamin Bibi*[2], *Ahmad Sher*[3], *Ayaz Mehmood*[1]
1. UNIVERSITY OF HARIPUR
2. Pir Mehr Ali Shah, Arid Agriculture University Rawalpindi
3. Bahauddin Zakariya University, Bahadur Campus Layyah

Water stress is a major threat to production of agricultural crops including wheat world-wide in arid and semi-arid regions. Lab and greenhouse experiments were conducted to evaluate wheat genotypes (GA-2002 and Chakwal-50) for water stress tolerance. Under laboratory condition modified MS medium solution supplemented with polyethylene glycol (PEG-6000) to induce osmotic stress of various concentrations (-2, -4, -6 and -8 bars) was used and data was recorded on germination indices, biochemical parameters and enzymes assay. The results revealed significant ($p<0.05$) differences among both genotypes for various traits under osmotic stress levels. Speed of germination, shoot, root and coleoptile length, root-shoot fresh and dry weight decreased with the increase in osmotic stress. Root-shoot dry weight susceptibility index, membrane stability index and relative water content decreased with the increase in osmotic stress. Free proline, total soluble sugar, total soluble protein, superoxide dismutase, catalase, peroxidase, malondialdehyde activity increased with the increase in osmotic stress. In greenhouse experiment various levels (80,60,40 and 20% field capacity) of water stress were created by gravimetric method and data was recorded for gas exchange measurements and yield attributes. The results revealed significant ($p<0.05$) differences among both wheat genotypes for various traits under different levels of field capacity. Photosynthesis, transpiration, stomatal conductance, leaf osmotic and water potential, number of grains spike^{-1},1, 000 grain weight and grain yield plant^{-1} decreased significantly with the increase in water stress however epicuticular wax content increased. Overall Genotype Chakwal-50 performed better as compared to GA-2002 under water stress conditions.

Dual-source nuclear monomers of UV-B light receptor direct photomorphogenesis in *Arabidopsis*

Chongzhen Qian[1], *Weiwei Mao*[1], *Yan Liu*[1], *Hui Ren*[1], *On Sun Lau*[2], *Xinhao Ouyang*[1], *Xi Huang*[1]
1. State Key Laboratory of Cellular Stress Biology, School of Life Sciences, Xiamen University
2. Department of Biological Sciences, National University of Singapore

Ultraviolet (UV)-B light of long wavelength and low fluence directs photomorphogenic development and UV-B acclimation in *Arabidopsis*. UV RESISTANCE LOCUS 8 (UVR8), a plant-specific chromoprotein, is responsible for UV-B light perception. Upon the exposure to UV-B light, homodimeric UVR8 performs rapid monomerization and associates with CONSTITUTIVELY PHOTOMORPHOGENIC 1 (COP1) to mediate light signaling cascades in the photomorphogenic developmental process. UVR8 localizes in both the cytoplasm and the nucleus, and UV-B illumination stimulates its nuclear accumulation. However, limited information is available with regard to light regulation of UVR8 in terms of its subcellular localization and physiological significance. Here we explore the functional relevance among the subcellular distribution of UVR8, its photobiological activity and UV-B signal transduction. We provide a biochemical presentation of UVR8 localization in combination with cell biology analysis, and dissect physiological roles of subcellular UVR8 proteins using a conditional localization system. We reveal that in the UV-B-induced photomorphogenesis, light signal transduction is essentially mediated by nuclear UVR8 monomers whose accumulation is UV-B-light enhanced and dual-source derived. Two types of UVR8-interacting proteins, COP1 and REPRESSOR OF UV-B PHOTOMORPHOGENESIS 1 (RUP1)/RUP2, play positive and negative roles respectively in the establishment and maintenance of nuclear UVR8 pool to ultimately control photomorphogenic UV-B signaling output.

Epigenetic variation of *ICE1* mediates CBF cold-response transcription pathway conferring cold-tolerant phenotype polymorphism of a plant

Sheng Qiang, *Hongjie Xie*
Nanjing Agricultural University

Cold stress is a major abiotic factor encountered by plants during their life cycle. Plants often demonstrate phenotypic polymorphisms for cold tolerance, but the innate mechanisms are poorly understood. DNA methylation is considered to be mainly involved in regulation of gene transcription and expression and determination of phenotypic plasticity. However, empirical evidences still lack to establish causal relationship between phenotypic polymorphisms and gene methylation variations. Cold/freezing damage indexes showed that there were all distinct cold/freezing-tolerance differentiations among geographical populations of *Arabidopsis thaliana*, Crofton weed (*Ageratina adenophora*), and weedy rice (*Oryza sativa*). It was found that only the cold response regulator *ICE1* in mainstream of CBF cold-response pathway had significant site variation of methylated cytosines, significantly negative relating to cold tolerance levels. Methylation variations were found in the promoter region, or coding region or both of ICE1 gene, which indicates that regulation of gene expression through DNA methylation is complex. The significant negative relation between the transcription levels of the primary CBF pathway members, except for *CBF2*, and the methylation levels among distinctly geographical populations demonstrated that the *ICE1* demethylation-upregulated transcription level of the CBF pathway caused this adaptive cold/freezing-tolerance evolution consequence. Those discoveries advance our understanding of the roles of DNA methylation in regulation gene expression and it may also suggest that the plasticity of any stress response in plants may be attributed to variations in methylation of a key gene in related pathways.

In vitro regeneration from organogenic callus and assessment of clonal fidelity in *Hemigraphis alternata* (Burm.F.) T. Anderson

Krishna R Nair, *Ashalatha S Nair*
University of Kerala, Thiruvananthapuram, Kerala, India

Hemigraphis alternata commonly known, as red flame ivy plant, belongs to the family Acanthaceae. It is a prostrate herb chiefly grown as an ornamental plant. In folk medicine the plant is used for its wound healing activity. Traditionally, the leaves are consumed to mend gall stones, excessive menstruation and as a contraceptive also it has immense power to pacify vitiated pitta, fresh wound, cuts, ulcers, inflammations and skin complaints. An efficient callus induction and plant regeneration system has been standardized for this potent ethnomedicinal plant. Two explants i.e. nodal and leaf segments were used for callus induction. Murashige and Skoog (MS) medium supplemented with 5.0 µM 2,4- dichlorophenoxy acetic acid (2,4-D) gave the optimum frequency (91%) of callus induction from leaf explant. Nodal segments inoculated on 2,4-D obtained basal compact callus. The results showed that the highest response in terms of percent callus regenerating (86%) and number of shoots (23) per culture was recorded on MS medium supplemented with 5.0 µM N6-benzylaminopurine (BA) and 2.5 µM α naphthalene acetic acid (NAA). The regenerated shoots were transferred to lower BAP concentration resulted in further elongation of shoots and rooting. On BAP supplemented medium, 100% of the shoots produced roots with a mean number of 5.6 roots per shoot. The rooted plantlets obtained were hardened successfully in the green house condition with 100% survival rate. Inter-simple sequence repeats (ISSR) were used to establish the clonal fidelity of regenerated plantlets and the banding profiles from callus derived plants were monomorphic and similar to those of mother plant, thus ascertaining the true-to-type nature of these plants.

Programmed cell death in maternal seed tissues controls grain size in barley

Volodymyr Radchuk[1], *Van Tran Thi Thuy*[1], *Ruslana Radchuk*[1], *Mercedes Diaz-Mendoza*[2], *Joerg Fuchs*[1], *Goetz Hensel*[1], *Manuel Martinez*[2], *Ljudmilla Borisjuk*[1]
1. Leibniz-Institute of Plant Genetics and Crop Plant Research (IPK)
2. Centro de Biotecnologia y Genomica de Plantas, Universidad Politecnica de Madrid, Instituto Nacional de Investigacion y Tecnologia Agraria y Alimentaria

Angiosperm embryo and endosperm are limited in space because they grow inside maternal seed tissues. Besides, maternal seed coat provides protection against environment and delivers nutrients to the developing endosperm and embryo. The elimination of cell layers of maternal seed coat by programmed cell death (PCD) could provide space and nutrition to the filial organs. Using barley seed as a model, we elucidate the role of pericarp-expressed vacuolar processing enzyme 4 (VPE4) in cereals by using an RNAi approach and targeting the enzymatic properties of recombinant protein. The recombinant VPE4 protein exhibited strong legumain and caspase-1 properties *in vitro*. A comparative characterization of transgenic versus wild type seeds includes transcriptional and metabolic profiling, flow cytometry, histology and nuclear magnetic imaging of grains. Pericarp disintegration was delayed in the *VPE4*-repressed grains leading to an increased number of vital cells in maternal tissues. Although the *VPE4* gene and enzymatic activity was decreased in early developing pericarp, the size of endosperm and embryo and accumulation of starch and lipids were reduced in the mature VPE4-repressed grains indicating that PCD in pericarp during early seed development affects later grain filling and grain size. The coordinated decrease of several caspase-like activities following *VPE4* repression indicates that the co-action of caspase-like protease activities is required to execute and/or regulate PCD processes in plants analogous to those that occur in animals. The persistence of pericarp in the *VPE4*-affected grains constrains endosperm and embryo growth and leads to transcriptional reprogramming, perturbations in signalling and adjustments in metabolic architecture. Cell number in endosperm of the *VPE4*-repressed grains was not changed. However endosperm cells were enclosed in smaller volume of tissue. Transgenic endosperm accumulated also less starch. We concluded that predominant role of pericarp PCD is to provide space for endosperm cell expansion. The delayed cell elimination in *VPE4*-repressed pericarp relieves a physical restraint for the growing endosperm, thereby prompting the early cellularization of smaller cells with lower levels of endoploidization and resulting in reduced starch accumulation later in development. Thus, endosperm cell expansion and the final grain filling and seed size are determined by PCD in maternal pericarp. We conclude that VPE4 repression impairs seed filling and size by executing PCD in pericarp and argue for the role of PCD in maternal control of seed size in cereals.

Preliminary study on the relationships between inflorescence architecture and optimal fruit and seed production in *Leucaena leucocephala* (Lam.) de Wit.

Jose I Ramirez Domenech
Interamerican University of PR - Ponce Campus

Implications of inflorescences architecture among mimosoid legumes are significant to predict the optimal fruits and seeds production in populations of plants among different eco-environments. Our research is focused on the relationship between inflorescences, number of fruits and seeds in a population of *Leucaena leucocephala* located in a hypersaline lagoon in Ponce, P.R. Specimens were collected from 5 line transects of 50 meters along the lagoon area. Inflorescences were examined at during early, mid-, and late developmental stages. A total of 65 fruits per plant and 24 seeds per fruit was counted from 20 inflorescences during late developmental stages during one season from August to November. Developmental studies show a pattern of division of labor conducive to optimize seeds and fruit production. Studies on populations of *L. leucocephala* are needed to develop management strategies on the invasive threats of this species in local ecosystems.

Leaf folding in *Bauhinia*

*Rita C.K. Chung, **Lawrence Ramsden***
University of Hong Kong SPACE, Kadoorie Centre

Leaf folding is a characteristic of several species of Bauhinia trees and lianas. The closing of leaves occurs along the central axis with the two halves of the heart shaped leaves folding upwards in contrast to the nyctinasty or sleep movement in many other plants where the leaves commonly fold downwards.This folding response appears to show variation in response to environmental conditions, it can occur at night with low light or also at high illumination in exposed sites at midday. Here we examine the hypotheses that this movement is related to 1) water stress responses, 2) reduction of photostress, or 3) a mechanism to avoid herbivory.
Bauhinia trees (*B. purpurea*) and a liana (*B. glauca*) were tested for leaf folding under various illumination conditions to examine rate of folding movements in response to stimulus. To establish the value of the folded state for the leaf, open and closed leaves were compared for transpiration and photosynthesis rates. In field trials the effect of permanently opening leaves or permannently closing leaves was examined for effect on leaf survival. The degree of herbivory was also compared between the opened and closed leaves. Our results indicate that high light stress rather than water stress is likely to drive leaf folding at midday as there was no appreciable difference in transpiration rates between open and closed leaves. However this cannot easily explain night time closing and it appears that herbivory avoidance is the main potential benefit by reducing the exposed leaf surface area. In this case it is possible that the response only uses a light dependent mechanism and may not need to respond to water stress signals, which will be the subject of further investigation.

Reproductive morphology and development of Thai endemic *Remirema* (Convolvulaceae)

Pantamith Rattanakrajang[1,2, 3], *Paweena Traiperm*[2], *George Staples*[4]
1. Master of Science Program in Plant Science, Faculty of Graduate Studies, Mahidol University, Bangkok
2. Department of Plant Science, Faculty of Science, Mahidol University, Bangkok
3. Department of Pharmaceutical Botany, Faculty of Pharmacy, Mahidol University, Bangkok
4. Herbarium, Royal Botanic Gardens, Kew, Richmond

Remirema Kerr is a monospecific genus in the morning glory family (Convolvulaceae). A single species endemic to Thailand, *R. bracteata* Kerr, is a herbaceous climber characterized by epipetalous scales at the filament insertion on the corolla, a deeply 4-lobed ovary, a gynobasic style insertion, and a unique fruit with 4 free cells, each containing one seed. These diagnostic traits have been used to distinguish *Remirema* from all other genera in the family. In order to understand more about some generic characters, flower-to-fruit development from various stages of the monospecific genus was investigated. Plant samples were collected from the natural habitat in Kanchanaburi province, Thailand. Paraffin method was applied for material sectioning and investigation using light microscopy. The results presented *R. bracteata* morphological features, its inflorescence consists of 2-5 flowers and it is covered with large bracts. Each flower is enclosed with 5-aposepalous with peltate glandular trichomes on the abaxial epidermis of calyx. Corolla is tubular-campanulate with five pointed lobes. The androecium comprises 5-epipetalous stamens. A gynoecium shows apocarpus pistil comprising 4 ovules in 4-lobed ovary which correspond to the previous literatures. Fruits are encircled in accrescent calyx and displayed at most 4 free nutlets. The early developmental stage shows 2 incompletely fused styles and 2 incompletely fused ovaries. In the later stages, the 2 styles are completely fused, forming one simple long style with a biglobose stigma, and 2 deeply bilobed ovaries. In the final fruit stage, the 2 bilobed ovaries appear as 4 distinct locules, each with a single nutlet. These developmental characters are revealed for the first time and might be additional evidence to support the recognition of *Remirema* as a distinct genus.

Sexual dimorphism and the evolution of sex-biased and sex-limited genes in the dioecious tree *Populus balsamifera*

Brian Sanderson[1], *Li Wang*[2], *Peter Tiffin*[3], *Zhiqiang Wu*[2], *Matthew Olson*[1]
1. Texas Tech University
2. Iowa State University
3. University of Minnesota

Animals have been shown to exhibit sexual dimorphism in gene expression in as many as 3/4 of their genes, and male-biased genes generally exhibit elevated rates of molecular evolution. Although ~5-6% angiosperm species are dioecious, little is known sexual dimorphism in gene expression or whether patterns of evolution differ for male- and female-biased genes. *Populus* exhibits clear sexual dimorphism in floral color, but few dimorphisms in non-floral traits. We characterized transcriptomes of two tissues (leaf and flower) of five male and five female individuals of *Populus balsamifera* from Fairbanks, Alaska. Five times as many genes exhibited sex limited expression in male floral tissues (476) than female floral tissues (76), and no genes exhibited sex limited expression in leaves. 11,068 genes were differentially expressed between male and female flowers, and only one gene exhibited significant differential expression between male and female leaves. Functional analyses of these genes revealed 15 enriched gene pathways. Notably, male and female flowers differed in energy-related pathways. Transcripts in photosynthesis and tetrapyrrole synthesis pathways were over-expressed in female flowers, whereas mitochondrial electron transport and TCA/org transformation pathways were over-expressed in male flowers. Surprisingly, the distribution of dN/dS ratios for sex-biased and sex-limited genes did not differ from that of randomly selected genes. Taken together, these results highlight that the expectation that sex-biased genes exhibit elevated rates of molecular evolution may depend on the mating system or biology of the species of interest. Sexual dimorphism in *P. balsamifera* primarily manifests in differences in short- and long-term energy pathways. These genes may have a limited opportunity for sexual selection, given their critical functional roles.

Biosynthesis and function of betalain pigments in the New Zealand native iceplant, *Disphyma australe*

Kathy Schwinn[1], *Gagandeep Jain*[2], *Tanja Karl*[2], *Ella Grierson*[1], *Yanfei Zhou*[1], *Simon Deroles*[1], *Ken Ryan*[2], *Kevin Davies*[1], *Kevin Gould*[2]

1. The New Zealand Institute for Plant & Food Research Limited

2. Victoria University of Wellington

Intriguingly, betalains replace the near ubiquitous anthocyanin pigments within the core Caryophyllales. Betalains (red or yellow) are formed in a pathway unrelated to that of the anthocyanins, having a tyrosine-derived central chromophore. Betalain taxa include species that survive in harsh environments such as sand dunes and salt marshes. The New Zealand native iceplant *Disphyma australe* has coastal sympatric red- and green-leaved morphs. The red morph accumulates red betalains (betacyanins) in response to salt stress, and it was observed to be more abundant than the green morph in areas with higher salinity. The green morph is unable to synthesise betacyanins unless it is fed a biosynthetic precursor. We have found that the betacyanins confer salt tolerance, and we are studying the mechanism behind this. Also, we are studying the biosynthesis of betalains and its regulation in this plant, and determining why the green morph does not produce betalains in vegetative tissue.

2. Royal Botanic Gardens, Kew

Nitrogen (N) and/or phosphorus (P) availability in the environment limits productivity across many ecosystems and agricultural settings. Because N and P frequently restrict plant growth, N fertilizers are used in vast quantities to sustain crop resources. Photosynthesis is demanding in N-usage because of its requirement for the protein Rubisco, which incorporates CO_2 into sugars in the dark reaction of photosynthesis. There is also a significant demand for N in building light harvesting pigment-proteins, which represent another major N-demand of photosynthesis. Growth also requires N, not only in the production of proteins, but also to build nucleic acids, these being amongst the most N and P demanding biomolecules of the cell. Given these competing demands, under nutrient limitation there is a potential trade-off between photosynthesis, growth and reproduction. To investigate this hypothesis, we have studied the impact of N and P availability in dwarf wheat (*Triticum aestivum* L. cv. USU-Apogee). The plants were grown in 16 different fertiliser conditions, comprising four concentrations of phosphate and four concentrations of N. By measuring chlorophyll fluorescence parameters, gas exchange and growth parameters, we investigated the impact of these nutrients on the efficiency of photosynthesis, growth and reproduction. We found that under nutrient limitation, wheat plants have a decreased efficiency of photosynthesis, under N limitation Vcmax is affected, and under P limitation Jmax, NPQ, qP and Fo are affected and, consequently there is a decrease in biomass production and seed production. The interaction between N and P is also essential for cell proliferation, growth and reproduction and we explore why the reasons for this.

Specification of vascular patterning in maize

Olga Sedelnikova, *Jane Langdale*

University of Oxford

Maize is a vital crop for food production and utilises the highly efficient C_4 photosynthetic pathway. The patterning of cell types in maize leaves (Kranz anatomy) is instrumental in allowing this biochemical pathway to function. One characteristic feature of Kranz anatomy is high vascular density, therefore vein initiation is a crucial step during Kranz development. Little is known about the genetic regulation of monocot vascular development, and whilst the ontogeny of early maize foliar development has been well characterised, the genetic factors that lead to Kranz anatomy are currently unknown. *In situ* hybridisation was used to investigate the expression of candidate regulatory transcription factors during the earliest stages of maize foliar development, leading to the identification of genes expressed specifically at the beginning of procambium development. The expression dynamics of these transcription factors suggest regulatory roles during vein development and allow their use as markers of procambium initiation in maize. Identification of Kranz developmental regulators would strongly contribute towards harnessing C_4 photosynthesis for crop improvement of major C_3 crops such as rice, with a predicted increase in photosynthetic efficiency of 50%, improved nitrogen use efficiency and doubled water use efficiency.

Exogenously applied 24-epibrassinolide (EBL) ameliorate detrimental effects of salinity by reducing K^+ efflux via depolarization-activated K^+ channels

Nazila Azhar[1], *Nana Su*[1,2], *Lana Shabala*[1], ***Sergey Shabala***[1]
1. University of Tasmania
2. Nanjing Agricultural University

This study has investigated mechanisms conferring beneficial effects of exogenous application of 24-epibrassinolides (EBL) on plant growth and performance under saline conditions. Barley seedlings treated with 0.25 mg/L EBL showed significant improvements in root hair length, shoot length, shoot fresh weight and relative water content when grown in the presence of 150 mM NaCl in the growth media. In addition, EBL treatment significantly decreased the Na^+ content in both shoots (by ~50%) and roots. Electrophysiological experiments revealed that pretreatment with EBL for 1 and 24 h both suppressed or completely prevented the NaCl-induced K^+ leak in the elongation zone of barley roots, but did not affect root sensitivity to oxidative stress. Further experiments using Arabidopsis loss of function *gork1-1* (lacking functional depolarization-activated outward-rectifying K^+ channels in the root epidermal cells) and *akt1* (lacking inward-rectifying K^+ uptake channel) mutants showed that NaCl-induced K^+ loss in the elongation zone of roots was reduced by EBL pretreatment over 200 fold in wild type Col-0 and *akt1*, but only 10 fold in *gork1-1* mutant. At the same time, EBL treatment shifted H^+ flux towards net efflux. Taken together, this data indicates that exogenous application of EBL effectively improves plant salinity tolerance by prevention of K^+ loss via regulating depolarization-activated K^+ channel.

P1085

Plant ionic relation and whole-plant physiological responses to waterlogging, salinity and their combination in barley

Zhinous Falakboland[1], *Meixue Zhou*[1], *Fanrong Zeng*[2], *Ali Kiani-Pouya*[1], *Lana Shabala*[1], ***Sergey Shabala***[1]
1. University of Tasmania
2. Zhejiang University

Waterlogging and salinity stresses significantly affect crop growth and global food production and are often interrelated, as waterlogging can lead to land salinization by transporting the salts to the surface. While the physiological and molecular mechanisms of plant responses to each of these environmental constraints have been studied in detail, much fewer studies dealt with mechanisms underlying plant tolerance to their combined stress. This gap in knowledge is jeopardizing the success of breeding programs and has to be bridged. In this work, we have studied physiological and agronomical responses of 12 barley varieties contrasting in salinity stress tolerance to waterlogging (WL), salinity (NaCl), and combined (Wl/NaCl) stresses. Stress damage symptoms were much stronger in plants under combined WL/NaCl stress compared to separate stresses. The shoot biomass, chlorophyll content, maximum photochemical efficiency of PSII and shoot K^+ content were significantly reduced under WL/NaCl conditions, while shoot Na^+ content increased. Plants exposed to salinity stress showed less damage indexes compared to WL. Chlorophyll fluorescence Fv/Fm value showed the highest correlation with the plant damage index under WL/NaCl conditions (R = -0.751) compared to other measured physiological traits and was nominated as a good parameter to rank the tolerance of varieties. The average fresh weight was reduced by 73 ± 2, 52 ± 1 and 23 ± 2 percentage of control upon NaCl, WL and combined WL/NaCl treatments, respectively. Generally, the adverse effect of WL/NaCl stress was much stronger in salt-sensitive varieties compared to more tolerant varieties. Na^+ content under control conditions was 97 ± 10 μmol/g, and increased to 1519 ± 123,179 ± 11 and 2733 ± 248 μmol/g under NaCl, WL and combined WL/NaCl stresses, respectively. K^+ content was 1378 ± 66,1260 ± 74,1270 ± 79 and 411 ± 92 μmol/g under control, NaCl, WL and combined WL/NaCl stresses, respectively. Overall, the reported results indicated that K^+ reduction in the plants under combined WL/NaCl stress but not stress-induced Na^+ accumulation in the shoot was most critical feature determining the overall plant performance under combined stress conditions.

Structural and biochemical analyses of pollen and stigma in sunflower

Rashmi Shakya[1], *Satish Chander Bhatla*[2]
1. Miranda House, Department of Botany, University of Delhi, Delhi
2. Department of Botany, University of Delhi, Delhi

Detailed structural and biochemical analyses of pollen and stigma in sunflower (*Helianthus annuus* L.) have been carried out in order to understand the process of initial events of pollen-stigma interaction. The exine pattern is of 'Helianthoid type' which allows easy communication between the pollen surface and the caveae, thus facilitating the exchange of water and physiologically active substances. Sunflower stigma bears extracellular secretions in the basal region of the papillae. The plasmodemic connections between papillae and the transmitting tissue indicate symplastic transport of various metabolites to the papillae and stigma surface. In the tryphine fraction of sunflower pollen grains, unsaturated and saturated free fatty acids make upto 55 and 30% of the total fatty acid content, respectively. The low lipid content in the stigma (2.7% of fresh weight) could be attributed to its semidry nature and absence of apparent stigmatic secretions. Six isoforms of acyl ester hydrolase activity in pollen grains and eight isoforms in the stigma have been detected. Lipase activity has been localized on the pollen coat which might be involved in the degradation of cuticle present on the surface of stigma. The nature of lipases reported in stigma, is yet to be elucidated and it is considerably less on the stigmatic papillae as compared to that in tryphine. These observations indicate the possible interaction of lipase localized on the tryphine zone, with triacylglycerides (TAGs) present on the stigmatic papillae, during pollen-stigma interaction.

Overexpression of receptor-like kinase *ERECTA* improves thermotolerance in rice and tomato

Hui Shen[1,2], *Xiangbin Zhong*[1], *Zuhua He*[1]
1. Institute of Plant Physiology and Ecology, SIBS, CAS
2. Shanghai Chenshan Plant Science Research Center, CAS, Chenshan Botanical Garden

The detrimental effects of global warming on crop productivity threaten to reduce the world's food supply. Although plant responses to changes in temperature have been studied, genetic modification of crops to improve thermotolerance has little success to date. Here we demonstrate that overexpression of the *Arabidopsis thaliana* receptor-like kinase ERECTA (ER) in *Arabidopsis*, rice and tomato confers thermotolerance independent of water loss and that *Arabidopsis er* mutants are hypersensitive to heat. A loss-of-function mutation of a rice *ER* homolog and reduced expression of a tomato *ER* allele decreased thermotolerance of both species. Transgenic tomato and rice lines overexpressing *Arabidopsis ER* showed improved heat tolerance in the greenhouse and in field tests at multiple locations in China during several seasons. Moreover, *ER*-overexpressing transgenic *Arabidopsis*, tomato and rice plants had increased biomass. Our findings could contribute to engineering or breeding thermotolerant crops with no growth penalty.

4. Catalan Institute for Research and Advanced Studies

Flower color is an important characteristic that determines the commercial value of ornamental plants. Orange- to red-colored flowers were difficult to produce by conventional breeding techniques in some floricultural plants, i.e. petunia, cymbidium, and irises. This is due to the deficiency in the formation of pelargonidin-derived anthocyanins, which confers orange to red colors in flowers. One reason for absence of pelargonidin is due to dihydroflavonoid 4-reduactase (DFR) substrate specificity. DFRs of petunia, cymbidium and irises do not catalyze dihydrokaempferol (DHK) to leucopelargonidin, the direct precursor of pelargonidin (Johnson *et al.,* 1999, 2001; Sasaki and Nakayama, 2015). Thus, cloning of *DFR* gene encoding a DHK-specific DFR is crucial to generate pelargonidin via genetic engineering. *Gentiana lutea* L. typically produces yellow corollas, but at the southwestern tip of its distribution range (Iberian Peninsula), the species blossoms with orange flowers. *G. lutea* with orange or yellow flowers are classified as *G. lutea* L. var. *aurantiaca* (hereafter abbreviated to *aurantiaca*) and *G. lutea* L. var. *lutea* (hereafter abbreviated to *lutea*), respectively. We found only *aurantiaca* petals accumulated exclusive pelargonidin glycosides, whereas no any anthocyanins were detected in *lutea* petals (Berman *et al.,* 2016). Pelargonidin glycoside synthesis in *aurantiaca* petals appears to reflect the higher steady state levels of pelargonidin synthesis gene [*CHS* (chalcone synthase), *F3H* (flavonone 3-hydroxylase), *DFR*, *ANS* (anthocyanidin synthase) and *3GT* (anthocyanidin-3-*O*-glucosyltransferase)] transcripts as compared to the *lutea* petals (Berman J *et al.,* 2016). The both *aurantiaca* and *lutea* petals expressed similar levels of *F3'H* (flavonoid 3'-hydroxlase) and *F3'5'H* (flavonoid 3', 5′-hydroxlase) mRNA, encoding enzymes involved in cyanidin and delphinidin biosynthesis, respectively. CHS, CHI (chalcone isomerase) and F3H must be functional in both varieties due to the accumulation of similar levels of flavonols in petals. Comparisons of deduced amino acid sequences encoded by the isolated anthocyanin cDNAs indicated that ANS1 and ANS2 are identical in both *aurantiaca* and *lutea* varieties whereas minor amino acid differences of the deduced DFRs between both varieties were observed. DFR1 copies between *aurantiaca* and *lutea* varieties differ by one amino acid, while DFR2 copies differ by three amino acids. Thus, possible changes in the substrate specificity of DFR enzymes may represent additional mechanisms for producing pelargonidin glycosides in petals of *aurantiaca*. We are investigating whether the *aurantiaca* DFR enzymes are able to preferentially reduce DHK, as well as identifying amino acid (s) in *aurantiaca* DFRs that potentially determines the substrate specificity through the stable transgenic tobacco (*Nicotiana tabacum*) overexpressing of *aurantiaca* DFRs or amino acid mutagenesis-based DFRs. This work was supported by the National Natural Science Foundation of China (31270344) and MICINN, Spain (BIO2014-54441-P; BIO2014-54426-P).

Secretory structures in *Casearia sylvestris* Sw. (Salicaceae): Diversity, mechanisms of secretion and exudate complexity

Valéria Ferreira Fernandes[1,2], *Marcela Thadeo*[3], *Vadnéa Casagrande Dalvi*[4], ***Renata Maria Strozi Alves Meira***[1]
1. Universidade Federal de Viçosa, Departamento de Biologia Vegetal, Programa de Pós-Graduação em Botânica, Viçosa, Minas Gerais
2. Universidade Estadual de Santa Cruz, Departamento de Ciências Biológicas, Programa de Pós-Graduacão em Botânica, Departamento de Ciências Biológicas, Ilhéus, Bahia
3. Universidade Estadual de Maringá, Departamento de Biologia, Maringá, Paraná
4. Instituto Federal de Educação, Ciência e Tecnologia Goiano, Rio Verde, Goiás

Casearia sylvestris Sw. is a shrub or tree, popularly known as "guaçatonga", which is widely used in traditional medicine for treatment of burns, wounds, herpes, snakebite and minor skin injuries. It has been suggested that such medicinal properties occur due to terpenoid and phenolic compounds present in the leaves. Idioblasts, cavities, ducts and colleters have been described in leaves of C. sylvestris, although the mechanisms and compartments involved in the secretory processes of these structures have not been clarified. This study aims to describe the chemical nature of the secretions produced by all secretory structures of C. sylvestris leaves and to identify the compartments and mechanisms of synthesis, storage and release of secretion. Shoot samples were collected and analyzed using standard techniques for both light and electron microscopy (transmission and scanning). Histochemical tests were performed in order to identify the main classes of exudate compounds. The subcellular compartments involved in the secretory process of the idioblasts, cavities, ducts and colleters were identified with all organelles being consistent with the chemical nature of secretion. Tannin secreted by the idioblasts is stored within the vacuole by fusion of vesicles filled with osmiophilic deposits that displaces the cytoplasm and nucleus to the periphery of the cell. As the tannin secretion increases, the vacuole of idioblasts may take on a large volume and the chloroplasts present well-developed membrane system and starch grains. In the colleters, plastids with osmiophilic compounds are related to the production of oil while dictiossomes are associated with syntheses of polysaccharide secretion. The smooth endoplasmic reticulum, periplastidial reticulum and plastids present in the secretory epithelium of the cavities and ducts produce the oleoresin, while dictiossomes are involved with hydrophilic secretion. Ultrastructure variation among the organelles of the four types of secretory structures studied, as well as the chemical complexity of exudates produced by them, revealed particularities and enabled the description of models for the secretory mechanism of each structure. The mechanisms involved in the release of secretion through the cell wall were presented and they brought new insights about our knowledge of the secretion biology. (FAPEMIG, CNPq, CAPES)

Suppression of extracellular invertase inhibitor gene expression improves seed weight in soybean (*Glycine max*)

*Xiaofei Tang[1], **Tao Su**[2,3], Mei Han[3], Hongbin Wei[2], Steffen Greiner[2], Thomas Rausch[2], Lijun Liu[1]*
1. Soybean Research Institute, Academy of Agricultural Sciences
2. Plant Molecular Physiology, Centre for Organismal Studies (COS), Heidelberg University
3. Co-Innovation Center for Sustainable Forestry in Southern China, Nanjing Forestry University

Cell wall invertase (CWI) and vacuolar invertase (VI) play multiple functions in plant growth. As well as depending on transcriptional and post-transcriptional regulation, there is growing evidence that CWI and VI are also subject to post-translational control by small inhibitory proteins. Despite the significance of this, genes encoding inhibitors, their molecular and biochemical properties, and their potential roles in regulating seed production have not been well documented in soybean (*Glycine max*). In this study, two invertase inhibitor isoforms, GmCIF1 and GmC/VIF2, were characterized to possess inhibitory activities in vitro via heterologous expression. Transcript analyses showed that they were predominantly expressed in developing seeds and in response to ABA. In accordance with this, surveys of primary targets showed subcellular localizations to the apoplast in tobacco epidermis after expressing YFPfusion constructs. Investigations using RNAi transgenic plants demonstrated marked elevations of CWI activities and improvements in seed weight in conjunction with higher accumulations of hexoses, starch, and protein in mature seeds. Further co-expression analyses of *GmCIF1* with several putative *CWI* genes corroborated the notion that GmCIF1 modulation of CWI that affects seed weight is mainly contingent on post-translational mechanisms. Overall, the results suggest that post-translational elevation of *CWI* by silencing of *GmCIF1* expression orchestrates the process of seed maturation through fine-tuning sucrose metabolism and sink strength.

Immunogold scanning electron microscopy can reveal the cell wall polysaccharide architecture of xylem elements

***Qiang Sun**[1], Mimo He[1], Yuliang Sun[2], Kevin Juzenas[1]*
1. University of Wisconsin-Stevens Point
2. University of Wisconsin-Madison

Many of the functions that cell wall performs are closely related to its polysaccharide composition and architecture. Currently, immunofluorescence microscopy and immunogold transmission electron microscopy (TEM) are the two main techniques used to detect polysaccharides in cell wall. Despite their important role in localizing cell wall polysaccharides, both have some major limitations including detection of polysaccharides at either low resolution or in highly restricted region. In this study we have developed a novel technique to study cell wall polysaccharide architecture. This technique combines immunocytochemistry with scanning electron microscopy (SEM). It not only makes possible the visualization of polysaccharides across a large wall surface and up to a high resolution but also generates tremendous advantages over the other two methods in studying cell wall polysaccharide architecture. When tested with multiple cell wall monoclonal antibodies (mAbs), the technique was demonstrated to be effective and reliable in localizing multiple groups of hemicellulosic and pectic polysaccharides in the cell walls of five xylem structures: vessel element, fiber, axial parenchyma cell, ray parenchyma cell and tylose. In addition, this technique was demonstrated to be effective in revealing details of the three-dimensional polysaccharide distribution in a cell wall as well as in analyzing polysaccharide compositional and structural modifications of cell walls during cell differentiation and pathogen-host plant interactions *etc*. Therefore, this technique is expected to be valuable in better understanding the polysaccharide composition, architecture and functions of cell wall.

Metabolic regulation during drought acclimation contribute to the acquisition of desiccation tolerance in resurrection plant *Boea hygrometrica*

Run-Ze Sun, *Xiao-Fei Zhang, Xin Deng*
Institute of Botany, the Chinese Academy of Sciences

Drought is a major environmental stress seriously compromises plant development, distribution and productivity. Most higher plants are unable to survive desiccation. Interestingly, however, a unique group of vascular angiosperm plants, referred to as 'resurrection plants' which can tolerate an extreme water deficiency of their vegetative tissues and resume normal physiological and metabolic activities after rehydration. The homoiochlorophyllous resurrection plant *Boea hygrometrica* is able to survive slow drying and possess inducible rapid desiccation after drought acclimation, thus can serve as a model system for understanding the mechanisms of dehydration tolerance acquisition in plants. Previous transcriptome analyses have revealed that transcripts involved in multiple metabolic pathways are favored during dehydration acclimation, yet, the metabolic changes underlying this adaptive process still remain practically unknown. Here, a gas chromatography-mass spectrometry (GC-MS) based global untargeted metabolite profiling analysis was conducted on leaves of *B. hygrometrica* plants that were hydrated (fresh, F), fast-dehydrated (FD), soil-dehydrated (SD), rehydrated after SD (acclimated, A) and fast-dehydrated after acclimation (AD). A total of 138 metabolites, including sugars, organic acids, amino acids, nitrogen compounds, hydrocarbons and other carbohydrates, were characterized from plant materials under different physiological conditions. The metabolite profiles between acclimated (SD, A and AD) and non-acclimated (F, FD) plant samples were well distinguished based on the principal-component and hierarchical cluster analysis, indicating that the drought acclimation response required for dynamic changes in metabolic adjustment. By using partial least-squares discriminant analysis, 26 marker metabolites were identified showing significant differences in abundance between the non-acclimated and acclimated plants. Notably, the content of some metabolites, such as maltose, L-Tryptophan (L-Tyr) and Vitamin E (VE) in acclimated plants was significantly higher than those in non-acclimated plants, suggesting that the accumulation of these compounds might lead to increased drought tolerance. Pathway analysis of transcriptome data revealed that the up-regulated expression of genes encoding starch branching enzyme (SBE) and isoamylase (ISA) required for maltose biosynthesis, 3-deoxy-7-phosphoheptulonate synthase (DHS), 3-phosphoshikimate 1-carboxyvinyltransferase (aroA) and 3-dehydroquinate synthase (aroB) required for L-Try biosynthesis during drought acclimation, as well as homogentisate phytyltransferase 1 (HPT1) and tocopherol cyclase (VTE1) in the VE biosynthetic pathway in both acclimation and rehydration plants was strongly associated with the metabolite differences among samples. Taken together, our observations indicate that the accumulation of important metabolites correlates with the transcriptional activity of biosynthetic related enzyme genes during drought acclimation might contribute to the desiccation tolerance acquisition of *B. hygrometrica*.

FtSAD2 and FtJAZ1 regulate the activity of the FtMYB11 transcription repressor in of the phenylpropanoid pathway in *Fagopyrum tataricum*

Meiliang Zhou[1], *Zhanmin Sun*[1], *Yanmin Wu*[1], *Yixiong Tang*[1], *Maria D. Logachevab*[2], *Ivan Kreft*[3]
1. Chinese Academy of Agricultural Sciences
2. Department of Evolutionary Biochemistry, AN Belozersky Institute of Physico-Chemical Biology, MV Lomonosov Moscow State University
3. Nutrition Institute, Tržaška 40, SI-1000 Ljubljana

Little is known about the molecular mechanism of the R2R3-MYB transcriptional repressors involved in plant phenylpropanoid metabolism. Here, we describe one R2R3-type MYB repressor, FtMYB11 from *Fagopyrum tataricum*. It contains the SID-like motif GGDFNFDL and it is regulated by both the importin protein 'Sensitive to ABA and Drought 2' (SAD2) and a JAZ protein, a repressor from the Jasmonates (JAs) signaling cascade. Yeast two hybrid (Y2H) and Bimolecular Fluorescence Complementation (BiFC) assays demonstrated that FtMYB11 interacts with SAD2 and the JAs-responsive repressor FtJAZ1. Protoplast transactivation assays demonstrated that FtMYB11 with FtSAD2 or FtJAZ1 act synergistically and directly represses its target genes via the MYB-core element AATAGTT. Changing the Asp122 residue to Asn in the SID-like motif results in cytoplasmic localization of FtMYB11 because of loss of interaction with SAD2, while changing the Asp126 residue to Asnresults in the loss of interaction with FtJAZ1. Overexpression of FtMYB11 or FtMYB11D126N in *F. tataricum* hairy roots resulted in reduced accumulation of rutin, while overexpression of FtMYB11D122N hairy roots did not lead to such a change.The resultsindicate that FtMYB11 acts as a regulator via interacting with FtSAD2 or FtJAZ1 to repress the phenylpropanoid biosynthesis, and this repression depends on two conserved Asp residues of its SID-like motif.

Characterization of autophagy pathway and its response to environmental stresses in *Cucumis sativus*

Pawaree Thanapipatpong, Supachai Vuttipongchaikij, ***Anongpat***

Suttangkakul
Kasetsart University

Autophagy is an important catabolic process used for recycling nutrients and eliminating unwanted substances within cells. Since the discovery of the genes responsible for this process in yeast, orthologs of autophagy (*ATG*) genes have been identified and characterized in various organisms, allowing better understanding of the mechanisms and functions of this pathway. In plants, this process is critical for responses to nutrient starvation, as well as biotic and abiotic stresses. *Cucumis sativus* (cucumber) is an important crop and also used as a model system for the Cucurbit family. Rapid environmental changes could have adverse effects on cucumber growth, and genetic improvements to increase tolerance to environmental stresses is important for the sustainability of cucumber production. However, potential effects of autophagy in responding to environmental stresses is not known in cucumber. We, therefore, identified and characterized key *ATG* genes in *C. sativus* as well as assessing the autophagic level in response to biotic and abiotic stresses including pathogen infection, oxidative stress, and nutrient starvation. The homologs of *ATG* genes in the conjugation pathway were identified based on protein sequence similarity to the yeast and *Arabidopsis* ATG proteins. The majority of *C. sativus ATG* genes were identified as gene families similar to what previously found in other plants. In addition, transcript variances were also identified. Quantitative RT-PCR showed that the expression of *ATG* genes and their transcripts variances were changed in response to downy mildew infection, hydrogen peroxide treatment and nitrogen starvation. However, the immunoblot analysis of ATG8, a marker for autophagy levels, did not reflect the changes in transcripts abundance. In summary, we identified autophagy genes in *C. sativus* and found that autophagy process is regulated at various levels, including transcription, mRNA splicing, protein expression and protein degradation, in response to environmental stresses. Understanding how autophagy is regulated in *C. sativus* may help with generating cucumber variety with increase tolerances to environmental stresses.

Developmental features of microspore tetrad and tapetum in male sterile mangosteen (*Garcinia mangostana* L.) compared with male fertile seashore mangosteen (*G. hombroniana* Pierre.)

Pornsawan Sutthinon[1], *Lacey Samuels*[2], *Upatham Meesawat*[1]
1. Prince of Songkla University
2. University of British Columbia

Pollen abortion in mangosteen (*Garcinia mangostana* L.) has been considered to be related with tapetum activity during microgametogenesis. Developmental events at cellular and sub-cellular level of tapetal cells at microspore tetrad stage were therefore needed to investigate by comparing with fertile anther of seashore mangosteen (*G. hombroniana* Pierre.). Ultrastructural features of microspore tetrad and tapetum were observed by transmission electron microscope (TEM), callose wall deposition around microspore tetrad were also obtained by aniline blue staining. The results revealed that tetrad cells of both species were contained remarkable amounts of stacked ER and mitochondria. In *G. mangostana* tapetal cells, mitochondrial breakdown was suggested by the presence of their unusual internal structures. This mitochondrial aberrance presumably indicated an abnormality in tapetum cell, which may initiate pollen abortion leading to an early degeneration of microspore tetrads in male sterility of mangosteen (*G. mangostana*).

Disruption of the *Arabidopsis* defense regulator genes *SAG101*, *EDS1*, and *PAD4* confers enhanced freezing tolerance

Weijuan Tan
Sun Yat-sen University

In *Arabidopsis*, three lipase-like regulators, *SAG101*, *EDS1*, and *PAD4*, act downstream of resistance protein-associated defense signaling. Although the roles of *SAG101*, *EDS1*, and *PAD4* in biotic stress have been extensively studied, little is known about their functions in plant responses to abiotic stresses. Here, we show that *SAG101*, *EDS1*, and *PAD4* are involved in the regulation of freezing tolerance in *Arabidopsis*. With or without cold acclimation, the *sag101*, *eds1*, and *pad4* single mutants, as well as their double mutants, exhibited similarly enhanced tolerance to freezing temperatures. Upon cold exposure, the *sag101*, *eds1*, and *pad4* mutants showed increased transcript levels of C-REPEAT/DRE BINDING FACTORs and their regulons compared with the wild type. Moreover, freezing-induced cell death and accumulation of hydrogen peroxide were ameliorated in *sag101*, *eds1*, and *pad4* mutants. The *sag101*, *eds1*, and *pad4* mutants had much lower salicylic acid (SA) and diacylglycerol (DAG) contents than the wild type, and exogenous application of SA and DAG compromised the freezing tolerance of the mutants. Furthermore, SA suppressed the cold-induced expression of DGATs and DGKs in the wild-type leaves. These findings indicate that *SAG101*, *EDS1*, and *PAD4* are involved in the freezing response in *Arabidopsis*, at least in part, by modulating the homeostasis of SA and DAG.

Aquaporins are involved in the amelioration of hypoxic aspen (*Populus tremuloides*) root hydraulics and *in planta* oxygen by exogenous ethylene

Xiangfeng Tan, *Janusz J. Zwiazek*
University of Alberta

Hypoxia caused by flooding is a great challenge for terrestrial plants. Ethylene plays a profound role in plant responses to flooding, but we still know very little about the effects of ethylene on aquaporin-mediated water transport in hypoxic plants. In the present study, the physiology and gene expression of aquaporins was investigated in aspen (*Populus tremuloides*) seedlings exposed to hypoxia and treated with exogenous ethylene. Roots of hydroponically-grown aspen plants were subjected to aeration, aeration with exogenous ethylene, hypoxia, and hypoxia with exogenous ethylene treatments. Physiological measurements included gas exchange, photosynthetic light responses, and leaf chlorophyll fluorescence measured with an infrred gas analyzer. Root hydraulic conductance was measured with a high-pressure flow meter, and root oxygen concentrations were determined with an oxygen microsensor. Root porosity was estimated by a pycnometer method and mRNA expression profiling was measured by qRT-PCR. Hypoxic seedlings showed lower gas exchange, light-saturated net photosynthetic rate (P_n), effective quantum yield, root hydraulic conductance and root oxygen concentrations. Exogenous ethylene also significantly enhanced P_n and transpiration rates. qPCR results showed that hypoxia had significant effect on *PtPIP1;2*, *PIP2;1*, *PIP2;2* and *PIP2;5* transcript levels and significant effects of exogenous ethylene on *PtPIP2;4* expression was detected by the two-way ANOVA. Root oxygen concentrations also increased with ethylene treatment compared to non-ethylene treated hypoxic plants, and this may partly be due to increased P_n. Our results suggest that exogenous ethylene may enhance root water transport in hypoxic plants through the effect on aquaporin expression. The enhanced root water transport by ethylene is likely responsible for the increase in P_n which, in turn, may have a positive effect on plant aeration.

3. Department of Biochemistry and Molecular Biology, University of Massachusetts, Amherst, Massachusetts 01003, USA

Polar auxin transport, facilitated by the combined activities of auxin influx and efflux carriers to maintain asymmetric auxin distribution, is essential for plant growth and development. Here, we show that *Arabidopsis RopGEF1*, a guanine nucleotide exchange factor and activator of ROPs (Rho GTPases of plants), controls polar distribution of auxin influx carrier AUX1 and differential accumulation of efflux carriers PIN7 and PIN2, and is important for embryo and early seedling development when RopGEF1 is prevalently expressed. Knock-down or knock-out of *RopGEF1* induces embryo defects, cotyledon vein breaks and delayed root gravity responses. Altered expression from the auxin response reporter *DR5rev:GFP* in the root pole of *RopGEF1*-deficient embryos and loss of asymmetric distribution of *DR5rev:GFP* at their gravistimulated root tips suggest that auxin distribution is affected in *ropgef1* mutants. Importantly, the polarity of AUX1 is altered in *ropgef1* embryos and roots, shifting from the normal apical membrane location to a basal location in embryo central vascular and root protophloem cells. *RopGEF1* mutations also reduced PIN7 accumulation at embryos and PIN2 distribution in gravistimulated roots. In establishing a role for RopGEF1 in AUX1 polarity and PIN differential accumulation, our results implicate that RopGEF1 is critical for cell polarity and polar auxin transport could impact auxin-mediated plant growth and development.

Photosystem I (PSI)-light-harvesting complex I (LHCI) super-complex and its sub-complexes PSI core and LHCI, were purified from a unicellular red alga *Cyanidioschyzon merolae* and characterized. PSI-LHCI of *C. merolae* existed as a monomer with a molecular mass of 580 kDa. Mass spectrometry analysis identified 11 core subunits (PsaA, B, C, D, E, F, I, J, K, L, O) in the core complex and three LHCI subunits, CMQ142C, CMN234C and CMN235C in LHCI, indicating that at least three Lhcr subunits associate with the red algal PSI core. PsaG was not found in the red algae PSI-LHCI, and we suggest that the position corresponding to Lhca1 in higher plant PSI-LHCI is empty in the red algal PSI-LHCI. The PSI-LHCI complex was separated into two bands on native PAGE, suggesting that two different complexes may be present with slightly different protein compositions probably with respective to the numbers of Lhcr subunits. Based on the results obtained, a structural model was proposed for the red algal PSI-LHCI. Furthermore, pigment analysis revealed that the *C. merolae* PSI-LHCI contained a large amount of zeaxanthin, which is mainly associated with the LHCI complex whereas little zeaxanthin was found in the PSI core. This indicates a unique feature of the carotenoid composition of the Lhcr proteins and may suggest an important role of Zea in the light-harvesting and photo-protection of the red algal PSI-LHCI complex.

FLOWERING LOCUS T (FT) encodes the mobile flowering hormone florigen that regulates the floral transition in many plant species by integrating environmental seasonal signals and internal cues at the transcriptional level. We have previously shown that two interdependent regulatory regions are necessary and sufficient to convey photoperiod responsiveness to *FT* expression in

Arabidopsis thaliana leaves. We now show that other *cis*-regulatory modules, located in introns and a newly discovered *FT* downstream enhancer, also participate in the regulation of *FT*. Furthermore, we explore the effect of natural variation located at regulatory regions on *FT* expression.

Expression of cyanobacterial bicarbonate transporters in *Arabidopsis* chloroplasts and their effects on the growth and photosynthetic performance

Susumu Uehara[1], *Yasuko Ito-Inaba*[3], *Izumi C Mori*[2], *Takehito Inaba*[1]
1. Fac. Agr., Univ. Miyazaki
2. IPSR, Okayama Univ.
3. TT Org., Univ. Miyazaki

It has been thought that photosynthesis in C_3 plants are inefficient due to photorespiration. In contrast, cyanobacteria have evolved CO_2-concentrating mechanism, including bicarbonate transporters, and are capable of decreasing photorespiration. Hence, installation of cyanobacterial bicarbonate transporters to the inner envelope membrane (IEM) of chloroplasts in C_3 plants has been thought to improve photosynthesis. However, the method to deliver cyanobacterial bicarbonate transporters to the chloroplast IEM remains to be established. In this study, we provide evidence that the cyanobacterial bicarbonate transporters, BicA and SbtA, can be specifically installed into the chloroplast IEM using the chloroplast IEM targeting signal in conjunction with the transit peptide. We fused the transit peptide and the mature portion of Cor413im1 to either BicA or SbtA isolated from *Synechocystis* sp. PCC6803. We confirmed that four chimeric bicarbonate transporters, designated as BicAI, BicAII, SbtAII, and SbtAIII, were expressed in *Arabidopsis*. Furthermore, these chimeric transporters were specifically targeted to the chloroplast IEM. They were also resistant to alkaline extraction but can be solubilized by Triton X-100, indicating that they are integral membrane proteins in the chloroplast IEM. Taken together, our results indicate that the addition of IEM targeting signals, as well as the transit peptide to bicarbonate transporters, allows us to efficiently target nuclear-encoded chimeric bicarbonate transporters to the chloroplast IEM. Moreover, we also report the effects of the expressed bicarbonate transporters on the growth and photosynthetic performance of *Arabidopsis*.

Arabidopsis PROTEIN S-ACYL TRANSFERASE4 mediates root hair growth

Zhi-Yuan Wan, *Sen Chai, Fu-Rong Ge, Qiang-Nan Feng, Yan Zhang, Sha Li*
Shandong Agricultural University

Polar growth of root hairs is critical for plant survival and necessitates fine tuned ROP signaling. Multiple ROP regulators participate in root hair growth. However, protein Sacyl transferases (PATs), mediating the Sacylation and membrane partitioning of ROPs, are yet to be found. By using a reverse genetic approach, combining fluorescence probes, pharmacological drugs, sitedirected mutagenesis, and genetic analysis with related roothair mutants, we have identified and characterized an Arabidopsis PAT, which may be responsible for ROP2 Sacylation in root hairs. Specifically, functional loss of PAT4 resulted in reduced root hair elongation, which was rescued by a wildtype but not an enzymeinactive PAT4. Membrane-associated ROP2 was significantly reduced in *pat4*, similar to that of Sacylation deficient ROP2 in wild type. We further showed that PAT4 and SCN1, a ROP regulator, additively mediate ROP2 stability and targeting. Results presented indicate that PAT4-mediated Sacylation mediates the membrane association of ROP2 at the root hair apex and provide novel insights into the dynamic ROP signaling during plant tip growth.

Maize microtubule-associated protein ZmGLR regulates leaves development by Brassinosteroids

Chenchen Wang, *Hua Zhang, Qian Zhao*
China Agricultural University

Brassinosteroids (BRs) is a major kind of growth-promoting plant hormone, participating in diverse plant growth and development process such as promotion of stem elongation and cell division, increase of tolerance to various stresses. Recent researches have illuminated BR signaling pathway and revealed major mechanisms of BR crosstalk with other signaling pathways. However, the exact executors of BR signaling is unclear. *ZmGLR* (*Zea mays L.* Glutamic acid and Lysine Rich) was isolated from maize which encodes a glutamic acid and lysine rich protein including a DREPP conserved domain. Co-sedimentation assay revealed that the ZmGLR recombinant protein can bind to microtubules *in vivo*. Moreover, the fluorescent co-location and negative staining assay indicated that ZmGLR bundled microtubules. Therefore, we concluded that ZmGLR is a microtubule associated protein from maize. The subcellular localization showed that ZmGLR was associated with the plasma membrane, and 25 amino acid of N-terminal sequence have an important effect on the location. Interestingly, the GFP fluorescence occurred in cytoplasm in condition of high Ca^{2+} concentration. Therefore, Ca^{2+} may have an impact on the subcellular localization of ZmGLR. To investigate the function of ZmGLR, we obtained *ZmGLR* overexpression and RNAi plants. Both *ZmGLR* overexpression and RNAi transgenic maize showed a severe dwarf phenotype and developed severely malformed leaves. *ZmGLR* overexpression maize showed totally curly leaves which even became a cylindet shape, and RNAi maize appeared tortuous and wrinkled blades. Moreover, blade epidermal cells in mutants became short and abnormal, whereas the wild-type cells were a uniform rectangular shape. Stomas in mutants were deformed, and the amount of stomas in overexpression plants have obviously decreased compare with wild-type, while the RNAi plants have increased stomas. Real-time PCR results showed *ZmGLR* expression enhanced by eBL treatment and depressed by IAA treatment. Then, we found the ZmBES1, a key transcription factor in BR signal pathway, can bind the promoter of ZmGLR and increase its activity. These results demonstrate that ZmGLR participates in both BR and auxin pathways as a final executor. BRs promote the correct arrangement of microtubule to ensure cell expansion and elongation by regulate the expression of microtubule-associated protein ZmGLR. However, how auxin regulates ZmGLR need to be investigated.

Functional diversity of ribosomal proteins in plant mitochondria

Chuande Wang, *Martine Quadrado, Céline Dargel-Graffin, Hakim Mireau*
Institut Jean-Pierre Bourgin, INRA

Expression of mitochondrial genes implies a tight cooperation between degenerated prokaryotic-like features and nuclear-encoded eukaryotic-derived factors that appeared throughout the evolution. This dual origin has resulted in complex mRNA expression processes that are still poorly understood at the molecular level. This is particularly true for mitochondrial translation, which has remained largely unexplored notably in higher plants. Yet, we know that the mitochondrial translation machinery differs profoundly from its bacterial counterpart in many essential aspects. To better understand the functioning of the plant mitochondrial machinery, we prepared and analysed mitochondrial ribosome footprints from Arabidopsis inflorescences. This allowed us to determine the extent of the *Arabidopsis* mitochondrial translatome and reveal interesting new features about the dynamic and the functioning of the mitochondrial translation apparatus in plants. In complement to this approach, we classified and analysed nuclear genes encoding potential mitochondria-targeted ribosomal proteins in *Arabidopsis thaliana*. This exhaustive survey led to us to observe that most ribosomal and ribosomal-like proteins are encoded in small gene families comprising up to 10 members. Further analyses suggested that several of such families might not correspond to multigene families *sensus stricto*. To explore the activity and the functional diversification of ribosomal proteins in plants, we selected and analysed in details several of the identified families. The sub-cellular distribution of selected proteins was determined by GFP fusion and Arabidopsis mutants affected in the corresponding genes were characterized at the molecular level. Very interestingly, our results revealed several cases of molecular exaptation and the acquisition of new functions in mitochondrial mRNA expression for certain ribosomal-like proteins. I will present our very last results on these approaches and discuss the evolution of RNA expression systems in higher plant mitochondria.

Phytochrome-interacting factors directly suppress *MIR156* expression to enhance shade avoidance response in *Arabidopsis*

Yurong Xie, Yang Liu, Xiaojing Ma, Baobao Wang, Hai Wang, ***Haiyang Wang***
Biotechnology Research Institute, Chinese Academy of Agricultural Sciences

As sessile organisms, plants have evolved a repertoire of strategies collectively termed the shade avoidance syndrome (SAS) to avoid canopy shade and compete with their neighbors for light. SAS, albeit beneficial for the survival of plants in the natural environment, is detrimental for crops to adapt to their high-density stands in modern agricultural practices. However, the signaling mechanism governing the adaptive changes of adult plant architecture to shade is not well understood, even in the model species *Arabidopsis thaliana*. Here we show that in *Arabidopsis,* several PHYTOCHROME-INTERACTING FACTORS (PIFs) overexpressors (*35S::PIF1-OE*, *35S::PIF3-OE*, *35S::PIF4-OE* and *35S::PIF5-OE*) all display constitutive SAS under normal high R:FR ratio conditions, and are less sensitive to the simulated shade, compared to the wild type plants. In contrast, *MIR156* overexpressors exhibit reduced SAS under normal high R:FR ratio conditions, and are more sensitive to the simulated shade, compared with the wild type. In addition, the simulated shade rapidly induces PIF protein accumulation, accompanied by reduced expression of multiple *MIR156* genes and a concomitant elevated expression of *SQUAMOSA-PROMOTER BINDING PROTEIN-LIKE* (*SPL*) family of transcription factors. Moreover, *in vivo* and *in vitro* assays indicate that these PIF proteins directly bind to the G-box motifs in the promoters of several *MIR156* genes and suppress their expression. Our results provide a direct link between the phytochrome-PIFs and miR156-SPL regulatory modules in mediating SAS during plant vegetative growth and development. Implications of our findings in modulating crop plant architecture for high density planting are discussed.

High-throughput assays for oxidative stress tolerance in cereals

Haiyang Wang, *Sergey Shabala, Lana Shabala, Meixue Zhou*
University of Tasmania

Soil salinity is a global issue and a major factor limiting crop production worldwide. One side effect of salinity stress is an overproduction and accumulation of reactive oxygen species (ROS), causing oxidative stress and leading to severe cellular damage to plants. While the major focus of the salinity-oriented breeding programs in the last decades was on traits conferring Na^+ exclusion, breeding for oxidative stress tolerance has been largely overlooked. The importance lies in its occurrence in almost all the environmental stresses, not only in salinity stress. This calls for the study on exploring the relationship between oxidative stress and abiotic stress and a need for finding a reliable and less time-consuming screening method for fine mapping of related quantitative trait loci (QTL) in cereals. In this work, we developed and compared several high-throughput assays for oxidative stress screening in a representative cereal crop: barley (*Hordeum vulgare*). In root growth assay experiment, we showed that the biggest difference of root elongation rate between salinity tolerant and salinity sensitive cultivars happened when plants were grown in the presence of 1 mM H_2O_2 in the growth media. Under these conditions, a significant negative correlation was found between root elongation rate and the overall salinity tolerance, whereas no difference has been found between cultivars in viability staining experiments on both root elongation zone and mature zone. By applying the MIFE technique for non-invasive ion flux measurements, we also found a significant positive correlation between ions (Ca^{2+} and K^+) fluxes and the overall salinity tolerance under 10 mM H_2O_2 treatment and also a clear difference in the matter of correction red fluorescence intensity (dead cells) in viability staining experiments among cultivars. Reliability of these high-throughput assays for plant breeding for oxidative stress tolerance are discussed.

UDP-glucose: anthocyanidin 3-*O*-glucoside-2”-*O*-glucosyltransferase is involved in further glucosylation of anthocyanins in purple sweet potato

Hongxia Wang, *Weijuan Fan, Peng Zhang*
Institute of plant Physiology and Ecology, SIBS, CAS

Further glycosylation contributes to the diversity and stability of anthocyanins in plants. In purple sweet potato Ayamurasaki, anthocyanin 3-O-sophoroside and its derivatives constitute the major anthocyanin compounds. Here we report a sweet potato UDP-glucose: anthocyanidin 3-O-glucoside-2’’-O-glucosyltransferase (Ib3GGT) that catalyzes the conversion of anthocyanidin 3-O-glucoside into anthocyanidin 3-O-sophoroside using UDP-glucose predominantly as the glycosyl donor. Homology-based protein modeling and site-directed mutagenesis of Ib3GGT suggested that Thr-138 is a key amino acid residue for UDP-glucose recognition and plays an important role in sugar donor selectivity. *Ib3GGT* overexpression in *Arabidopsis* produced the new component cyanidin 3-O-sophoroside without altering the existing anthocyanins, and complemented the purple phenotype in *ugt79b1* mutants. *Ib3GGT* expression was associated with anthocyanin accumulation in different organs during plant development, mainly in immature leaves and storage roots of Ayamurasaki plants; in addition, the novel enzyme was regulated by the IbMYB1 transcription factor. Localization assay of Ib3GGT showed that further glucosylation occurred in both the endoplasmic reticulum and Golgi apparatus. In sweet potato, *Ib3GGT* overexpression resulted in increased anthocyanin accumulation, while its silencing reduced anthocyanin accumulation and affected anthocyanin release from anthocyanic vacuolar inclusions into vacuoles. Overall, Ib3GGT is the key glucosyltransferase responsible for further glycosylation in a UDP-glucose dependent manner, and causes anthocyanin accumulation in purple sweet potato.

Duplicated *TT2-like* MYB genes from *Freesia hybrida* play divergent roles in the biosynthesis of proanthocyanidins

Xiaotong Shan, Yueqing Li, Song Yang, Ruifang Gao, Li Wang,* ***Xiang Gao****
Key Laboratory of Molecular Epigenetics of MOE and Institute of Genetics & Cytology, Northeast Normal University

Flavonoids are one of the largest classes of plant secondary metabolites involved in plant development and defense, which mainly include flavonols, anthocyanins, and proanthocyanidins. In our previous studies, a considerable amount of the three kinds of flavonoids were detected in the flower of “Red River®”, a representative cultivar of a perennial monocotyledonous plant, *Freesia hybrida*, and they showed diverse temporal-spatial accumulation patterns during the development of the flowers and in 5 different flower tissues. Previous studies have focused on the regulation of anthocyanin biosynthesis. However, the transcription regulation mechanisms for other two branches still remain to be elucidated.
In this study, four R2R3-type MYB transcription factors phylogenetically clustered with *AtTT2* were isolated from the flowers of “Red River®”, tentatively designated as *FhTT2L1*, *FhTT2L2*, *FhTT2L3* and *FhTT2L4*. Two groups of expression patterns were observed for the four *TT2-like* MYB regulatory genes aforementioned. *FhTT2L1*, *FhTT2L2*, and *FhTT2L4*, which were clustered together and separated with *FhTT2L3*, showed an identical expression profiles significantly correlated the *FhLAR*, the gene involved in the biosynthesis of catechin-derived proanthocyanidins. In contrast, the expression of *FhTT2L3* was found to be synchronous to *FhANR*, which is responsible for epicatechin-derived proanthocynidins biosynthesis. Therefore, it is reasonable to deduce that the duplicated *TT2-like* genes in *Freesia* might function divergently to control the biosynthesis of the two categories proanthocyanidins. However, it is not always clear whether the functions of *FhTT2L1*, *FhTT2L2*, and *FhTT2L4* are partially or completely redundant because of their differential expression levels. In accordance with TT2-like proteins from model plant as well as other extensively studied plant species, FhTT2Ls could interact with bHLH proteins participating in the MBW complex (mainly comprising of AtTT2, AtTT8 and AtTTG1 in *Arabidopsis*) and they were capable to activate the expression of late anthocyanin biosynthetic genes (LBGs) as well as proanthocyanidin related *AtBAN* gene when co-transfected with *AtTT8* and *AtTTG1* in *Arabidopsis* leaf protoplasts. Unexpectedly, FhTT2Ls could also activate the expression of *AtCHS* gene when transiently expressed alone, whereas AtTT2 could not, indicating a plausible divergent transactivation capacity of TT2-like regulators between the *Freesia* and *Arabidopsis*. Furthermore, the four *FhTT2L* genes were successfully ectopically expressed in tobacco plants, hyper-accumulation of proanthocyanidins was observed in individual transgenic lines, which was consistent with the up-regulation of the expressions of *NtDFR*, *NtANS*, *NtLAR*, *NtANR* genes. In conclusion, it can be speculated that the duplicated *TT2-like* MYB genes might play divergent roles in the biosynthesis of proanthocyanidins in *Freesia hybrida*, and their transcription regulation manners might also evolve differentially compared with *Arabidopsis*. After the confirmation of target genes and existence of MBW complexes in *Freesia*, the conclusion will be further strengthened. To our knowledge, this is the first reports of the *TT2-like* genes isolated from flowers of *Freesia* and even in Liliales plants, the finds will not only provide new insights into the transcriptional regulation of proanthocyanidin biosynthesis in monocot plants, they will also pave the way to dissect the crosstalk networks controlling multiple flavonoids biosynthesis which are simultaneously accumulated in the same plant organs with diverse patterns.

The SMC5/6 complex couples cell cycles checkpoint and DNA repair to maintain genome stability and stem cell identify

Lili Wang, *Shunping Yan*
College of Life Science and Technology, Huazhong Agricultural University

Stem cells are hypersensitive to DNA damage. In response to DNA damage, cells activate checkpoints to arrest cell cycle progression and provide sufficient time to repair DNA. Previous studies have identified different sets of checkpoint and repair proteins. How cells coordinate these two processes is not well-understood. The evolutionarily conserved SMC5/6 complex is believed to play multiple essential roles in DNA repair. Here we show that the SMC5/6 complex also regulates G1/S checkpoints by repressing E2F transcription factors. Mutation in *SNI1*, a subunit of the SMC5/6 complex, results in defective G1/S transition and eventually causes disorganized root meristem and short-root phenotypes, mimicking *E2F* overexpression. Consistently, mutations in *E2F*s suppresses the *sni1* mutant and overexpression of *SNI1* suppresses *E2F* overexpression plants. Remarkably, SNI1 directly binds the activation domain of E2Fs and represses their transcriptional activity. Our study demonstrates that the SMC5/6 complex is the key link to couple checkpoint and DNA repair to maintain genome stability and stem cell identity.

CYP86A1, a key enzyme in suberin biosynthesis, is pivotal for salt tolerance in *Arabidopsis*

Pei Wang, *Li Gao, Haili Yang, Qing Ma, Yannong Cui, Suomin Wang*

State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University

Soil salinity is one of the major environmental stresses restricting agricultural production, higher plant developed several protective strategies to adapt to salt stress, including forming apoplastic barriers to limit Na^+ radial transport in roots. Suberin, a macromolecular heteropolymer combined by lipid and phenolic compounds deposited on the cell wall of root endodermis and periderm, is an important component of apoplastic barriers in roots, prevents the free apoplastic diffusion of ions and water, however, it is still undefined how suberin functions in responding to salt stress. Cytochrome P450 ω-hydroxylase encoded by *CYP86A1* (*HORST*) catalyzes mid-chain fatty acid to create ω-hydroxy acid and α, ω-diacid, which are the most major monomers of suberin. In this study, the functional mechanisms of suberin in plant adaptation to salt stress were investigated by using *Arabidopsis cyp86a1* mutant. Results showed that moderate NaCl induced suberization and the expression of *CYP86A1* gene in *Arabidopsis* roots. c*yp86a1* mutant displayed a salt-hypersensitive phenotype in the adult stage, including growth inhibition and disordered leaf membrane system under salt stress compared with wild-type (WT) plant. The level of suberization declined in *cyp86a1* mutants through FY088 tracing. GC-MS analysis also showed suberin monomer contents decreased sharply in *cyp86a1* mutants than WT under normal condition, and NaCl increased suberin content in WT while did not change in *cyp86a1*. Loss function of CYP86A1 resulted in more Na^+ accumulation in shoots via trans-cellular pathway transport, accompanied by shoots K^+ content decreased. In addition, mutation of *CYP86A1* led to an increase in root hydraulic conductivity and photosynthetic capacity of rosette leaves under normal condition, while showed an opposite trend under 30 mM NaCl. c*yp86a1* had a lower water use efficiency than WT with or without NaCl. Furthermore, transcript profiling showed that genes involved in cell wall metabolism, phytohormones, nutrient uptake, lipid metabolism and cellular signaling network were inhibited in *cyp86a1,* compared with WT. Taken together, our results indicate that suberin affects Na^+ accumulation, root water permeability and leaf photosynthetic capacity under salt stress by altering its own monomer content, meanwhile, functions in growth and metabolic regulation, thereby changes the salt tolerance of *Arabidopsis*.

C_4 photosynthesis in C_3 rice: A theoretical analysis of biochemical and anatomical factors

Shuyue Wang[1], *Danny Tholen*[2], *Xinguang Zhu*[1]

1. CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences

2. Institute of Botany, Department of Integrative Biology, University of Natural Resources and Applied Life Sciences, BOKU Vienna

Engineering C_4 photosynthesis into rice has been considered a promising strategy to increase photosynthesis and yield. A question that remains to be answered is whether expressing a C_4 metabolic cycle into a C_3 leaf structure and without removing the C_3 background metabolism improves photosynthetic efficiency. To explore this question, we developed a 3D reaction diffusion model of bundle-sheath and connected mesophyll cells in a C_3 rice leaf. Our results show that integrating a C_4 metabolic pathway into rice leaves with a C_3 metabolism and mesophyll structure may lead to an improved photosynthesis under current ambient CO_2 concentration. We analysed a number of physiological factors that influence the CO_2 uptake rate, which include the chloroplast surface area exposed to intercellular air space, bundle-sheath cell wall thickness, bundle-sheath chloroplast envelope permeability, Rubisco concentration and the energy partitioning between C_3 and C_4 cycles. Among these, partitioning of energy between C_3 and C_4 photosynthesis and the partitioning of Rubisco between mesophyll and bundle-sheath cells are decisive factors controlling photosynthetic efficiency in an engineered C_3-C_4 leaf. The implications of the results for the sequence of C_4 evolution are also discussed.

Effects of short-term osmotic stress on leaf hydraulic conductivity and plasma membrane intrinsic proteins genes mRNA accumulation in maize seedlings

Wei-Feng Wang[1,2], *Liang-Min Wang*[1], *Sui-Qi Zhang*[2]

1. College of Forestry, Shanxi Agricultural University

2. State Key Laboratory of Soil Erosion and Dryland Farming on the Loess Plateau, Northwest A&F University

Plants maintain water balance by varying hydraulic properties, and plasma membrane intrinsic proteins (PIPs) may be involved in this process. Leaf xylem and root hydraulic conductivity and the mRNA contents of four highly expressed ZmPIP genes (*ZmPIP1;1*, *ZmPIP1;2*, *ZmPIP2;2* and *ZmPIP2;5*) in maize (*Zea mays*) seedlings were investigated. Under well watered conditions, leaf hydraulic conductivity (K_{leaf}) varied diurnally and was correlated with whole-plant hydraulic conductivity. Similar diurnal rhythms of leaf transpiration rate (E), K_{leaf} and root hydraulic conductivity (K_{root}) in well-watered plants can be important for maintaining whole-plant water balance. After 2 h of osmotic stress treatment induced by 10% polyethylene glycol 6000, the K_{root} of stressed plants decreased but K_{leaf} increased, compared with well-watered plants. The mRNA contents of four *ZmPIP*s were significantly up-regulated in the leaves of stressed plants, especially for *ZmPIP1;2*. Meanwhile, *ZmPIP2;5* was significantly down-regulated in the roots of stressed plants. After 4 h of osmotic stress treatment, the E and leaf xylem water potentials of stressed plants unexpectedly increased. The increase in K_{leaf} and a partial recovery of K_{root} may have contributed to this process. The mRNA content of *ZmPIP1;2* but not of the other three genes was up-regulated in roots at this time. In summary, the mRNA contents of these 4 *ZmPIP*s associated with K_{leaf} and K_{root} change in maize seedlings during short-term osmotic stress, especially for *ZmPIP1;2* and *ZmPIP2;5*, which may help to further reveal the hydraulic resistance adjustment role of *ZmPIP*s.

Small RNA and transcriptome deep sequencing provides insight into pistil mutations in alfalfa possibly derived from an infection of RNA virus

Xiaojuan Wang[1], *Haichen Zhou*[2]

1. Shanghai Science & Technology Museum/Natural History Research Center

2. Lanzhou University/School of Pastoral Agriculture Science and Technology

Alfalfa (*Medicago sativa* L.) is considered as one of the most studied agronomical plants. Its multi-pistil mutant MP-1 exhibited two to three pistils compared with its wild-type plant, which is highly valuable in the study of floral development in alfalfa. Our previous study revealed that MP-1 was partial-female-sterile, significantly decreasing the production yield. In this study, we conducted high-throughput sequencing of the miRNAs and transcriptomes of the alfalfa mutant florets (MP-1) and its wild-type florets (WT) to gain insights into pistil development in alfalfa. A total of 151,359 putative unigenes with mean length of 631 bp were generated from WT and MP-1 transcriptomes. Comparative profiling showed that 2306 differentially expressed genes were identified, including 1100 up-regulated unigenes and 1206 down-regulated unigenesin MP-1 vs WT. The up-regulated genes in MP-1 belong to biological processes such as RNA-directed DNA polymerase activity-dependent DNA replication, DNA metabolic process, DNA polymerase activity, DNA integration and DNA replication by GO enrichment analysis. In addition, the expression of genes encoding capsid protein and RNA dependent RNA polymerase were significantly abundant, which were found highly similar to a RNA virus (white clover cryptic virus). Besides, a total of 148 known miRNAs, belonging to 72 families, were identified from two small RNA libraries of MP-1 and WT. Comparative profiling revealed that 110 miRNAs exhibited differential expression between MP-1 and WT, 43 of which were novel. The correlation analysis of small RNA and transcriptome revealed that 18 highly differentially expressed miRNAs and their 28 target genes were closely associated withpistil development. KEGG pathway and GO annotation indicated that high-ranking miRNA target genes were involved in the metabolic and signal transduction pathways. This implied that the feature of the mutant might origin from the over-duplication and assembly of the related genes in the plants after the infection of the two-chain RNA virus. Our work provides a comprehensive genetic resource which can be used to better understand alfalfa pistil development and to identify candidate genes for female sterility in alfalfa.

Chicory R2R3-MYB transcription factors CiMYB3 and CiMYB5 regulate fructan 1-exohydrolase expression in response to abiotic stress and hormonal cues

Hongbin Wei[1], *Hongbo Zhao*[2], *Tao Su*[3], *Thomas Rausch*[1]

1. Heidelberg University

2. South China Agricultural University

3. Nanjing Forestry University

In the biennial *Cichorium intybus*, inulin-type fructans accumulate in the taproot during the first year. Upon cold or drought exposure, fructans are degraded by fructan exohydrolases, affecting inulin yield and degree of polymerization. While stress-induced expression of *1-FEH* genes has been thoroughly explored, the transcriptional network mediating these responses has remained unknown. In this study, several R2R3-MYB transcriptional regulators were analyzed for their possible involvement in *1-FEH* regulation via transient transactivation of *1-FEH* target promoters and *in vivo* co-expression with target genes under different stress and hormone treatments. CiMYB3 and CiMYB5 selectively enhanced promoter activities of *1-FEH1*,1-*FEH2a* and *1-FEH2b* genes, without affecting promoter activities of fructosyltransferase genes. Both factors recognized the MYB-core motif (C/TNGTTA/G) abundantly present in *1-FEH* promoters. *In vivo*, *CiMYB5* displayed co-expression with its target genes in response to different abiotic stress and phytohormone treatments, whereas correlations with *CiMYB3* expression were less consistent. Oligofructan levels indicated that the metabolic response depended on the balance of the relative expression levels of fructan exohydrolases and fructosyltransferases. In summary, CiMYB5 and CiMYB3 act as positive regulators of fructan degradation in chicory.

In vitro spore germination, polyembryony induction and plant regeneration of *Pteris tripartita* Sw., a critically endangered fern from south India

Baskaran Xavier Ravi

Fairy Lake Botanical Garden, Shenzhen & Chinese Academy of Sciences

An efficient protocol was developed for *in vitro* spore germination, polyembryony development and micropropagation of *Pteris tripartita* Sw. Spores were germinated after 15 days in MS medium fortified with pH, sucrose and hormones. Significant spore germination (84%) was exhibited in 70 g/L of sucrose and 79.33% in pH

5.7 of culture medium. In both pH 5.7 and 6.7, maximum size of gametophyte lengths (484.39 and 507.72 µm) and widths (846.58 and 1270.98 µm) were displayed. At 4 mg/L of GA$_3$, highest rate of spore germination (95%) and rhizoid formation were observed. Highest length of rhizhoid (787.69 µm) with maximum gametophyte length (307.74 µm) and width (834.36 µm) were noticed in 1 mg/L of GA$_3$. In our present study, Di to Octa numbers of polyembryony or juvenile sporophytes was induced in the midrib of gametophytes after 5 months culture period. The numbers of juvenile sporophytes per gametophyte, its lengths, and the total number of polyembryony or juvenile sporophytes per culture treatment were counted, and their lengths were measured after 8 months of culture period. Among five concentrations of BAP (1–5 mg/L), Di, Tri, Tetra, Hexa, and Octa numbers of polyembryony or juvenile sporophytes were observed from a single gametophyte at 3 mg/L of BAP. Of them, significant lengths (1.00,0.70,1.16,1.00,1.13 cm) were observed in Di, Tri, Tetra, Hexa, Octa polyembryony or juvenile sporophytes per gametophyte, respectively. Octa numbers of juvenile sporophytes were induced per gametophyte with 1.13 cm of length and were observed only at 3 mg/L of BAP. Three months old gametophytes were sub-cultured in MS medium supplemented with different concentrations of BAP, KIN and GA$_3$. Among five concentrations of BAP, highest numbers of sporophytes were induced with 4.16 cm of height and 1.51 cm of root length at 4 mg/L. In both 3 and 5 mg/L of BAP; 55 and 54 numbers of sporophytes were developed with 3.84 cm and 3.57 cm of shoot lengths along with 1.45 cm and 1.35 cm of root lengths, respectively. The MS medium supplemented with Kinetin (4 mg/L) induced sporophytes (56.03 mean numbers) after five months and reached about 2.61 cm height along with 1.39 cm length of root. Among various concentration of GA$_3$, highest mean numbers of juvenile sporophytes (59.66) were induced with 2.64 cm mean lengths of sporophytes along with about 2.23 cm of root length at 4 mg/L of GA$_3$ in MS culture medium. Finally, plantlets were transferred to small cups containing a mixture of sterilized soil, sand and vermiculite (1:1:1) in growth chambers with controlled temperature and light. Plantlets were sprayed regularly with water and covered with a porous polyethylene bag to maintain high humidity (90%–95%). The potted plantlets were kept under *in vitro* conditions and acclimatized with 90% of a survival rate. Our present protocol could be use useful for the rehabilitation of this critically endangered fern and also reduce the pressure on natural population.

Functional analysis of *SecF* and *SecY* homologs in rice and maize

Meiling Xia, Yuan Zhou, Bo Song, Yingchun Zhang, ***Xiaoquan Qi***
Institute of Botany, Chinese Academy of Sciences, Beijing

A vast majority of proteins are secreted to cytoplasmic membrane via the Sec system in bacteria. The Sec system consists of the SecYEG, SecA and SecDF complex that forms an evolutionarily conserved membrane channel for protein trafficking. However, the function of Sec system in plant is largely unknown. In our previously study two genes, *HvSecF* and *HvSecY*, which control a quantitative trait locus *Rphq4* for resistance to leaf rust were cloned. The phylogenetic analysis suggested that *HvSecF* and *HvSecY* are co-evolved and only exist in Poaceae family. There are 3 pairs of homologs, *OsSecF1/OsSecY1*, *OsSecF2/OsSecY2*, and *OsSecF3/OsSecY3* in rice, and 2 pairs, *ZmSecF1/ZmSecY1*, *ZmSecF2/ZmSecY2* in maize. We are creating mutants for each gene in rice and maize by use of CRISPR/Cas9 system. So far we obtained multiple mutant lines for *OsSecF1* (2 lines), *OsSecY1* (2 lines), *OsSecF2* (4 lines), *OsSecY2* (2 lines), *OsSecF3* (2 lines) and *OsSecY3* (3 lines). The increase of plant height for ca. 20% was observed in the mutant lines of *OsSecF2*, *OsSecY2*, *OsSecF3* and *OsSecY3* comparing to the transformed plants with Cas9 empty vector. These results suggest that this Sec system may play an important role in plant development.

Tissue culture and rapid propagation of *Chirita wentsaii*

Kanghua Xian, Chuanming Fu, Fengluan Tang, Yunping Shi, Jinxiang He, ***Ningzhen Huang***
Guangxi Institute of Botany, Guangxi Zhuangzu Autonomous Region and Academia Sinica

Tissue culture and rapid propagation of Chirita wentsaii were studied by using the fleshy leaves as explants. The results showed that the initial medium for the callus induction and seedling regeneration was MS + 6-BA 0.1 mg L^{-1} + NAA 0.1 mg L^{-1}. The subculture media for bud proliferation and sound seedling cultivation were MS + 6-BA 0.5 mg L^{-1}+ NAA 0.2 mg L^{-1}+ banana 10% and MS + 6-BA 0.5 mg L^{-1} + NAA 0.5 mg L^{-1} + banana 10%, and their proliferation coefficients were 6.7 and 4.8 every 60 d respectively. The optimal rooting medium was MS, and the rooting rate was 100%. The rooting plantlets were transplanted in greenhouse and the highest survival rate was about 94%.

Functional anaysis of *Torenia* ALOG gene family reveals underlying regulation of petal fusion

Wei Xiao
State Key Laboratory of Biocontrol and Guangdong Key Laboratory of PlantResources, School of Life Sciences, Sun Yat-sen University, Guangzhou, China

The ALOG (*ArabidopsisLSH1* and *OryzaG1*) gene family, widely existingin angiosperm, is recruited in the regulation of flower architecture. Flower architecturecan be specialized by adopting different strategies including fusion of petals. Previous studies demonstrate divergent developmental mechanismshave been involved in the establishment of petal fusion. However, whether ALOG gene family participates in this procedure is still largely unknown. Here, we isolated seven ALOG family members from *Toreniafournieri*, and characterized the evolutionary process, subcellular localization and expressional patterns of these factors. We further explored the function of a petaltube specific gene *TfALOG1* by transgenic. We found the angiosperm ALOG genes divided into two clades, an ancestral ALOG clade and a core eudicots clade. Most of *Torenia* ALOG members were localized in nuclear region except *TfALOG7*. *TfALOG1* and *TfALOG3* were highly expressed in the boundary regions of petal tubes indicating their possible functions in petal development. Ectopic expression of *TfALOG1* exhibits abnormal flowers manifested in elongated of petal tube region together with enlarged epidermal cells, suggesting potential role of *TfALOG1* in the regulation of petal fusion. Our resultssupport the idea that ALOG family proteins widely function inflower architectureformation such as petal fusion.

Probing the effects of mutation of PsbV-Y137 on photosystem II

Yanan Xiao[1], *Guangye Han*[1], *Jianren Shen*[1,2]
1. Institute of Botany, the Chinese Academy of Sciences
2. Okayama University

Photosystem II (PSII) performs light-induced water-oxidation, leading to the splitting of water into electrons, protons and oxygen. The structure of cyanobacterial PSII has been studied extensively, which showed that water-oxidation is catalyzed by a Mn_4CaO_5-cluster bound to the protein matrix of PSII. In order to perform the water-splitting efficiently, it is important to pump the protons generated at the reaction site to the outside of the protein complex. The latest high-resolution structure of PSII has revealed the presence of several well-defined H-bond networks leading from the Mn_4CaO_5 cluster to the lumenal bulk solution, which may be important for the transport of protons out of its reaction site. PsbV-Tyr137 is located in the exit of one such H-bond network starting from the D1-Try161-His190 residue pair close to the Mn_4CaO_5-cluster, and located in the interfaces between the D1, CP43, and PsbV subunits. In order to probe the function of PsbV-Y137, four mutants, PsbV-Y137A, PsbV-Y137F, PsbV-Y137G, and PsbV-Y137W, were generated with *Thermosynechococcus vulcanus* (*T. vulcanus*). Photoautotrophic growth measured at a light intensity of 40 μmol of photos m^{-2} s^{-1} indicated that these mutants showed slightly slower growth rates than that of the wide type (WT) strain; however, their oxygen-evolving activity was apparently lower than that of the WT strain, and reached to about 43%, 64%, 40% and 68% of the oxygen-evolving activity of the WT strain, respectively. In addition, the thylakoid membranes isolated from PsbV-Y137A, PsbV-Y137G mutants lost the oxygen-evolving activity almost completely. On the other hand, PSII-complexes purified from the PsbV-Y137F and PsbV-Y137W mutants contained two PSII fractions, one of which lacks the three extrinsic proteins PsbO, PsbV and PsbU and showed almost no oxygen-evolving activity, whereas the other one contained the three extrinsic proteins and showed a lower oxygen-evolving activity than that of the WT-PSII. These results suggested that the PsbV-Y137 residue is required for the stable binding of the extrinsic proteins to PSII and also has a role in maintaining the oxygen-evolving activity.

Unsaturation of very-long-chain ceramides protects plant from hypoxia-induced damages by modulating ethylene signaling in *Arabidopsis*

Li Juan Xie, Qin Fang Chen, ***Shi Xiao***
Sun Yat-sen University

Lipid remodeling is crucial for hypoxic tolerance in animals, whilst little is known about the hypoxia-induced lipid dynamics in plants. Here we performed a mass spectrometry-based analysis to survey the lipid profiles of *Arabidopsis* rosettes under various hypoxic conditions. We observed that hypoxia caused a significant increase in total amounts of phosphatidylserine, phosphatidic acid and oxidized lipids, but a decrease in phosphatidylcholine (PC) and phosphatidylethanolamine (PE). Particularly, significant gains in the polyunsaturated species of PC, PE and phosphatidylinositol, and losses in their saturated and mono-unsaturated species were evident during hypoxia. Moreover, hypoxia led to a remarkable elevation of ceramides and hydroxyceramides. Disruption of ceramide synthases LOH1, LOH2 and LOH3 enhanced plant sensitivity to dark submergence, but displayed more resistance to submergence under light than wild type. Consistently, levels of unsaturated very-long-chain (VLC) ceramide species (22:1,24:1 and 26:1) predominantly declined in the *loh1*, *loh2* and *loh3* mutants under dark submergence. In contrast, significant reduction of VLC ceramides in the *loh1-1 loh3-1* knockdown double mutant and lacking of VLC unsaturated ceramides in the *ads2* mutants impaired plant tolerance to both dark and light submergences. Evidence that C24:1-ceramide interacted with recombinant CTR1 protein and inhibited its kinase activity *in vitro*, enhanced ER-to-nucleus translocation of EIN2-GFP and stabilization of EIN3-GFP *in vivo*, suggests a role of ceramides in modulating CTR1-mediated ethylene signaling. The dark submergence-sensitive phenotypes of loh mutants were rescued by a ctr1-1 mutation. Thus, our findings demonstrate that unsaturation of VLC ceramides is a protective strategy for hypoxic tolerance in *Arabidopsis*.

Ice active proteins in New Zealand tussocks, *Chionochloa* species

Haoyu Xiong[1], *David Wharton*[2], *Janice Lord*[3], *Craig Marshall*[1]
1. Department of Biochemistry, The University of Otago
2. School of Zoology, The University of Otago
3. Department of Botany, The University of Otago

Unlike fishes and insects that secrete cryoprotectants to depress the freezing point of body fluids, overwintering plants produce ice active agents with much lower thermal hysteresis but higher ability to inhibit ice recrystallization. Plants also minimize the damage from freezing by triggering ice formation at high sub-zero temperatures with ice nucleation agents. *Chionochloa* are tussocks mainly endemic to New Zealand and dominate the alpine grasslands. Previous studies indicated significant ice nucleation activity (INA) (~-5°C), in two alpine *Chionochloa* species, *C. macra* and *C. rigida*, but provided no more information about other ice activities in this genus. We investigated 17 of 34 *Chionochloa* species and found seasonal variations of ice activities in most collections with winter collections showed the highest activities. We show here that intrinsic proteins are essential in maintaining all three types of ice activity, which showed different responses to treatments including heat, pH, high salt, proteinase K, lysosome, reducing and oxidizing agents. Ice affinity purification indicated the presence of antifreeze proteins in *C. macra*, which was confirmed by mass spectrometry and transcriptome analysis from overwintering *C. macra*. Amino acid alignment analysis showed highly conserved ice-binding domains in the recrystallization inhibition proteins (RIPs) among *C. macra* and grass species including *Lolium perenne* and *Deschampsia antarctica*. Phylogenetic analysis of cold stress related genes, IAPs, C-repeat binding factors and fructosyltransferase, in *C. macra* and other grass species indicated these genes from *C. macra* evolved differently to the core *Pooideae* family and genes from *Brachypodium distachyon*. Protein expression in *E. coli* confirmed ice activities of codon optimized ice active genes from *C. macra*.

Comparative transcriptome analysis of axillary buds in response to the shoot branching regulators gibberellin and cytokinin in the perennial woody plant *Jatropha curcas*

Jun Ni[1,2]*, Mei-Li Zhao*[1,3]*, Mao-Sheng Chen*[1]*, Bang-Zhen Pan* [1]*, Yan-Bin Tao* [1]*,* ***Zengfu***[1] ***Xu***

1. Key Laboratory of Tropical Plant Resources and Sustainable Use, Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences

2. Institute of Technical Biology & Agriculture Engineering, Hefei Institutes of Physical Science, Chinese Academy of Sciences

3. College of Life Sciences, University of Chinese Academy of Sciences, Beijing

Cytokinin (CK) is the primary hormone that positively regulates axillary bud outgrowth. However, in many woody plants, such as *Jatropha curcas*, gibberellin (GA) also promotes shoot branching. The molecular mechanisms underlying GA and CK interaction in the regulation of bud outgrowth in *Jatropha* remain unclear. To determine how axillary buds respond to phytohormones GA and CK, we performed a comparative transcriptome analysis of the axillary buds of *Jatropha* seedlings treated with GA$_3$ or benzyladenine (BA, a synthetic CK). Multiple GA$_3$- or BA-responsive genes were identified, and 255 genes were shown to be co-regulated, with similar expression profiles, in response to GA$_3$ or BA. Seven *NAM/ATAF1/CUC2* (*NAC*) family members were down-regulated after treatment with both GA$_3$ and BA, whereas these genes were up-regulated after treatment with the shoot branching inhibitor strigolactone. Furthermore, the bud dormancy-related genes *Dormancy-Associated Protein1* (*DRM1*), *DRM1-LIKE* and *BELL1* were negatively regulated by GA$_3$ or BA. Additionally, the expressions of the cell cycle genes *Cell Division Control 6* (*CDC6*), *Cell Division Control 45* (*CDC45*) and *Growth Regulation Factor 5* (*GRF5*) were up-regulated after treatment with both GA$_3$ and BA, suggesting that these hormones may promote bud outgrowth, in part, via regulation of the cell cycle machinery. Overall, the comprehensive transcriptome data set provides novel insight into the responses of the axillary buds to GA and CK.

P1124

The maize chromatin remodeler ZmCHB101 plays an essential role in osmotic stress response via both transcriptional regulation and alternative splicing

Xiaoming Yu, Xinchao Meng, Yutong Liu, Bao Liu, ***Zheng-Yi Xu***

Key Laboratory of Molecular Epigenetics of the Ministry of Education (MOE), Northeast Normal University

Drought and osmotic stresses are recurring and severely constraint crop production. Accumulated evidence in *Arabidopsis thaliana* suggests that components of the SWI/SNF chromatin remodeling complexes play essential roles in abiotic stress responses. Here we show that *ZmCHB101*, a homologue of *A. thaliana SWI3D* in maize, plays an essential role in osmotic and dehydration stress responses. Transcriptome profiling revealed that ZmCHB101 modulates transcriptional expression landscape of osmotic stress responsive genes. Co-immunoprecipitation assay showed that ZmCHB101 associates with RNA polymerase II (RNAPII) *in vivo*, which might be a prerequisite for the proper occupancy of RNAPII on the promoter and proximal regions of transcription start sites of stress response genes. In addition, ZmCHB101 plays a role in the occurrence of alternative splicing of stress response genes under normal and osmotic stress conditions, probably mediated by alternation of chromatin states and changes in transcriptional elongation rates. However, the regulatory roles of ZmCHB101 in gene expression and alternative splicing are largely uncoupled, pointing to diverse molecular functions of ZmCHB101 in transcriptional and posttranscriptional regulations of gene expression. Taken together, our findings have unraveled novel regulatory roles of ZmCHB101 in affecting gene expression and alternative splicing by remodeling chromatin states and directly associating with RNAPII.

Phytoplasma infection altered photosynthetic and sugar metabolism in Chinese jujube (*Ziziphus jujuba* Mill.)

Chaoling Xue[1]*, Zhiguo Liu*[2]*, Jiaodi Bu* [1]*, Zihui Jiang* [1]*, Mengjun Liu*[2]*, Li Dai* [2]*, Jin Zhao**[1]

1. College of Life Science, Hebei Agricultural University

2. Research Center of Chinese Jujube, Hebei Agricultural University

Phytoplasma is a class of cell-wall-free prokaryotic organisms that are parasitized in plant phloem tissues. Its genome is lack of the genes required to complete their own metabolic energy, but with well-developed sugar transporters to absorb nutrients from the host. Jujube witches' broom disease (JWB) caused by phytoplasma is a destructive disease of Chinese jujube. Its typical symptoms include yellow leaves, phyllody and witches' broom or condensed branch with tiny leaves. The primary symptom of jujube leaves caused by phytoplasma infection is yellowing, meaning that its photosynthesis is significantly affected. To further reveal the pathogenic mechanism, the influence of JWB phytoplasma on photosynthetic and sugar metabolism of jujube trees were systematically studied at the transcriptional, physiological and structure levels. Transcriptome data revealed that the expression of the genes related to starch, sucrose and glucose synthesis (the *1,5-diphosphate ribulose carboxylase* (*RuDPCase*), *phosphoenolpyruvate enzyme* (*PEPC*), *sucrose phosphate synthase* (*SPS*), *sucrose synthase* (*SuSy*), *invertase* (*INV*), *glucose-1-phosphate adenylyltransferase* (*GPAT*), *starch synthase* (*SS*) and *granule-bound starch synthase II-1* (*GSBBII-1*)) in diseased leaves were significantly increased, suggesting that the sugar metabolism in jujube was enhanced by phytoplasma infection. Accorrdingly, the higher contents of starch, sucrose and glucose in diseased leaves were examined by starch kit and HPLC, respectively, which were consistent with the transcriptome data. Furtherly, the result of transmission electron microscope (TEM) showed that the number of starch granules in mesophyll cell of diseased leaves increased, the grana and stroma lamellar of chloroplast were destroyed structurally and formed the original lamellae. The content of chlorophyll, PSII activity and the expression of photosynthesis-related genes in diseased leaves were also significantly lower than that in healthy ones. In addition, the result of TEM found that the P protein agglutinated and callose deposited in the sieve wall of diseased young stem, implying that the transport of nutrients was inhibited in diseased trees. On the whole, phytoplasma infection disturbed the operation and formation of photosynthate of jujube trees, caused the disorder of sugar metabolism and particularly stimulated the abnormal accumulation of starch in chloroplast. The increasing of sugar content is benefitical to phytoplasma proliferation temporarily, however the excessive damage in structure and metabolism of host jujube lead to the exhaustion of jujube.

Tudor-SN, a component of stress granules, regulates the growth under salt stress by modulating GA20ox3 mRNA levels in *Arabidopsis*

Chunxia Yan
College of Life Sciences, Inner Mongolia University

The Tudor-SN protein (TSN) is universally expressed and highly conserved in eukaryotes. In *Arabidopsis*, TSN is reportedly involved in stress adaptation, but the mechanism involved in this adaptation is not understood. Here, we provide evidence that TSN regulates the mRNA levels of *GA20ox3*, a key enzyme for gibberellin (GA) biosynthesis. The levels of *GA20ox3* transcripts decreased in TSN1/TSN2 RNA interference (RNAi) transgenic lines and increased in TSN1 over-expression (OE) transgenic lines. The TSN1 OE lines displayed phenotypes that may be attributed to the overproduction of GA. No obvious defects were observed in the RNAi transgenic lines under normal conditions, but, under salt stress conditions, these lines displayed slower growth than wild-type (WT) plants. Furthermore, two mutants of *GA20ox3*, *ga20ox3-1* and *ga20ox3-2*, also showed slower growth under stress than WT plants. Moreover, a higher accumulation of *GA20ox3* transcripts was observed under salt stress. The results of a Western blot analysis indicated that higher levels of TSN1 accumulated after salt treatment than under normal conditions. Subcellular localization studies showed that TSN1 was uniformly distributed in the cytoplasm under normal conditions but accumulated in small granules and co-localized with RBP47, a marker protein for stress granules (SGs), in response to salt stress. The results of RNA immunoprecipitation experiments indicated that TSN1 bound *GA20ox3* mRNA *in vivo*. On the basis of these findings, we conclude that TSN is a novel component of plant SGs that regulates growth under salt stress by modulating levels of *GA20ox3* mRNA.

Type B ARRs play an integrative role in the transcriptional regulation of *TAA1* in response to developmental and environmental cues

Zhenwei Yan[1], *Xin Liu*[1], *Karin Ljung*[2], *Shuning Li*[1], *Wanying Zhao*[1], *Meiling Wang*[1], *Yi Tao*[1]
1. School of Life Sciences, Xiamen University, Xiamen Plant Genetics Key Laboratory
2. Swedish University of Agricultural Sciences, SE-90183, Umeå

Auxin and cytokinin are key hormones required for plant development. During embryogenesis and organ formation, establishing proper gradient is critical for auxin function, which is achieved through coordinated regulation of both auxin metabolism and transport. Expression of auxin biosynthetic genes is often tissue specific and is regulated by environmental signals. However, the underlying regulatory mechanisms remain elusive. Here, we investigated the transcriptional regulation of a key auxin biosynthetic gene, *TAA1* (L-Tryptophan aminotransferase of *Arabidopsis* 1). Two cis-elements, required for tissue specific expression of *TAA1*, were identified in the promoter and the second intron of *TAA1*. C-terminal of ARR1, a type B ARRs (*Arabidopsis* response regulators), directly binds to both cis-elements and activates the expression of *TAA1*. Mutation in ARR1,10 and 12 not only affects cytokinin induced expression of *TAA1* but also reduces auxin levels, suggesting multiple type B ARRs participate in the transcriptional regulation of *TAA1*. We further demonstrated that the ARRs also mediate the transcriptional regulation of *TAA1* by SCARECROW and light, and DELLA proteins interact with ARR1 and promote its transcriptional activity. We propose that the ARR proteins act as key transcriptional regulators of *TAA1* by integrating hormonal, environmental and developmental signals.

Pollen tube guidance in fowering plants: The interplay between male and female gametophytes

Weicai Yang, *Hongju Li*, *Tong Wang*, *Mengxia Zhang*
Institute of Genetics and Developmental Biology, University of Chinese Academy of Sciences, Chinese Academy of Sciences

Novel reproductive structures and mechanisms have evolved to adapt to terrestrial land environment in plants during evolution. In flowering plants, such evolutionary development is manifested by the flower, multicellular gametophyte, double fertilization, loss of sperm motility, and siphonogamy in which the immotile sperm was delivered to the egg by a pollen tube produced by the male gametophyte (pollen), a process named pollen tube guidance (PTG). Previous studies suggested that PTG requires the intimate interactions between the pollen tube and maternal tissue of the pistil and the female gametophyte respectively. Although signaling molecules, such as LURE1 peptide produced by the synergid cell of the female gameptophyte (embryo sac) to attract and guide the pollen tube growth, were identified (for review see Higashiyama and Takeuchi, *Annu Rev Plant Biol,* 2015), how the pollen tube recognizes and responds to the guiding molecule is not yet clear. Through genetic screen, we isolated a number of *Arabidopsis* mutants that disrupt PTG processes. *CCG*, a central cell-specifically expressed gene, is required for the female gametophyte to attract the pollen tube. *CCG* encodes a nuclear protein that regulates the expression of a number genes important for PTG via CBP1 which interacts with RNA polymerase II, the Mediator complex and AGL transcription factors in the central cells and also *LURE1* expression in the synergid cells indirectly (Chen *et al.*, Plant Cell, 2007; Li *et al.*, Plant Cell, 2015). *POD1*, a pollen tube-expressed gene, is required for the male gametophyte to respond to the female signals. *POD1* encodes a ER protein that interact specifically with CRT3 which is implicated to control the foldin gof Leucine-Rich Repeat Receptor-Like Kinases (LRR-RLKs). These data suggest that POD1 might play a role in the protein folding of putative receptor proteins. Recently, we identified the male MDIS/MDIK receptor complex that recognizes the female attracting signals (Wang *et al.*, Nature, 2016). At the same time, another LRR-RLK PRK6 has also been reported to be LURE1 receptor in *Arabidopsis* (Takeuchi and Higashiyama, *Nature*, 2016). These findings provide novel insight to mechanims controlling PTG and will be discussed.

Competition between branch components of *Haematococcus lacustris* for control of algal carotenoid biosynthesis

Lao Yong Min[1], *Jin Hui*[2], *Zhou Jin*[1], *Zhang Huai Jin*[2], *Cai Zhong Hua*[1]
1. The Division of Ocean Science and Technology, Graduate School at Shenzhen, Tsinghua University
2. School of Life Sciences, Tsinghua University

Cyclization of acyclic lycopene by cyclases marks an important regulatroy point in carotenoid biosynthesis. Though some algal lycopen epsilon cyclases (LCYEs) have been predicted computationally, very few have been functionally identified. Little is known about the regulatory mechanisms of algal LCYEs. Recent comparative genomic analysis suggested that Haematococcus lacustris contained only the beta type cyclase (HlLCYB). However, in this study, carotenoid profiling found trance alpha-carotene in the salt-treated cells, indicating the *in vivo* activity of HlLCYE, a missing component for alpha-branch carotenoids. Thus, genes coding for HlLCYB and HlLCYE were isolated and functionally complemented in *Escherichia coli*. Expression pattern studies, comparative promoter analysis, and site-directed mutagenesis assays showed that both cyclases were differentially regulated by the regulatory *cis*-acting elements in promoters and the key regulatory residues in proteins to correlate with primary and secondary carotenoid biosynthesis under environmental stresses. Substrate specificity assays revealed an exclusive cyclization order of HlLCYE to HlLCYB for the biosynthesis of heterocyclic carotenoids. Identification of the branch components in algal carotenoid biosynthesis revealed a mechanism for control of metabolic fulx into alpha- and beta-branch by the competition and cooperation between HlLCYE and HlLCYB, and supplied a promising route for molecular breeding of cyclic carotenoid biosynthesis.

Selection and application of DNA barcodes for wood identification of *Dalbergia* species: A case study on vouched samples of wood xylarium

Min Yu, *Lichao Jiao, Juan Guo, Tuo He, Xiaomei Jiang, Yafang Yin*
Chinese Academy of Forestry

The increasing in illegal logging and timber trade of CITES-listed tropical species necessitates the development of unambiguous identification methods at species level. DNA barcoding has been promoted as a promising tool for species identification. However, the main barrier and obstacle of extensive application of DNA barcoding is the lack of a comprehensive and reliable DNA reference library. Vouched wood xylarium samples are potentially an enormous and reliable resource of materials. In this study, the wood specimen of nine species were selected from *Dalbergia* genus stored in the Wood Collection of the Chinese Academy of Forestry and DNA was then extracted from them for further PCR amplification. Eight potential DNA barcode sequences and their different combinations were used to test discrimination ability by three methods, i.e., the character based, tree-based and TAXONDNA method. It was shown that the discrimination ability of DNA barcodes combination was higher than single DNA marker at the species level. The present results demonstrate the applicability of the DNA barcoding to species identification from wood xylarium samples.

Effects of exogenous hydrogen peroxide on flower bud differentiation in tobacco

Yuanyuan Li, Yingying Huang, Shixin Zhu, Jinyong Huang, Zhen Wei, Jian Du, ***Caipeng Yue***
School of Life Sciences, Zhengzhou University

A preliminary study on reactive oxygen species (ROS) metabolism and flower bud differentiation in tobacco was completed through pot experiment, by spraying exogenous hydrogen peroxide at different time points. The results showed that: (1) Spraying H_2O_2 significantly changed the ROS metabolism and launched an endogenous protective enzyme system in tobacco within 24 hours. H_2O_2 content rapidly increased in tobacco after spraying H_2O_2. Sequentially, the O_2^- content and MDA content rose as well. The activity of POD enzyme was quickly activated in tobacco. Later the activity of CAT was also activated. The CAT activity was slightly weaker than POD enzyme at beginning stage, then it increased much greater than POD activity. The response of SOD enzyme to H_2O_2 was later than the POD and CAT. In mid and late stage, O_2^- content remained at a high level, but H_2O_2 content significantly decreased. (2) In long term response to H_2O_2 (measured at every five days till 30 days), exogenous H_2O_2 made ROS metabolism into an unbalanced state in tobacco, relatively higher content of O_2^- and lower content of H_2O_2. This unbalanced state influenced the transition of the growth and development of tobacco apical bud. The anatomical observation of tobacco apical bud and the number of leaves during flowering stage showed that the floral development was earlier than control when spraying 5 d-25 d of

H_2O_2. The leaf number at flower budding stage was related to the changes of H_2O_2 content in tobacco. Therefore, we assumed that the changes of ROS metabolic balance affect the flowering transition of tobacco and promote flower bud differentiation, to a certain extent. This article only investigated the relationship between reactive oxygen metabolism and tobacco floral development from a physiological aspect. The molecular mechanisms and signaling pathways, which reactive oxygen species regulate flowering, will be further explored.

The *Arabidopsis MUR4* contributes to cell wall strength and salt tolerance

Omar Zayed[1], *Chunzhao Zhao*[1,2], *Jian-Kang Zhu*[1,2]
1. Purdue University
2. Shanghai Center for Plant Stress Biology

Salinity is one of the widely-studied plant abiotic stresses that substantially limits crop yield and production. Salt affects plant growth and development by different manners including reduction of plant cell wall flexibility. Maintaining cell wall elasticity and integrity is an important criterion for enhancing salt stress tolerance. Presence of wall arabinose-containing polymers had been suggested to be the key structural component responsible of the unique abiotic stress tolerance characteristic of plants. Screening for *Arabidopsis* mutants, defective in growing in sodium chloride medium, was applied to identify genetic loci involved in salt tolerance. One of these mutants, *mur4* showed hypersensitivity to salt, with around 50% reduction in cell wall arabinose content. *MUR4* encodes a UDP-xylose-4-epimerase, which catalyze the conversion of UDP-xylose to UDP-arabinose, the main pathway of arabinose biosynthesis in plant. It was shown that arabinose-containing polymers confer different contribution to plant salt tolerance. Arabinan and extensin are considered to be the major cell wall structures required for salt tolerance. In addition to the reduction of arabinose and arabinose-containing structures in the cell wall, reactive oxygen species (ROS) and hydrogen peroxide H_2O_2 were shown to be over-accumulated in *mur4* plants after salt treatment compared to wild type. Our data suggest that *MUR4* play a key role in salt tolerance by decreasing ROS in plants grown under salinity conditions. The increment of H_2O_2 in mur4 after salt treatment, was coincide with downregulation of cell wall peroxidases genes along with Xyloglucan endotransglucosylase/hydrolase (XTH) and Expansins (EXP) genes, that may cause reduction in root expansion. PLAT (Polycystin, Lipoxygenase, Alpha-toxin and Triacylglycerol lipase) are plant-stress proteins that are found to promote salt tolerance. Nevertheless, little information is known regarding their specific functions and regulation in plant species. It is suggested that *PLAT* regulate salt tolerance by affecting the catalytic activity and substrate specificity of some membrane proteins. However, the mechanism and the associated proteins are still unknown. Our data showed that both *MUR4* and *PLAT1*, which are induced by salt stress, positively regulate salt tolerance. Using Co-immunoprecipitation, Split-LUC and yeast two hybrid, we confirmed that *MUR4* directly interacts with *PLAT1*. Altogether, our data suggest that arabinose content is an important factor in salt tolerance and *PLAT1* is involved in the regulation of *MUR4* activity.

Formation of a characteristic volatile constituent in tea (*Camellia sinensis*) leaves exposed to multiple stresses

Lanting Zeng[1,2], *Ying Zhou*[1], *Xiumin Fu*[1], *Xin Mei*[1], *Ziying Yang*[1]
1. South China Botanical Garden, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Indole not only serves as an important signal substance and precursor of indole-3-acetic acid (IAA), but also is a characteristic volatile constituent in tea (*Camellia sinensis*), especially oolong tea, a famous semi-fermented tea. Our previous study indicated that indole was mostly accumulated at the turn over stage of oolong tea manufacturing process. However, formation of indole in tea leaves remains unknown. In this study, one tryptophan synthase α-subunit (TSA) and three tryptophan synthase β-subunits (TSBs) from tea leaves were isolated, cloned, sequenced, and functionally characterized. Combination of *CsTSA* and *CsTSB*2 recombinant protein produced in *Escherichia coli* exhibited the ability of transformation from indole-3-glycerol phosphate to indole. *CsTSB*2 was highly expressed during the turn over process of oolong tea. Continuous mechanical damage, simulating the turn over process, significantly enhanced the expression level of *CsTSB2* and amount of indole. These suggested that accumulation of indole in oolong tea was due to the activation of *CsTSB*2 by continuous wounding stress from the turn over process. Black teas (fully fermented tea) contain much less indole, although wounding stress is also involved in the manufacturing process. Stable isotope labeling indicated that tea leaf cell disruption from the rolling process of black tea did not lead to the conversion of indole, but terminated the synthesis of indole. Our study provided evidences concerning formation of indole in tea leaves for the first time.

Physiological responses of the inoculation seedlings of *Dalbergia odorifera* to drought stress

Hong-Xing Zhan, *Xue-Gang Zhou*, *Xue-Ying Zhuang*, *Yong-Bin Wu*
South China Agricultural University

The impacts of drought stress on the physiological characteristics of the mycorrhizal seedlings of *Dalbergia odorifera* were studied with inoculation growth experiment. The results showed that variations of the leaf relative conductivities and MDA contents of the seedlings with inoculated mycorrhizal fungi were less than the non-inoculated seedlings (CK), but their proline contents and soluble protein contents were significantly higher than CK under drought stress. The variations in chlorophyll contents among the inoculation treatment and CK were not significant. The inoculation with the endophytic fungi could enhance the seedling drought adaptability of *Dalbergia odorifera* than the non-inoculated seedlings (CK). The drought tolerances of the seedlings inoculated with *Glomus margarita* was higher than those inoculated with *Glomus etunicatum.*

OsRACK1A, a circadian clock-regulated WD40 protein, is a negative regulator of salt-stress adaptation in rice

Dongping Zhang[1], Yuzhu Wang[1], Jiansheng Liang[1,2]
1. Yangzhou University
2. Southern University of Science and Technology

The receptor for activated C kinase 1 (RACK1) is a WD40 type protein that is involved in multiple signaling pathways and is strongly conserved from prokaryotes to eukaryotes. Here, we showed that rice *RACK1A* (*OsRACK1A*) is regulated by circadian clocks and plays an important role in the salt stress response. *OsRACK1A* was found to follow a rhythmic expression profile under circadian conditions at both the transcription and translation levels, although the expression was arrhythmic under salt stress. Analysis of plant survival rates, fresh weight, proline content, malondialdehyde, and chlorophyll showed that suppression of *OsRACK1A* enhanced tolerance to salt stress. The ion concentration in both roots and leaves revealed that *OsRACK1A*-suppressed transgenic rice could maintain low Na^+ concentrations and high K^+. Furthermore, *OsRACK1A*-suppressed transgenic rice accumulated significantly more abscisic acid (ABA) and more transcripts of ABA- and stress-inducible genes compared with the wild-type plants. Transcriptome analysis revealed that many stress-response genes were up-regulated in the *OsRACK1A*-suppressed transgenic rice line, including AP2/ERFs transcription factors. Real-time PCR analysis confirmed that many stress-related genes were also up-regulated in the *OsRACK1A*-suppressed transgenic rice line. These results suggest that *OsRACK1A* is involved in the regulation of circadian rhythm, ABA, and salt stress responses.

A rice heterotrimeric G protein γ subunit positively regulates development of endosperm cells and starch accumulation of grains

Dongping Zhang[1], Yuzhu Wang[1], Bing Lv[1], Jiansheng Liang[1,2]
1. Yangzhou University
2. Southern University of Science and Technology

Heterotrimeric G protein-mediated signal transduction is one of the most important and highly conserved signaling pathways in eukaryotes, which involves in the regulation of many important biological processes. As an atypical Gγ protein, rice qPE9-1 controls grain size and yield in rice, but its molecular mechanism remains elusive. Here, we confirm the interaction between qPE9-1 and rice G protein β subunit RGB1, and find that qPE9-1 is mainly localized to the plasma membrane. Wuyunjing 8 (WYJ8), which contain qPE9-1 allele (qpe9-1), have smaller grain size, less endosperm cells and lower starch content than its qPE9-1-covering transgenic line WYJ8 (qPE9-1). In WYJ8 (qPE9-1), the content of zeatin riboside (ZR), a kind of cytokine, is more than those in WYJ8 at the early stage of grain development. Furthermore, the expression levels of genes encoding grain filling-related enzymes are significantly higher in WYJ8 (qPE9-1) than those of WYJ8 at the late stage of grain filling. Contents of two phytohormone, abscisic acid (ABA) and indole-3-acetic acid (IAA), which were reported to involve in grain filling regulation, are also significantly higher in the WYJ8 (qPE9-1) grains than those in WYJ8 at the late stage of grain filling. In addition, both exogenous ABA and IAA treatments enhance the starch accumulation and expression of genes encoding grain filling-related enzymes in the grains of WYJ8 (qPE9-1), whereas only IAA has the same effect in WYJ8. Based on these results, we conclude that, as a G protein γ subunit, qPE9-1 promotes endosperm cells proliferation through cytokine (ZR) at the early stage of grain development, and also positively regulates starch accumulate largely through ABA and IAA, which enhance the expression of genes encoding several starch biosynthesis at the late stage of grain filling.

Two tonoplast MATE proteins function as turgor-regulating chloride channels in *Arabidopsis*

Haiwen Zhang[1,2,3], Legong Li[2], Sheng Luan[4]
1. Beijing Academy of Agriculture and Forestry Sciences
2. College of Life Sciences, Capital Normal University
3. School of Life Sciences, Nanjing University, Nanjing
4. Department of Plant and Microbial Biology, University of California, Berkeley

Turgor pressure is the driving force for cell growth in plants and the large central vacuole provides the major space for turgor regulation. The vacuolar membrane (tonoplast) contains a large number of transporters that mediate fluxes of solutes and water thereby adjusting cell turgor in response to developmental and environmental signals. However, the molecular identity and function of many tonoplast transporters remain unknown. Here, we showed that two tonoplast Detoxification efflux carriers (DTX)/Multidrug and Toxic Compound Extrusion (MATE) transporters, DTX33 and DTX35, function as chloride channels essential for turgor regulation in *Arabidopsis*. Ectopic expression of each transporter in *Nicotiana benthamiana* mesophyll cells elicited a large voltage-dependent inward chloride current across the tonoplast, demonstrating that DTX33 and DTX35 each constitute a functional channel. Both channels are highly expressed in *Arabidopsis* tissues including root hairs and guard cells that experience rapid turgor changes during root hair elongation and stomatal movements. Disruption of these two genes, either in single or double mutants, resulted in shorter root hairs and smaller stomatal aperture with double mutants showing more severe defects, suggesting that these two channels function additively to facilitate anion influx into the vacuole during cell expansion. In addition, *dtx35* single mutant showed lower fertility as a result of defect in pollen tube growth. Indeed, patch-clamp recording of isolated vacuoles indicated that the inward chloride channel activity across the tonoplast was impaired in the double mutant. As MATE proteins are widely known transporters of organic compounds, finding MATE members as chloride channels expands the functional definition of this large family of transporters and opens new doors to understanding their physiological roles in plants.

Expansion and functional divergence of flowering locus T

genes in monocots

***Liangsheng Zhang**, Xing Liu*
Center for Genomics and Biotechnology, Haixia Institute of Science and Technology, Fujian Agriculture and Forestry University

Flowering locus T (*FT*) gene is crucial in regulating flowering time. How it evolved and contributes to flowering diversity remain elusive. In this study, through phylogenetic analysis of *FT* genes in all angiosperm clades, we show that few *FT* genes exist in eudicots and more *FT* genes are encoded in monocots, especially in grasses. Furthermore, monocot *FT* genes can be grouped into three clades: M1, M2 and M3. M1 clades are conseverd and under purifying slection, contains mostly florigen functioning genes, showing the M1 clade is the ancestor of FT genes in monocots .For M2 and M3, many gene duplication events have contributed significantly to the FT copy number increase in monocots. Compare with M1 clades, we identified 6 and 8 positive selection sites in M2 and M3 clades, respectively, suggesting the functional divergence of these genes. Gene expression analysis reveals diverse patterns for different *FT* genes across tissues, further supporting functional divergence of these genes. Our study provides a global picture of *FT* gene evolution in angiosperm, particularly in monocots.

P1139

Influence of drought stress and semi shade environment on health of 10 ground cover seedling species during roof greening

***Peng-Qian Zhang**, Jia-De Bai, Yan-Ju Liu, Zheng Yang, Tian Liu*
The Department of Ecology Research, Beijing Milu Ecological Research Center

Roof greening, the “Fifth surface greening of city”, can mitigate the urban heat island effect, improve air quality and enrich urban biodiversity. Beijing, a typical northern super-city in China, has to develop the roof green industry to improve the environment. Due to the climate limitations in Beijing, the plants applied to the roof green are suffered with restricted rainfall in the winter, spring and some times in the summer. According to the “Beijing local standards-roof greening specification guidelines”, there are 10 recommended ground cover seedling species applied in the roof green, including *Paeonia lactiflora*, *Hemerocallis dumortieri*, *Physostegia virginiana*, *Iris lacteal*, *Hylotelephium erythrostictum*, *Sedum lineare*, *Iris germanica*, *Cosmos bipinnata*, *Hosta plantaginea* and *Dianthus barbatus*. This research is trying to select the plant species with strong drought resistance through drought stress test. This research sets 3 different drought stress degrees by controlling the soil relative water content (RWC), including moderately drought stress (40% ± 2% < RWC < 45% ± 2%), strong drought stress (RWC < 30% ± 2%) and control group (RWC > 75% ± 2%). When the seedlings survived the stress test after 5 days, the damaging rate of permeability (DRP), total chlorophylls concentrations (Chl), Superoxide Dismutase (SOD), Peroxidase (POD) and Ascorbate Peroxidase (APX) of seedlings will be measured. Finally, a subordinate function method was applied to assess these species’ drought resistance. The result shows the species of *Cosmos bipinnata* and *Physostegia virginiana* was dead after having suffered with moderately drought stress and strong drought stress, respectively. Although other species survived, the individual variation was huge especially for physiological and biochemical index. The species *Hemerocallis dumortieri*, *Iris lactea* and *Hosta plantaginea’s* DRP had little change when they lived in the normal water condition and suffered with drought stress. The semi-shaded condition reflects the change of Chl obviously. 6 species’ Chl increased when they suffered with moderately drought stress compared with the control group. This may indicate these plant seedlings have strong adaptation to poor light. The change of SOD activity is sensitive to drought stress. The most of the species (except *Paeonia lactiflora* and *Sedum lineare*) showed a lower SOD activity during moderately drought stress compared with the sufficient soil water condition and strong drought stress condition. The changes of plants’ POD activity and APX activity are very similar: when drought stress enhanced, the activity of protect enzyme reduced. According to the subordinate function method, the order of plants’ resistance to the moderately drought is as follow: *Iris germanica* > *Hemerocallis dumortieri* > *Hosta plantaginea* > *Iris lactea* > *Sedum lineare* > *Dianthus barbatus* > *Hylotelephium erythrostictum* > *Physostegia virginiana* > *Paeonia lactiflora*. And the order of plants’ resistance to the strong drought is as follow: *Hosta plantaginea* > *Sedum lineare* > *Iris germanica* > *Hylotelephium erythrostictum* > *Paeonia lactiflora* > *Dianthus barbatus* > *Hemerocallis dumortieri* > Iris lacteal > *Ph*ysostegia virginiana = *Cosmos bipinnata*.

P1140

Genome-wide characterization of the MADS-Box gene family and their contribution to organ development in Carnation (*Dianthus caryophyllus* L.)

***Xiaoni Zhang**, Dandan Li, Xiaopeng Fu*
Key Lab of Horticultural Plant Biology (MOE), College of Horticulture & Forestry Sciences, Huazhong Agricultural University

The MADS-box gene family is key regulator in flower development, especially in flowering time regulation and floral organogenesis formation. The systematic identification and characterization of MADS-box gene family has been reported in many plant species such as *Arabidopsis thaliana*, *Oryza sativa*, Orchids, and *etc.*, while it has not been reported in Carnation (*Dianthus caryophyllus* L.). In this study, 39 MADS-box genes were identified from the carnation genome and transcriptome data by the phylogenetic analysis between carnation and *Arabidopsis thaliana*, which were categorized into four subgroups (30 MIKC^c, 2 MIKC*, 2 Mα, 5 Mγ). Meanwhile, the MADS-box domain, gene structure and conserved motif compositions of the carnation MADS genes were analyzed. The MADS-box domain is highly conserved in TypeII class, while duplicated in Type I . Additionally, the expression of DcaMADS genes were systematically investigated in stems, leaves, flower buds and individual flower organs. Some crucial DcaMADS genes correlated with its putative function were validated. The subcellular localization of the 16 DcaMADS proteins in each subclass was investigated. This report is the first to describe genome-wide characterization of the MADS-box gene family in Carnation, and these results could provide valuable information to explore the potential functions of these subfamily.

Biochemical elucidation of the tailing processes for isoflavonoid biosynthesis in kuduzu plant

Yansheng Zhang*, Jia Li, Xin Wang, Changfu Li*
Wuhan Botanical Garden, Chinese Academy of Sciences

As a traditional Chinese medicine, kuduzu root is used for the treatment of cardiovascular diseases and diabetes for a long history in China and other Asia countries as well. The active compounds attributable to those pharmacological activities of *P. lobata* are believed to be isoflavonoids in its root. Previous phytochemical studies revealed that most isoflavonoids in kuduzu roots are derived from daidzein, which is glucosylated at C-7, 8, and 4' positions while the O-methylation takes place at its C-4' and C-3' positions. Despite of important benefits to human health, the knowledge regarding how these daidzein derivatives are formed in kuduzu roots is lacking at present. By the combinatory usage of molecular biological and biochemical techniques, we report here the biochemical mechanism of the tailing processes for the biosynthesis of these unique isoflavonoids in kuduzu roots. This report helps people better understand the biosynthetic pathways to isoflavonoid production in kuduzu plant, and opens a window for a large-scale production of these unique isoflavonoid compounds in microorganisms using synthetic biology techniques in the future.

Mean germination time of Sudangrass seed lots (*Sorghum sudanense*) predicts seed vigor and germination performance in soil

Ye Zhang*, Huifang Yan, Hang Cheng, Peisheng Mao*
China Agricultural University

With the development of animal husbandry, the quality of Sudangrass (*Sorghum sudanense*) seed is becoming increasingly important. But research shows that lab routine germination rate test can not accurate represent germination performance in soil . It is essential to develop a new method to assess the vigor of Sudangrass seed. Previous work on maize and other crops has showed that measurements of mean germination time (MGT; 2mm radicle) is a possible alternative assessment of vigor. Five lots of Sudangrass seeds and two methods (germination in rolled paper test and emergence test simulating field condition) were used in this experiment. The objective of this study was to estimate that weather mean just germination time (MJGT) and mean germination time (MGT) in rolled-paper test could be used to predict the seed vigor of Sudangrass by measuring the related indicators of germination. In the rolled paper germination test of five lots, the result showed that MJGT and MGT were significant negatively correlated with the rate of seed germination, the average length of seedlings and emergence rate at both 18°C and 20-30°C, but were positively related to mean emergence time.It is concluded that the MGT can be used as a reliable method to predict the seed vigor of Sudangrass seed. Meanwhile, the method is time saving and environmental protection.

Middle Triassic Linjia flora from eastern Liaoning, China and its paleoclimatic implication

Yi Zhang[1]*, Shao-Lin Zheng*[1]*, Yong-Dong Wang*[2]
1. College of Paleontology, Shenyang Noraml University; Key Laboratory for Evolution of Past Life in Northeast Asia, MLRC
2. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

The Middle Triassic flora of eastern Liaoning is represented by fossil plants collected from the Linjia Formation of the Linjiawaizi in Benxi of eastern Liaoning, China. The Linjia flora is very spectacular because its components are complicated, representing the only one well-known fossil flora of the Middle Triassic age in NE China. Both typical Paleozoic elements, such as *Lobatannularia*, *Taeniopteris*, *Pterophyllum*, *Psygmophyllum*, *Pecopteris lativenosa*, *P. orientalis*, *P. candolleana* and *Cordaites* as well as typical Mesozoic ones, such as *Pleuromeia*, *Neocalamites*, *Danaeopsis*, *Symopteris*, *Scytophyllum*, *Thinnfeldia*, *Sinozamites*, *Yabeiella*, *Sphenobaiera* and *Podozamites* are documented in this flora. Among them, *Lobatannularia*, *Pleuromeia*, *Scytophyllum* and *Sinozamites* are typical elements from the Northern Hemisphere. The flora also includes some interesting taxa, for example, *Benxiopteris*, similar to the typical element of the Southern Hemisphere, *Dicroidium* in its basic leaf structure, but different in reproductive organs; *Yabeiella*, as a typical element from the Southern Hemisphere; *Glossopteris*-like plants very like *Glossopteris* in its leaf morphology but their reproductive organs unclear. The flora also includes components which are difficult to be assigned, such as *Symopteris*, which is very similar to the Late Paleozoic element, *Fascipteris*. In this flora, two specimens with their counterparts preserved, probably represent the *Gigantopteris*. In one of these two specimens, scars possibly representing the areas of ovule or seed attachment are also preserved. Cathaysian elements, e.g., *Lobatannularia*, *Taeniopteris*, *Gigantopteris* and *Pecopteris lativenosa* mixed with typical Mesozoic components in this flora indicate that the distribution area of the Linjia flora probably represents the known final extinction area of the relict Cathaysian elements in the world. Because the distribution area of the flora was located in the northeastern North China Plate in Middle Triassic, which was controlled by the special warm and humid coast climate, it is reasonable for the relict Cathaysian elements to survive in that time.

Growth and antioxidant enzyme activities of *Hemarthria altissima* and *Cynodon dactylon* in the water-level-fluctuating zone responses to water depth gradient

Zhiyong Zhang[1,2]*, Chengyan Wan*[1]
1. Institute of Hydroecology, Ministry of Water Resources and Chinese Academy of Sciences
2. College of Resource and Environment, Huazhong Agricultural University

Water-level- fluctuating zone (WLFZ) is most common and important in regulated rivers. The Three Gorges Project reached the normal water level of 175 m on October 26, 2010, which resulted in the formation of the WLFZ (up to 30m in elevation) with exposed in summer and submerged in winter. The original vegetation, especially trees and shrubs, could not survive because they could not tolerate the winter submergence and summer drought, while herb was the most abundant life form. Vegetation in the WLFZ zone was dominated by perennial herbs such as *Hemarthria altissima* and *Cynodon dactylon*. Therefore, it is important to examine the ecophysiological adaption mechanisms the dominant species in submergence duration for vegetation restoration in this reservoir. To investigate clone growth and antioxidant enzyme activities of dominant plants in the WLF of the Three Gorges Reservoir, height, cover, sprout number, biomass, content of total protein and Malondiadehyde (MDA), enzyme activity of superoxide dismutase (SOD) and peroxidase (POD) of root system of *H. altissima* and *C. dactylon* were detected at four water depths (0,2, 5 and 15 m) in situ experiment from December in 2014 to May in 2015. Both plants were cultivated in plastic pots hanged on a floating platform. The correlation coefficients of among total protein and antioxidant enzyme activities of root system were also analyzed. The results showed that height, cover, sprout number, biomass, total protein, enzyme activity of SOD, content of MDA of root system declined compared with non-flooded (0 m). However, the activity of POD of root system increased. Height, cover, sprout number, the content of total protein and the activity of SOD decreased with increasing water depths. However, the activity of POD increased significantly. The results of regression analysis showed that significant positive correlation was observed between the content of MDA and the activity of SOD. Submergence may play a role in correlation coefficients of between total protein and antioxidant enzyme activities. The coefficients among SOD and POD, MDA and SOD of root system were lowest at the water depth of 15 m. The coefficients of among enzymes of *C. dactylon* were higher than those of *H. altissima*.

Genome-wide identification, characterization of the MADS-Box gene family in Chinese jujube and their involvement in flower development

Liman Zhang[1], ***Jin Zhao***[1], *Weilin Gao*[1], *Mengjun Liu*[2], *Jiurui Wang*[3]
1. College of Life Science, Hebei Agricultural University
2. Research Center of Chinese Jujube, Hebei Agricultural University
3. College of Forestry, Hebei Agricultural University

MADS-box genes encode transcription factors that are involved in plant development control (particularly in floral organogenesis) and signal transduction pathways, though a comprehensive analysis of MADS-box family proteins in Chinese jujube (*Ziziphus jujuba* Mill.) is still missing. Here, we report a genome-wide analysis of the MADS-box gene family in Chinese jujube. Based on phylogenetic analyses, 52 jujube MADS-box genes were classified into 25 MIKC^{C}-type, 3 MIKC*-type, 16 Mα, 5 Mβ and 3 Mγ genes. 37 genes were randomly distributed across all 12 putative chromosomes. We found that the type II genes are more complex than the type I genes and that tandem duplications have occurred in three groups of MADS-box genes. Meanwhile, some gene pairs in the same clade displayed similar or distinct expression profiles, suggesting possible functional redundancy or divergence. MIKC^{C}-type genes exhibited typical temporal and spatial expression patterns in the four whorls of floral tissues. The expressions of B, C/D and E-type genes were significantly suppressed in phyllody as compared to flower, providing valuable evidence for their involvement in flower development. This study is the first comprehensive analysis of the MADS-box family in jujube, and provides valuable information for elucidating molecular regulation mechanism of jujube flower development.

Effect of shading manipulations and growth regulators on shell differentiation in walnut (*Juglans regia*)

Shugang Zhao[1], *Hongxia Wang*[2], *Jing Wen*[2], *Shuang Wang*[2], *Zhihua Zhang*[2]
1. College of Life Sciences, Hebei Agricultural University, Baoding, Hebei
2. Mountain Area Research Institute, Hebei Agricultural University, Baoding, Hebei

Walnut (*Juglans regia* L.) shell, is often overlooked, plays an important role in nut development, transportation, washing and storage. In particular, kernel quality has close relations to shell seal grade and thickness. Walnut shell structure is influenced by cultivars, illumination intensity and harvest period, effective mechanism is not well understood. In this study, the morphologic characteristics and composition of nutshell were studied with applications of different plant growth regulators and two levels of shading. Result show that mature shell is composed of three parts, sclereid layer, sclerenchyma cell layer and fiber-like cell layer, from outside to inside respectively. 30% and 70% shading treatment caused shell thickness to thin and number of sclereid layer to reduce, content of lignin and polyphenol to decrease, number of fiber-like cell layer to increase. In addition, 70% shading treatment significantly caused shell seal grade to reduce. 50mg/L GA_3 treatment dramatically caused shell thickness and number of sclereid layer to increase. 100mg/L paclobutrazol treatment significantly caused shell thickness and number of sclereid layer to thin, content of lignin and polyphenol and seal grade to reduce. From these data light and plant regulators are important affected the nutshell structure.

The impact of inoculation with mycorrhizal fungi *in vitro* on growth and resistant enzymes of *Rhododendron moulmainense*

Yujie Zhou, *Jiuxiang Huang*
College of Forestry and landscape Architecture, South China Agricultural University

We conducted a study of *Rhododendron moulmainense* inoculation with mycorrhizal fungi to select the better strains, and to provide the reference for improving breeding efficiency, also to reveal the mechanism of improving plant resistance by mycorrhizal fungi. 7 kinds ericoid mycorrhizal fungis, separated from wild *Rhododendron moulmainense*, were used to inoculate *Rhododendron moul-*

mainense tissue culture seedling. Growth situation was observed regularly, and height growth rate, biomass growth rate, mycorrhizal infection rate, disease index, PAL and LOX activity were determined. The result showed that: (1) Plants of control group were wizened after 2 weeks, but plants of mycorrhizal inoculation treatment were viable. (2) Height growth rates and biomass growth rates of NO.7 treatment were the highest, 71.81% and 83.62% respectively, NO.17 and NO.14 treatment fllowed. Mycorrhizal infection rates of NO.16 treatment were the highest, NO.1 treatment were the lowest. Disease indexes of NO.7 were the lowest, NO.5 and NO.3 were the highest. PAL and LOX activity of each mycorrhizal inoculation treatment all higher than control group. PAL and LOX activity of NO.16 treatment were the highest, 4.82 U/mg and 0.88 U/mg respectively, PAL activity of NO.1, NO.5, NO.17 were the lowest, 1.90~2.20 U/mg, LOX activity of NO.1, NO.3 were the lowest, 0.29~0.38 U/mg. The correlation analysis showed that, colonization intensity were positively correlated with PAL and LOX activity significantly, but disease index were negatively correlated with PAL and LOX activity. Each of the 7 kinds ericoid mycorrhizal fungi could form mycorrhizal symbionts with *Rhododendron moulmainense*, but different fungis had different impact on growth of host plants, the result showed that, NO.7 (*Bionectria ochroleuca*) was the optimal fungi, NO.14 (*Aspergillus sydowii*) and NO.17 (*Paecilomyces javanicus*) were the second choices. Higher mycorrhizal infection rate help to improve PAL and LOX activity. It may have an impact on resistant and growth of plants, but resistant and growth of plants were more impacted by species of fungi.

Regulation of β-carotene biosynthesis and accumulation in maize endosperm

Changfu Zhu[1,2], *Chao Bai*[2], *Xin Jin*[2], *Judit Berman*[2], *Gemma Farre*[2], *Teresa Capell*[2], *Paul Christou*[2,3]
1. Changchun Normal University
2. University of Lleida-Agrotecnio Center
3. Catalan Institute for Research and Advanced Studies

Over the last two decades, many carotenogenic genes have been cloned and used to generate plants accumulating higher levels of carotenoids. However, comparatively little is known about the regulation of endogenous carotenogenic gene expression in higher plants, and this limits our ability to predict how engineered plants will perform in terms of carotenoid content and composition. Maize (*Zea mays* L.) is one of the most widely grown crops in the world, and is an important source of human food, animal feed and bioenergy. Maize β-carotene hydroxylase 2 (BCH2 also termed crtRB1, or HYD3) governs critical steps in the carotenoid biosynthetic pathway in endosperm. *ZmBCH2* alleles associated with reduced transcript expression correlate with higher β-carotene accumulation. Here we report that *ZmBCH2* is preferentially transcribed in maize endosperm and is regulated developmentally, further confirming the important role of ZmBCH2 in carotenoid biosynthesis in the endosperm. Moreover silencing of maize *BCH2* resulted in increased β-carotene content in the endosperm in different maize genetic backgrounds. In order to understand the regulatory mechanisms controlling *ZmBCH2* expression, the full-length *ZmBCH2* promoter and a series of its 5′-deletions were fused to the β-glucuronidase (*GUS*) reporter gene and transferred into rice (*Oryza sativa*) to test the promoter activities. The results showed that the 2,036 bp upstream region from the translational start site drove GUS expression preferentially in the endosperm, but not in leaves of transgenic rice plants which is consistent with the *ZmBCH2* expression pattern in maize. We also demonstrated that the 5′-untranslated region containing the first intron in *ZmBCH2* plays a critical role in terms of conferring high levels of expression in endosperm. We found that the 774 bp 5′-flanking region upstream from the translation start site contained all the necessary *cis*-regulatory elements responsible for higher GUS expression in transgenic rice endosperm. This basal promoter region of 774 bp 5′-flanking sequence of *ZmBCH2* contained a single prolamin box and one AACA motif which are specifically recognized and bound by endosperm-specific prolamin-box binding factor (PBF) and GAMYB transcription factors, respectively. The expression patterns of isolated *ZmPBF* and *ZmGAMYB* genes were similar to that of *ZmBCH2* which is preferentially transcribed in maize endosperm and is regulated developmentally. We are currently in the process of determining whether ZmPBF and ZmGAMYB act individually or synergistically to regulate seed-specific *ZmBCH2* expression.

Physiological and molecular mechanisms mediating xylem Na^+ loading in barley in the context of salinity stress tolerance

Min Zhu, *Meixue Zhou, Lana Shabala, Sergey Shabala*
School of Land and Food, University of Tasmania

Control of xylem sodium loading is crucial to salinity stress tolerance in plants. In this study we screened a large number of barley genotypes for their ability to exclude Na^+ for its loading into the xylem and delivery to the shoot. Using four genotypes contrasting in salinity stress tolerance, we then studied kinetics of xylem Na^+ and K^+ loading at multiple time points and linked it with overall plant performance and sequestration of Na^+ and K^+ in leaf tissues. Our results showed that both leaf and xylem K^+/Na^+ ratios had positively correlated with overall plant salt tolerance after prolonged (5 weeks) exposures to salinity stress. Interestingly, it was Na^+ but not K^+ content that determined this correlation. In shorter terms, accumulation of Na^+ in the xylem sap of salt-tolerant genotypes TX9425 and CM72 was higher than in salt-sensitive genotypes Naso Nijo and Gairdner. It reached its peak 5 days after salt application and then declined. Salt-sensitive varieties were less efficient in controlling xylem Na^+ loading and showed a gradual increase in the xylem Na^+ content over the time. The MIFE (microelectrode ion flux measurement) technique was then applied to study some aspects of salt stress signalling and Na^+ loading into the xylem, through measuring net fluxes of Ca^{2+}, K^+ and Na^+ from xylem parenchyma tissue of control- and salt-grown plants in response to two known second messengers H_2O_2, and ABA. Our results indicates that NADPH oxidase-mediated apoplastic H_2O_2 production acts upstream of xylem Na^+ loading and is causally related to ROS-inducible Ca^{2+} uptake systems in the xylem parenchyma tissue. It was also found that ABA regulate (directly or indirectly) the process of Na$^+$ retrieval from the xylem. Transcript levels of *HvHKT1;5_like* and *HvSOS1_like* genes in root stele was observed to decrease after salt stress while there was an increase in *HvSKOR_like* gene, indicating that these ion transporters are involved in primary Na$^+$/K$^+$ movement into/out of xylem.

Probing the efects of mutation of *PsbO-D158* in photosystem II

Qingjun Zhu[1], *Yanyan Yang*[1], *Guangye Han*[1], *Jian-Ren Shen*[1,2]

1. Institute of Botany, the Chinese Academy of Sciences
2. Okayama University

Photosystem II (PSII) is a large membrane-bound protein complex containing 20 subunits, which performs light-induced charge separation and a series of electron transfer reactions that lead to water oxidation and plastoquinone reduction. Mn$_4$CaO$_5$ cluster is the catalytic heart where water oxidation takes place. The protons generated by water oxidation need be transferred to the lumenal side of thylakoid membrane, in order to form trans-membrane proton gradient for the synthesis of ATP. It is generally accepted that protons are transported by hydrogen bond networks formed by water molecules and amino acid residues. Based on the high-resolution structure of PSII, *PsbO-D158* participates in one of the hydrogen bond networks starting from the Mn$_4$CaO$_5$ cluster. In order to study the role of this site in proton channel, three mutants were generated where *PsbO-D158* was changed to K, N or E, respectively. The photoautotrophic growth of these three mutants was found to be roughly the same, but slower than that of the wild type. The oxygen evolving activity of three mutant cells was approximately 35% of the oxygen evolving activity of wild type. However, the isolated thylakoid membrane of three mutants showed no oxygen evolving activity, which was found to be due to the loss of peripheral proteins during the isolation process. These results suggest that *psbO-D158* may play an important role in maintaining the binding of *PsbO* with the PSII complex.

Evaluating antioxidant activity and some secondary methabolits in wild almond (*Amygdalus scoparia L,*)

Lale Ziaebrahimi, *Somayeh Fariabi*

Islamic Azad University, Kerman Branch

The purpose of this study was to evaluate the antioxidant activity, total phenol and flavonoid content in methanol extracts of fruits and flowers of three Almond subspecies. The content of total phenol and flavonoid pigments was measured with colorimetric method. Antioxidant capacity of plant extracts were evaluated by DPPH method. In the present study the highest antioxidant activity measured in Archen. IC50 values in the methanol extract of three sub-species of bitter almond, sweet almond and Archn was 126,115 and 85 µg/ml respectively that in comparison with BHT, indicating a relatively high antioxidant capacity. The highest level of Phenol and flavonoid was in Archen, then in Sweet Almond and Bitter almonds Respectively. The results indicate that green exocarp of the three subspecies have higher antioxidant effect than the flowers.

4. Senckenberg Museum of Natural History Görlitz, Department of Botany
5. German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig
6. International Institute Zittau, Technische Universität Dresden

Leaf venation traits are important for many research fields such as systematics and evolutionary biology, plant physiology, climate change, and paleoecology. In spite of an increasing demand of vein trait data, studies are often data-delimited because traditional destructive methods for imaging vein networks are slow. Recently, non-destructive X-ray technology proved useful as an alternative. However, the utility of rapid 2D X-ray was partially limited because image resolution was often insufficient to visualize the smallest veins. Here, we advance X-ray technology to increase image resolution and thereby the utility of high-throughput visualization of leaf venation together with new standards for very high resolution imaging using microfocus X-ray computed tomography. For 2D microradiography, we developed a new method, which allowed us to achieve an image resolution of 7 µm, i.e. almost a 4-fold increase compared to the industrial standard. In the majority of the samples, there was a significant improvement in estimates of minor vein density even without applying a contrasting agent. In X-ray computed tomography, our approach outcompeted traditional imaging of chemically cleared venation in terms of vein resolution. In conclusion, our study demonstrates that the here established 2D X-ray imaging approach is a significant advancement for high-throughput visualization of leaf venation networks. Additionally, with our methodological advancement, microfocus X-ray tomography becomes a valuable alternative to traditional methods of very-high resolution imaging of leaf venation.

Interaction of microfilaments with microtubules mediated by AtFH14

Jiaojiao Wang, Xiuhua Xue, Xiangfei Wang, Bailing Hu, ***Haiyun Ren***

Key Laboratory of Cell Proliferation and Regulation Biology of Ministry of Education, College of Life Science, Beijing Normal University

Arabidopsis formin 14 (AtFH14) decorates preprophase bands, spindles, and phragmoplasts, and may function as a linking protein between microtubules and microfilaments. Here, we compare the binding activity of AtFH14FH1FH2 to actin filaments (AFs) and microtubules (MTs), and quantitative analyses reveal that the binding affinity of AtFH14FH1FH2 to microtubules is 20-folds higher than to actin filaments. However, AtFH14FH1FH2 cannot interact with monomeric tubulin and the microtubule-binding AtFH14 FH1FH2 can bind to the side of actin filaments and inhibits the nucleation, suggesting that the microtubule-binding AtFH14FH1FH2 cannot interact with the end of actin filament. Furthermore, we employ TIRFM and single-molecule imaging technology to find that AtFH14 FH1FH2 can recruit AFs to microtubules, and the AFs can slide on microtubules physically randomly. The quantitative assays indicate that the elongation and sliding rates of AFs bind to microtubules are decreased by AtFH14FH1FH2. AtFH14FH1FH2-RFP and microfilament /microtubules fluorescence marker are transiently co-expressed in onion epidermal cells. The results indicate that AtFH14 FH1FH2-RFP co-localize with cortical microtubules marked by MAP4-GFP, that is identify with the in vitro result of higher ability to bind with microtubules. The binding of FH1FH2-RFP to microtubules were revealed to be dynamic by fluorescence recovery after photobleaching experiment. Time-lapse confocal microscopy showed that FH1FH2-RFP could display a dynamics similar to the microtubule dynamic instability. Pharmacological assays on the double fluorescence labeled cells with latrunculin B indicate that reorganization of microfilaments is easier to bind with microtubules marked by FH1FH2-RFP than MAP4-GFP. Our results suggest that AtFH14 function as a cross-linker between microfilaments and microtubules in regulating dynamics of actin and microtubule cytoskeletons by recruiting actin filament to microtubules via binding the side of actin filament in plant cells.

P1405

Studies of the mechanisms that AtFH14 bundles microfilaments and microtubules

Zhanhong Ren, Yunqiu He, Shanwei Li, Xiuhua Xue, ***Haiyun Ren***
Key Laboratory of Cell Proliferation and Regulation Biology of Ministry of Education, College of Life Science, Beijing Normal University, Beijing, China

Microtubles and microfilaments are two major cytoskeletal networks found in plant cells. Both of them play important roles in many aspects of fundamental processes of plant cell growth and development, such as cell division, cell expansion, intracellular organization and motility. AtFH14, a type II formin from *Arabidopsis thaliana*, was found to bundle and crosslink microtubule and microfilament arrays, these processes of which are vital to plant cell growth and morphogenes.However, the mechanism by which AtFH14 bundle microtubule and microfilaments in plant is still not well understood. In this study, we found that AtFH14FH2 contains three highly conserved basic amino acids which are considered to interact with the negative charge surface of microfilaments and microtubules in mDia1. Compared with AtFH14, the bundling ability of the three sites mutagenesis protein (Lys845Ala, Arg850Ala and Lys855Ala in AtFH14) is weaken, which indicates that these three amino acids have an effect on the bundling ability of AtFH14, but may not act as critical roles in actin filament bundling. Then we purified AtFH14FH2△N which was acquired via protease digestion of α-chymotrypsin. Although the post subdomain of AtFH14FH2△N contains Lys845, Arg850 and Lys855 which may constitute a binding interface with other proteins such as F-actin, it lacks the amino terminal. And the result of high and low speed co-precipitation experiments indicate that AtFH14FH2△N neither bind nor bundle microfilament and the amino terminal of AtFH14 FH2 plays an important role in actin filament bundling. In summary, we propose that the amino terminal (1-93) of FH2 play a critical roles in the binding and bundling of AtFH14 to microfilaments and microtubules.

Characterization of a putative microtubule-associated protein of *Arabidopsis thaliana*

Pingzhou Du, Lu Deng, Lu Liu, Xiuhua Xue, ***Haiyun Ren***
Key Laboratory of Cell Proliferation and Regulation Biology of Ministry of Education, College of Life Science, Beijing Normal University

Highly dynamic microtubules, regulated by many microtubule-associated proteins (MAPs), play acritical role in many important physiological processes, such as cell morphogenesis, cell expansion and cell division. We derived a possible microtubule-associated protein 96 (MAP96) from *Arabidopsis thaliana*. Our preliminary results showed that AtMAP96-GFP localized in a transverse filamentous network manner at the pericellular, distributed radially around the nucleus, or simultaneously had the former two forms of distribution in stable transgenic BY-2 cells in interphase. During mitosis, the localization of AtMAP96 changed in consistent with specific microtubule or microfilament arrays, such as the preprophase band, the spindle apparatus, phragmoplasts. To verify whether AtMAP96 is co-localized with microtubule or actin filaments, pharmacological experiments were applied. After treatment with a microtubule depolymerizing drug, oryzalin, we found that AtMAP96-GFP filamentous network became disorder as thedepolymerization of intracellular microtubules. While AtMAP96-GFP filamentous network was stillcomparative integrity treated with the latrunculin B, a microfilament depolymerizing drug. In addition, immunofluorescence results showed that AtMAP96 and microtubules were co-localized in different stages during the cell cycle progression. These data suggest that AtMAP96 co-localizemainly with microtubules in living plant cells and it may regulate the dynamics of microtubule cytoskeleton, thereby participating in cell growth and division.

Microscopic study of chloroplast development in the albino mutant *bzs20* in *Arabidopsis*

Wing Shing Wong*, Na Li, Zheze Zhao, King Shing Wong, Junxian He*
School of Life Sciences, State Key Laboratory of Agrobiotechnology, The Chinese University of Hong Kong, Sha Tin, New Territories, Hong Kong SAR, China

Chloroplasts are essential organelles which dedicate to undergo photosynthesis to provide energy for plant survival and development. In the early stage of seed development, chloroplasts already exist in embryo. During embryo maturation, photosynthetic active chloroplasts dedifferentiate to etioplasts which are non-photosynthetic and colorless because of loss of pigments (chlorophylls and carotenoids). While upon seed germination, light exposure converts the etioplasts into chloroplasts which contain activated chlorophylls required for photosynthesis. Normal biogenesis and development of chloroplasts ensure plants to obtain optimal amount of energy form photosynthesis. Previous studies in our laboratory have discovered a novel albino mutant *bzs20* in *Arabidopsis thaliana*. *bzs20* is a recessive T-DNA insertion mutant which is seedling lethal and shows albino cotyledons and pale green true leaves. Thus, *bzs20* mutation might have caused some defects in chloroplast development or synthesis of the green pigment chlorophyll. However, the detailed mechanisms causing these defects remain unknown. Therefore, the aim of my thesis project is to perform further detailed phenotypic studies to the *bzs20* mutant, particularly to the chloroplast ultrastructure during seedling development. To this end, different approaches and methodologies have been applied to illustrate the chloroplast development defects in the *bzs20* mutant plant. Ultrastructural analysis with TEM reveals that the mutant is destructive in thylakoid network and lacking starch grains in chloroplast. Phenotypes of *bzs20* embryos during embryogenesis have been observed with light microscopy. However, no significant morphological difference was observed between *bzs20* and wild-type embryos, indicating that the albino phenotype is not formed during embryogenesis. Therefore, we will test whether the albino phenotype is formed during seedlings process or during or after seed maturation processes. These structural studies of chloroplast development in the novel albino mutant *bzs20* will help understanding the function of *BZS20* gene in regulating the normal development of chloroplasts in plants. This work was supported by the GRF grants (14121915,14148916) and an AoE grant (AoE/M-05/12) from the Research Grant Council of Hong Kong, the Shenzhen Science & Technology Research & Development Funding - Peacock Scheme, and the Direct Grants from The Chinese University of Hong Kong.

An *Arabidopsis* mutant deficiency in sphingolipid desaturase is used as a tool to investigate function of plasmodesmata

Ning-Jing Liu[1], *Pei-Shuang Chen*[1], ***Yong-Mei Qin***[1], *Yu-Xian Zhu*[1,2]
1. The State Key Laboratory of Protein and Plant Gene Research, College of Life Sciences, Peking University
2. Institute for Advanced Studies, College of Life Sciences, Wuhan University

Sphingolipdis along with sterols are essential constituents of plasma membrane located raft-like domains, detergent-resistant membranes (DRMs) suggested by the presence of glycosylphospatidylinositol (GPI)–anchored proteins and receptor-like kinases. DRMs contribute to the sorting, trafficking and targeting of specific plasma membrane proteins, which are involved a range of cellular processes. Plasmodesmata (PD) mediate intercellular transport of nutrients, RNA, metabolites, plant viruses, and plays vital roles in plant developmental events and cooperative responses to environmental stimuli. A link between DRM and PD has been suggested based on the identification of the first DRM marker protein, Remorin. Proteomic approaches identified Remorin and GPI-anchored proteins on PD, suggesting the presence of plasmodesmata DRMs. Here, we showed that *Arabidopsis* double mutant *sld1/sld2* lacking sphingolipid long chain-base delta 8 desaturase (SLD), exhibiting leaf yellowing and spontaneous cell death. A fast increase of free phytosphinganine (t18:0) in the leaves was detected after the plants were challenged by fungal wilt pathogen *Verticillium dahlia* or bacterium *Peudomonas syringae* pv *tomato*. Exogenous application of t18:0 promoted the wild-type plants to enhance their resistance against *V. dahliae* or *Pst* DC3000. In consistent with this observation, the *sld1/sld2* plants accumulated in t18:0 displayed enhanced resistance to these pathogens. Further, we extracted and purified PD-enriched membrane fractions. Lipid profiles indicated that t18:0-based glycosylinositolphosphoceramides were enriched in the *sld1/sld2* compared with the wild-type. The transcripts of the genes encoding callose synthase significantly accumulated, which correlated with the increased callose synthase activity in the *sld1/sld2*. Results of Aniline blue staining and dye-loading indicated that the *sld1/sld2* plants increased callose deposition and lowered PD trafficking activity. Our data suggests that phytosphinganine acts as a key component of complex sphingolipids for regulation of PD structure and function during immune-responses to pathogen infections in *Arabidopsis* plants.

Ultrastructure of plastids in secretory cells in relation to secretion composition in *Cleome* (*Cleomaceae*)

Alexandra Ivanova[1,2], ***Nuria Koteyeva***[1], *Elena Voznesenskaya*[1]
1. Komarov Botanical Ibstitute
2. St. Petersburg State University

Plastids and endoplasmic reticulum in secretory cells are the main sites of secondary metabolite secretion biosynthesis. The structure of plastids is very multifarious in secretory cells; it was concluded to be related to secretion composition. Ultrastructure, secretion composition and development of glandular trichomes was studied in 15 *Cleome* species to expand our knowledge of plastid functioning and ontogeny. Glandular trichomes of four main types were distinguished in *Cleome*. In the most studied species glandular trichomes produce more or less hydrophilic secretion that consists of terpenoids, carbohydrates, phenylpropanoids. Secretion accumulates in subcuticular space in C. *viscosa,* C. *paradoxa* and in *C. droserifolia* large trichomes. In other species and trichome types secretion the secretion trickles down the trichome to the plant surface. It is well known that plastids in secretory cells producing monoterpenes are leucoplasts with undeveloped thylakoid system. In contrast, developed grana are contained in plastids of secretory cells in *Cleome* species except *C. viscosa* that produce hydrophobic oleoresin. Analogous to *Artemisia annua*, lower cell layer in the glandular head of *Cleome* trichomes contain chloroplasts, upper layers contain leucoplast-like plastids. Endoplasmic reticulum (ER) is abundant, smooth ER prevails usually except trichomes located over veins on the leaves of *C. monophylla*, *C. gynandra* and *C. viridiflora* where granular ER is developed. Plastids in *Cleome* secretory cells have multiple and/or long contacts with smooth ER elements that is characteristic to resin producing cells. Opaque granules within reticular cisternae are thought to be terpenoids on their way via ER to periplasmic space and than to subcuticular space. The sections of plastids in secreting cells are multiple, they are ameboid in the most species. Sections in the same cell are so different in *C. droserifolia* that they seem to be plastids of different types, chloroplasts and leucoplasts. But serial sections and reconstruction of plastids provide evidences that plastids in secretory cells are large branched structures; in *C. droserifolia* they contain different compartments. Number of plastids is significantly less than in progenitor tissues and moreover in the secretory cells at presecretory stage. Plastid degradation by autophagy during maturation of secretory cells was shown in glandular trichomes of *C. africana* and *C. hassleriana*. In conclusion, glandular trichomes in *Cleome* species as well as and plastids in their secretory cells have the common characters with terpenoid secreting ones and special features (like chloroplast in secretory cells) that are interesting for the future research. The study of plastid morphology in closely related species may be useful to reveal the correlations between specific characters of ultrastructure and the synthesis of certain groups of metabolites in secretion. The research was partly supported by core facility “Molecular and cell technologies” of St. Petersburg State University.

A putative MYB-like transcription factor involved in secondary cell wall formation in *Arabidopsis*

Chunming Wang, *Meihui Yu, Junxian He*

School of Life Sciences and State Key Laboratory of Agribiotechnology, The Chinese University of Hong Kong. Shatin, New Teritorries, Hong Kong SAR

Secondary cell walls (SCWs) are important for plants to support their growth and adapt to changing environments. SCWs are composed mainly of three biopolymers, namely lignin, cellulose and hemicellulose. Studies have suggested that the biosynthesis of these biopolymers is regulated by a complex transcriptional network. However, the details of this transcriptional network have not been fully uncovered. From an activation tagging based genetic mutant screen in *Arabidopsis*, we identified a new mutant, *rif1* (*Respressor of Interfascicular Fibers 1*), which has severe defects in secondary wall formation in stems, making the plant cannot stand erectly. Microscopy study indicated that the SCW deposition in interfascicular fibers of *rif1* is completely missing, and SCW components assay showed that the levels of the three biopolymers are all significantly decreased in the *rif1* mutant. *RIF1* encodes a MYB like transcription factor in *Arabidopsis* which has not been characterized before. RIF1 is localized in nucleus and has putative transcriptional regulatory activity. From a protoplast transcription transient assay, we demonstrate that RIF1 acts as a transcriptional repressor and negatively regulate several important SCW biosynthesis genes. Our results suggest that RIF1 may define a novel negative transcription regulator in SCW formation in plants. This work was supported by the GRF grants (14121915 and 14148916) and the AoE grants (AoE/M-05/12, AoE/M-403/16) from the Research Grant Council of Hong Kong, the Shenzhen Science & Technology Research & Development Funding - Peacock Scheme, and the Direct Grants from The Chinese University of Hong Kong.

2. Kazan Institute of Biochemistry and Biophysics of Kazan Science Centre of the Russian Academy of Sciences, Laboratory of Physiology and Genetics of Plant Cell Cultures

3. Kazan Federal University, Institute of Fundamental Medicine and Biology, Department of Botany and Plant Physiology

4. Department of Cell Biology, Faculty of Biology and Environmental Protection, University of Silesia in Katowice

The data that was obtained during the cultivation of tissue cultures on different plants demonstrated an increase in genetic variability. The morphogenic calli of *Fagopyrum tataricum* (Tartary buckwheat), which together with non-morphogenic clones make a unique system for studying the mechanisms that are responsible for this genetic instability/stability, are an interesting exclusion from this rule. The morphogenic calli of Tartary buckwheat are able to preserve genetic stability and high morphogenic potential through ten years of cultivation. This feature appears to be unique in the plant kingdom. Tartary buckwheat is a wild species in Europe and is treated as a weed. However, it is widely used as a food crop in Asia. Tartary buckwheat is a source of rutin and other bioflavonoids and these compounds are powerful antioxidants that can be used to prevent cardiovascular diseases and cancer. In this work, we used histological sections and transmission electron microscopy to identify and describe the micro- and ultrastructure of the nuclei in morphogenic and non-morphogenic callus lines. We demonstrated that the embryogenic callus cells had prominent round nuclei in contrast to the non-morphogenic callus lines, in which we found multilobed nuclei. Flow cytometry analysis revealed significant differences in the relative DNA content between the analysed calli. The results of flow cytometry showed that the non-morphogenic calli are of an aneuploid nature. The TUNEL test enabled us to visualise the nuclei that had DNA fragmentation in both the morphogenic and non-morphogenic lines. We revealed significantly higher frequencies of positively labelled nuclei in the non-morphogenic callus lines than in the morphogenic ones. These results clearly indicate greater genome stability in the morphogenic callus lines.

Effect of ethyl methanesulphonate on broad bean (*Vicia faba* L.)

Moumita Basu

University of Gour Banga

Broad bean or Fava bean is widely used in the Mediterranean region as source of protein in both human and animal nutrition. Broad bean (*Vicia faba* L.), referred to as broad bean, horse bean or field bean – is a major food and feed legume because of the high nutritional value of its seeds. But modern agronomic demand is of high yielding cultivars of the crop. There are certain limitations of producing high yielding cultivars through traditional hybridization method. Mutation breeding is such a technology which can fulfill the mission by overcoming all sorts of agronomic hazards. Now-a-days the mutation breeding is no doubt neglected to some extent avoiding laborious field experimentations and monumental skills. Not only this, it is a chance factor to achieve a desirable promising line. In present study, attempt has been made to ascertain the magnitude of induced genetic variability followed by mutagenesis with EMS (Ethyl methanesulphonate) and also magnitude of associations between yield and its component characters in M1 generation. The broad bean varieties differed in response to the mutagenic treatments regarding quantitative traits, viz; plant height at 50% flowering phase(cm),days to 50% flowering phase, total number of branches per plant, length of leaf(cm), total number of pods per plant, length of pod(cm), total number of seeds per pod, plant height at maturity(cm),100 seeds weight(g), yield per plant(g). Analysis of variance (ANOVA) showed highly significant differences among the genotypes for almost all the characters studied, there by suggesting the presences of considerable amount of variability among the six genotypes of broad bean under study. It is evident that there were very little differences in GCV and PCV for length of leaf(cm), length of pod(cm), total number of seeds per pod, plant height at maturity(cm), 100 seeds weight(g),-yield per plant(g) among the character studies. This indicates that these characters changed a little due to effect of the environmental factors, while other characters showed higher degree of environmental influences. Higher GCV values in major characters like total number of pods per plant, yield per plant(g) proved the existence of justifiable genetic variation among the genotypes under study. High heritability combined with high genetic advanced over mean was observed for 100 seeds weight (g), yield per plant(g), length of leaf(cm) showing additive gene effect. Therefore, it is logical that selection based on the phenotypic performance on those traits would be effective. The inter relationship among the nine characters were studied in the population of six genotype (to control and four M1 lines) through ‘correlation co-efficient analysis’.The results revealed that the positive correlations of one-character pair e.g, 100 seeds weight(g) vs. plant height at maturity(cm), indicates that increasing one character would result in increase in other character. Thus, the results of co-heritability estimates and evaluations of genotypic and phenotypic correlations speak the same language as for as important characteristics

Transcriptome and chloroplast genome sequencing decipher the origin and diversification of allotetraploid *Brassica napus*

Hong An[1]*, Xinshuai Qi*[2]*, Michael Barker*[2]*, J. Chris Pires*[1]
1. University of Missouri
2. University of Arizona

Brassica napus is a worldwide multiuse crop, especially as a very important edible oil resource. It is an allopolyploid species naturally hybridized from *Brassica rapa* (AA=20) and *Brassica oleracea* (CC=19) about 7,500 years ago. Now, it mainly has three groups: *B. napus subsp. oleifera*, *B. napus subsp. rapifera* and *B. napus subsp. pabularia*. To study its origin and diversification, we collected 187 *B. napus*, 137 *B. rapa*, 43 *B. oleracea* and 22 other C genome related accessions, and then generated high density genome-wide nuclear and chloroplast SNPs data based on these collections from high-throughput RNA-seq and GSS data. According to our nuclear genome data, we confirmed it originated from Europe and the *B. napus subsp. oleifera* group was diversified into spring type, European winter type and East Asian winter type. Besides that, we also found that A sub-genome and C sub-genome had different nuclear phylogenies and nucleotide diversity, which suggests A and C sub-genome may have experienced different selection. We will use whole chloroplast genomic SNPs to construct chloroplast phylogeny among all our collections to explore the multi- or single- origin hypothesis and the maternal species of *B. napus*. The selective sweep regions and founder haplotypes will also be studied to get a better understand of their diversification. These results have implications for understanding the evolutionary patterns and processes after their initial domestication and will facilitate further studies of Brassica genomics and *Brassica napus* crop improvement.

Isolation and screening of viable mutants for yield contributing traits in groundnut (*Arachis hypogaea* L.)

Jeevakoti Apparao Boddu
Jijamata College of Science and Arts, Bhende.

In the present investigation, an attempt was made to induce genetic variability in yield contributing traits, viz., plant height, number of primary branches per plant, number of pods per plant, number of seeds per pod, days to maturity, days to flowering, hundred seed weight and seed yield per plant, in groundnut (*Arachis hypogaea* L.), employing gamma radiation (γ). Germplasms of a locally adopted cultivar of groundnut, JL-24, were irradiated with different doses (10, 15, 20, 25 and 30 KR) of gamma rays and were sown in the field to raise M_1 progeny. Subsequently M_2 and M_3 progenies were raised using M_1 and M_2 seeds. The progeny plants in M_2 generation were screened for presence of mutations in yield contributing traits. They showed presence of 6 different types of plant type mutations viz., tall mutants, pod mutants, early maturing mutant, high yielding mutant and seed coat colour mutants, as compared to control. All these 6 different types of mutations were recovered even in the M_3 generation, as viable mutants. Remarkable achievement of the present investigation is isolation of early maturing and high yielding mutants. The early maturing mutants were at least 8-10 days early in flowering and in attaining maturity. The high yielding mutants showed significant increase in almost all yield contributing traits as compared to control. Some of these viable mutants seemed to be very promising and can be used in breeding programs aimed at genetic improvement of groundnut.

Comparative transcriptome analysis and phenotypic monitoring of *Trifolium pratense* (Fabaceae) under land use scenarios

Denise Herbert, *Annette Becker*
Justus Liebig University Giessen

Red clover (*Trifolium pratense*) is an important forage crop worldwide and of great interest to agriculture, offering a high nutritional value and soil improving characteristics, which can improve intake in livestock farming and reduce the need of fertilizer. Unfortunately, its persistence to environmental perturbation is low such that red clover shows drastic phenotypic plasticity, affecting the whole plant morphology, architecture and growth behavior in response to grazing and mowing. We address the question on the exact nature of these morphological changes in response to mowing/grazing as well as which genetic pathways lead to the induced phenotypic plasticity. A combination of phenotypic monitoring, including the measurement of a large scale of morphological important traits to describe the temporal changes in response to grazing/mowing andtranscriptome analysis from plants grown on different field sites and treatments. This will provide a deeper insight gene expression changes underlying the observed morphological plasticity. This allows the identification of candidate genes for further functional analysis including transgenic approaches to ultimately understand the complex molecular mechanism of the red clover's phenotypic plasticity in response to mowing/grazing. We will provide results of the digital gene expression analysis between combinations of different transcriptomes and their preliminary functional analysis. Genes acting as chromatin remodelers and others involved in the gibberellin pathway may be responsible for the phenotypic changes during regrowth.

snRNA 3' end processing by a CPSF73-containing complex essential for development in *Arabidopsis*

Liu Yufeng, ***Bin Yu***
Center for Plant Science Innovation and School of Biological Sciences, University of Nebraska, Lincoln, NE 68588–0660, USA

Uridine-rich small nuclear RNAs (snRNAs) are the basal components of the spliceosome and play essential roles in splicing. The biogenesis of the majority of snRNAs involves 3′ end endonucleolytic cleavage of the nascent transcript from the elongating DNA-dependent RNA ploymerase II. However, the protein factors responsible for this process remain elusive in plants. Here, we show that DEFECTIVE in snRNA PROCESSING 1 (DSP1) is an essential protein for snRNA 3′ end maturation in *Arabidopsis*. A hypomorphic *dsp1-1* mutation causes pleiotropic developmental defects, impairs the 3′ end processing of snRNAs, increases the levels of snRNA primary transcripts (pre-snRNAs), and alters the occupancy of Pol II at snRNA loci. In addition, DSP1 binds snRNA loci and interacts with Pol-II in a DNA/RNA-dependent manner. We further show that DSP1 forms a conserved complex, which contains at least four additional proteins, to catalyze snRNA 3′ end maturation in *Arabidopsis*. The catalytic component of this complex is likely the cleavage and polyadenylation specificity factor 73 kDa-I (CSPF73-I), which is the nuclease cleaving the pre-mRNA 3′ end. However, the DSP1 complex does not affect pre-mRNA 3′ end cleavage, suggesting that plants may use different CPSF73-I-containing complexes to process snRNAs and pre-mRNAs. This study identifies a complex responsible for the snRNA 3′ end maturation in plants and uncovers a previously unknown function of CPSF73 in snRNA maturation.

Measurement of stomata and pollen as an indirect indicator of polyploidy in five species of the genus *Polylepis* (Rosaceae)

Joselin Caiza, *Dominique Vargas, Camila Olmedo, Mario Arboleda, Anahí Boada, Osmar Acurio, María Claudia Segovia-Salcedo*
Fuerzas Armadas-ESPE University

Polylepis forest (Family: Rosaceae), are originated in the Andes and considered one of the most threatened forest ecosystems. In Ecuador, eight of the 30 species have been described: one endemic *P. lanuginosa*, one introduced *P. racemosa* and six natives (*P. sericea, P. incana, P. weberbaueri, P. pauta, P. microphylla*, and *P. reticulata*). Throughout their evolutionary history they have shown several episodes of polyploidy affecting their process of speciation. Cell structures such as pollen and occlusive cells are highly influenced by the number of genes in each species, representing morphometric parameters to estimate the degree of ploidy. In this study, the relationship of pollen grain size, length of occlusive cells was analyzed with genome size and chromosome number. Additionally, the pollen viability of species of *P. pauta*, *P. sericea*, *P. racemosa*, *P. incana*, and *P. microphylla* was analyzed using staining techniques. Pollen grains and stomata were photographed at a magnification of 400×, their length was measured in micrometres, using ImageJ program 1.49v. The results show that there is a positive correlation $r = 0.56$ and $r = 0.79$ for stomata, $r = 0.71$ and $r = 0.48$ for pollen, therefore it serves as an indirect analysis method for polyploidy. These data are important for reforestation, restoration and conservation projects of *Polylepis* in Ecuador, allowing prior identification of potential hybrid individuals and cytotypes along the Andes quickly and inexpensively. Additionally it opens the possibility of the use of this data in studies of climate change. It is intended to extend this project to the rest of species of this genus.

Cloning and functional characterization of epidermis-specific promoter *MtML1* from *Medicago truncatula*

Weiwei Chai, *Ye Tian, Mengci Chen, Li Wei, Hongju Yin, Suomin Wang*
State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University

Constitutive and tissue-specific promoters driving transgene expression specifically in vascular bundles, roots and floral organs have been widely used for the genetic improvement of alfalfa.

However, ectopic expression of specific functional genes such as the cuticle-related gene need epidermis-specific promoters with few studies focused on. The *MERISTEM LAYER 1* (*AtML1*) promoter from *Arabidopsis thaliana* is believed to drive gene expression specifically in the epidermis, both in the shoot apical meristem (SAM) and leaves. Nevertheless, the epidermis-specific promoter from the model legume *Medicago truncatula* has not been reported. In this study, we firstly cloned a 5′ flanking sequence from the upstream -2150 bp to the start ATG codon of *MtML1* gene. The sequence analysis showed this region contained promoter feature elements such as TATA box and CAAT box, as well as elements involved in light response. Compared with the promoter of *Arabidopsis AtCER6* expressed specifically in the epidermis, *MtML1* promoter had a plurality of 5′ UTR Py-rich stretch motif conferring high transcription levels identical with *AtML1* promoter. The GUS histochemical analysis showed *MtML1* promoter could drive *GUS* gene expressed transiently in *Nicotiana tabacum* leaves as the same as *AtML1* and *AtCER6* promoters. Furthermore, tissue-specific expression analysis of *MtML1* promoter in *A. thaliana* revealed the spatiotemporal expression patterns involving in high expression levels in leaves and siliques rather than in roots. In addition, the leaf cross-section observations indicated that *MtML1* were exclusively expressed in leaf epidermis. The results confirmed the epidermis-specific promoter *MtML1* was the foundation for driving the cuticle-related gene to express in epidermis, which could dress the alfalfa in waxy coat withstanding the drought, UV, heat, frost and pathogens.

Identification of differentially expressed proteins on large and small rubber particles in rubber tree (*Hevea brasiliensis*)

Chada Chantrachamnong[1,2], *Panida Kongsawadworakul*[1,2], *Onrapak Reamtong*[3], *Jarunya Narangajavana*[4], *Unchera Viboonjun*[1]

1. Department of Plant Science, Faculty of Science, Mahidol University

2. Department of Pharmaceutical Botany, Faculty of Pharmacy, Mahidol University

3. Department of Molecular Tropical Medicine and Genetics, Faculty of Tropical Medicine, Mahidol University

4. Department of Biotechnology, Faculty of Science, Mahidol University

Natural rubber is a biopolymer which could be economically produced from rubber tree (*Hevea brasiliensis*). The rubber biosynthesis occurs on the surface of rubber particles. In vitro assays revealed that small rubber particles (SRPs) contained higher levels of rubber biosynthesis activity than the large rubber particles (LRPs). However, its underlying molecular mechanism is still elusive. In this study, LRPs and SRPs protein expression patterns were investigated by 2-dimensional gel electrophoresis (2-DE). The differentially expressed protein spots were analyzed by ESI-LC-MS/MS coupled to protein database search. The results demonstrated that rubber elongation factor (REF, 14.7 kDa) and small rubber particle protein (SRPP, 22.3 kDa) were almost equally localized on both LRPs and SRPs whereas another isoforms of REF (19.6 kDa) and SRPP (25.6 kDa) were higher expressed on LRPs. Additionally, hevamine, a component involving in a latex coagulation was higher accumulated on LRPs leading to the possibility that LRPs may play important role in the latex coagulation. More information on proteomic data should help to unravel molecular mechanisms of rubber biosynthesis and might serve as a novel biomarker for rubber tree breeding program.

Genetic dissecting of seed oil and protein content and identification of network associated with oil content in *Brassica napus*

Hongbo Chao[1], *Hao Wang*[2]

1. Huazhong University of Science and Technology

2. Shaanxi Rapeseed Branch of National Centre for Oil Crops Genetic Improvement

High-density linkage maps could improve the precision of QTL localization. A high-density linkage map which contained 3106 SNP-bins and 101 non-SNPs covering 3072.7 cM of *Brassica napus* genome was constructed in KN DH population. A total of 164 and 68 identified QTLs were detected for seed oil content in 12 trials and seed protein content in 11 trials and could highest explain 22.24% and 27.48% of the phenotypic variation respectively. After meta-analysis, 67 and 38 consensus QTLs for seed oil and protein content were identified with an average confidence interval of 5.26 and 4.38 cM respectively. Thirty-eight associated genomic regions from BSA overlapped with and/or narrowed the SOC-QTLs, which further confirmed QTL mapping based on the high-density linkage map. Potential candidates related to lipid metabolism and seed storage protein underlying SOC and SPC respectively were identified and analyzed, while six among of them were checked and showed expression differences between the two parents during different embryonic development periods. Meanwhile, a whole genome search was implemented to acquire distribution of orthologs related to lipid metabolism, and a total of 3058 orthologs of *A. thaliana* lipid-related genes were identified in the whole genome. Minor acyl-related genes enrichment/prevalence in the CI of SOC-QTLs was found as compared to whole genome. In addition, a magnificent primary carbohydrate pathway based on potential candidates underlying SOC and SPC-QTLs, and interaction networks based on potential candidates underlying SOC-QTLs, were constructed in order to dissect complex mechanism from the aspects of metabolism and gene regulation, respectively. Accurate QTL mapping and potential candidates identified based on high-density linkage map and BSA provide new insights to the complex genetic mechanism of oil and protein accumulation in seeds of rapeseed.

Authentication of the medicinal plants in Smilaceae by DNA barcoding technique

Chaozhi Chen, *Yuanjing Duan, Yue Yu, Zhentao Wang, Shuyuan Li*

Guangdong Pharmaceutical University

Smilaceae is one of the hot plant populations with medicinal value and food nutritional value, which are widely used in the world, especially in China. However, the morphological characters of this family are similar, even geographical distance of this family may lead to a small range of genetic varia. So we chose four sequences (ITS2, psbA-trnH, matK, rbcL) to establish the DNA barcoding system of Smilaceae. The related data of those sequences were analyzed using the software Codon Code Aligner V 3.7.2 and MEGA 6.0. The Kimura-2-Parameter distances were calculated and the phylogenetic tree was constructed using the Neighbor-Joining method, NJ tree shows that they can be distinguished from molecular level obviously. We have identified potential barcodes of the medicinal plants in Smilaceae by comparing DNA barcoding sequences. For better comparison, the Wilcoxon signed rank test was employed to test the difference of those samples by choosing psbA-trnH, matK and rbcL sequences. In conclusion, DNA barcoding technique not only can be used for authentication of the medicinal plants in Smilaceae, but also has established a model platform for the effective authentication of crude drug in Smilaceae furtherly.

Evolution of MIKC^{c}-type MADS-box genes in gymnosperms and angiosperms implicates the origin of flowers

***Fei Chen**, Xingtan Zhang, Xing Liu, Liangsheng Zhang*
Fujian Agriculture and Forestry University

MIKC^{c}-type MADS-box genes encode transcription factors that control floral organ morphogenesis and flowering time in flowering plants. Here, in order to determine when the subfamilies of MIKC^{c} originated, we sampled and analyzed the genomes and large-scale transcriptomes representing all the Orders of gymnosperms and basal angiosperms. Through phylogenetic inference, the subfamily MIKC^{c}-type MADS-box genes were subdivided into 14 monophyletic clades based on sequence and functional similarity. Among them, the gymnosperm orthologs of *AGL6-SEP-AP1*, *GMADS*, *SOC1*, *AGL32-AP3*/*PI*, *SVP*, *AGL15*, *ANR1*, *AG* were identified. We identified and characterized the origin of a novel subfamily *GMADS* within gymnosperms, and lost orthologs in monocots and Brassicaceae. ABCE model prototype genes were relatively conserved in terms of gene number in gymnosperms, and expanded in angiosperms, whereas *SVP*, *SOC1*, and *GMADS* had dramatic expansions in gymnosperms, but conserved in angiosperms. In summary, our results provide the evolutionary history of all MIKC^{c} gene members in gymnosperms and angiosperms. Although the near complete set of MIKC^{c} genes evolved in gymnosperms, the duplication of MIKC^{c} genes in the ancestor of angiosperms triggered the first flower.

P1163

How much positive selection exists in a certain genome —— Joint analysis of McDonald–Kreitman test and site-based LRTs in *Arabidopsis*

***Qipian Chen**[1], Ziwen He[1], Hao Yang[1], Chung-I Wu[1,2], Suhua Shi[1]*
1. State Key Laboratory of Biocontrol and Guangdong Provincial Key Laboratory of Plant Resources, Sun Yat-sen University
2. Department of Ecology and Evolution, University of Chicago, Chicago, Illinois, USA

Estimating the extent of positive selection is a fundamental problem in the study of molecular evolution. The fraction of adaptive substitutions (α) could be estimated based on the McDonald–Kreitman (MK) test that contrast polymorphism and divergence between selectively and neutrally evolving sites (McDonald and Kreitman, 1999). While site-based likelihood-ratio tests (LRTs) in PAML (Phylogenetic Analysis by Maximum Likelihood) software uses codon substitution models to identify amino acid sites under diversifying selection (Yang *et al.,* 2000). In this study, we choose 1,135 *Arabidopsis thaliana* genomes along with other four cruciferous plants' genomes to infer positive selection signature in a total of 15,064 orthologs. We find that a small proportion of adaptive nonsynonymous fixations in *A. thaliana* vs *A. lyrata* (α=0.05) based on MK test, whereas average advantageous amino acids sites is 4.66 per gene based on site-based LRTs. Weak positive correlation between these two methods are found based on a few evidences. First, on a gene by gene basis, positively selected genes that are detected by MK tests and site-based LRTs have a very poor overlap (341 vs 830 genes that are significant, with only 38 shared) across the genome. Second, in a broader scale, a similar tendency was found between these two methods when genes are ranked and pooled together based on one method and send to the other for a test. For their lack of consistency, one explanation is that the two methods focus on different aspects of the different evolutionary processes. Hence, we did a series of simulations that allow positive selection happened in different time-scales with different selection coefficient distributions. The result can be partly explained by it. Since no method are available to detect the full selection pressures, the positive selections might be substantially underestimated.

CIN-clade TCP transcription factor TCP4 modulates leaf morphogenesis through associating with histone deacetylase HDA6 in *Arabidopsis*

***Kai Cheng**[1], Song-Guang Yang[1], Ke-Qiang Wu[2]*
1. Key Laboratory of Plant Resources Conservation and Sustainable Utilization, South China Botanical Garden, Chinese Academy of Sciences
2. Institute of Plant Biology, National Taiwan University

Leaf morphogenesis is a strictly programmed proceed and is regulated by various transcription factors, such as CIN-clade TCPs, notably TCP4, which connects cell proliferation to leaf development. However, the TCP4-mediated transcription regulatory networks remain largely unknown. In this study, we found that TCP4 genetically interplayed with a histone deacetylase HDA6. Compared with *tcp4* and the *hda6* mutant line *axe1-5*, *tcp4/axe1-5* double mutant plants displayed more severe curved and serrated leaves. Real-time quantitative PCR revealed that the expression of leaf development and cell cycle-related genes were changed in all these mutant plants. Global transcriptome analysis indicated that TCP4 and HDA6 coordinately regulated the expression of genes that were involved in cell proliferation and expansion, leaf morphogenesis, and phytohormone signals. Furthermore, we demonstrated that TCP4 interacted with HDA6 in vitro and in vivo, and the transcriptional activity of TCP4 was affected in the presence of HDA6. Taken together, these results suggested that TCP4 may modulates leaf morphogenesis by collaborating with HDA6.

Comparative analysis of three *Zabelia* species (Linnaeaceae) by complete chloroplast genome

Kyeong-Sik Cheon, *Kyung-Ah Kim, Ki-Oug Yoo*
Kangwon National University

The complete chloroplast genome sequences of three *Zabelia* speices (Linnaeaceae), *Z. coreana*, *Z. insularis*, and *Z. tyaihyoni*, were determined in this study. The total genome length of three *Zabelia* species ranged from 157,961 (*Z. tyaihyoni*) to 158,416 (*Z. insularis*). Each genome contains 128 known genes, including 78 protein coding genes, 37 tRNA genes, and 8 rRNA genes. Among these genes, 16 genes contained one or two introns. In comparison of genome structure, gene order between two species (*Z. coreana* and *Z. insularis*) was confirmed to be identical. However, one inversion of large gene block (*trnT-UGU-rbcL*) in the LSC region was identified cp genome between *Z. tyaihyoni* and the aforementioned two species. The total number of SSRs were 49 in two plastomes (*Z. conreana* and *Z. insularis*), and 51 in *Z. tyaihyoni* cp genome. Also, tandem repeats were 49 in all three species. A comparison of coding genes and non-coding regions among the three species revealed divergent site, the divergent value was 0.01 or more in 9 regions. The complete chloroplast genome sequence information regarding the three *Zabelia* will be helpful for elucidating phylogenetic relationships of *Zabelia* and Linnaeaceae.

This study was supported by grants from Scientific research (KNA1-2-13,14-2) of Korea National Arboretum.

Identification and analysis of circular RNAs in plants

Qinjie Chu, *Xingcheng Zhang, Li Chen, Chuyu Ye, Longjiang Fan*
Institute of Crop Science and Institute of Bioinformatics, Zhejiang University

Circular RNAs (circRNAs) are covalently closed loops derived from back-splicing of precursor mRNAs. Recently, a large number of circRNAs have been detected among diverse organisms. For the first time in plants, we have identified 12,037 and 6,012 circRNAs in *Oryza sativa* and *Arabidopsis thaliana*, respectively, with 56% (10/18) of the sampled rice exonic circRNAs validated experimentally. We demonstrated that circRNAs are widespread in plants and revealed the common and distinct features of circRNAs between plants and animals. Additionally, a software for prediction of plant circRNAs, termed PcircRNA_finder, was developed, which is more sensitive and precise in detecting plant circRNAs than other frequently used programs, such as find_circ and CIRCexplorer, by analyzing simulated and real rRNA-depleted/RNase R-treated RNA-Seq data from *A. thaliana* and *O. sativa*. Another software, termed circseq-cup, was also developed, which can assemble the full-length sequences of circRNAs using the back-splicing RNA-Seq reads and their corresponding paired-end reads. We for the first time identified full-length sequences of nearly 3,000 circRNAs in *O. sativa* by applying “circseq-cup” to an rRNA-depleted/RNase R-treated RNA-Seq dataset. We further showed that alternative circularization of circRNA is a common feature in *O. sativa* and, surprisingly, found that the junction sites of a large number of circRNAs are flanked by diverse non-GT/AG splicing signals in *O. sativa* while most human exonic circRNAs are flanked by canonical GT/AG splicing signals. Moreover, we have created a database (PlantcircBase, http://ibi.zju.edu.cn/plantcircbase/) of plant circRNAs. We have collected publicly available circRNAs identified in recent years by bioinformatics prediction and/or experimental validation, as well as circRNAs newly identified by our own lab. Totally, PlantcircBase includes 40,314,35,884,496,854 and 47 unique circRNAs in *O. sativa*, *A. thaliana*, *Zea mays*, *Solanum lycopersicum* and *Hordeum vulgare*, respectively. Apart from the detailed and comprehensive information for each circRNA entry, PlantcircBase also provides basic tools including browsing, searching and downloading as well as advanced tools, including visualizing structures of circRNAs and predicting circRNAs.

Effects of colchicine exposure time on ploidy level of *Globba williamsiana* ‘White Dragon’ *in vitro*

Rodjanacorn Chuengpanya[1,2], *Ngarmnij Chuenboonngarm*[2], *Thaya Jenjittikul*[2], *Kanchit Thammasiri*[2], *Puangpaka Soontornchainakseang*[2], *Atchara Muangkroot*[2]
1. Ph.D. Program in Botany, Faculty of Graduate Studies, Mahidol University
2. Department of Plant Science, Faculty of Science, Mahidol University

Globba, a member genus of the Zingiberaceae, has gorgeous inflorescence for using as ornamental plant. The demand of *Globba* from floral industry is increasing every year. However, new appearances such as big flower size, long stem, and long vase life of ornamental plant are always need and so do *Globba*. Searching of new *Globba* sp. couple with breeding program for dealing the floral markets are necessary. *Globba williamsiana* ‘White Dragon’, which has big white bract with long beautiful yellow inflorescence and is sold as cut-flower in some floral market of Thailand, was selected as studied plant for *in vitro* plant mutation breeding program. To increase ornamental quality, tetrapliod induction through colchicine treatment is generally done by plant breeder. In this study, the effects of colchicine on ploidy level of *in vitro G. williamsiana* were investigated. Young leafy-shoots, 1.5 cm high, were treated with 0.2% (w/v) colchicine at 0,4, 8, and 12 days. After transferring the treated explants onto MS gelrite medium for 8 weeks, the highest survival percentage (50%) was obtained from the 4-day treatment. The survival percentage decreased when colchicine exposure time increased. The increase of colchicine exposure time reduced the formation of leafy-shoot and root, amount of green leafy-shoot, and leaf maturation of the colchicine-treated M_1V_1 plants. At M_1V_3 generation, although all of treated plants grew as the same rate as control (0-day treatment), some of them showed wrinkled leaf morphology. This abnormal morphology was found in every colchicine exposure time. After investigation the ploidy level of M_1V_3 plants by flow cytometry, four ploidy levels, which were diploids, tetraploids, and 2 types of mixoploids

(2x+4x and 2x+8x), were found. Percentage of each ploidy level was 43.11, 33.16, 18.88, and 4.85, respectively. The highest tetraploid percentage was obtained from the 4-day treatment. All abnormal leaf morphological plants in M_1V_3 plants were 2x+8x. Size of stomata and density of epidermal cell and stomata were also observed from M_1V_4 plants. The results showed that the tetraploid plants had stomata size significantly larger than the diploid plants. Lower density of epidermal cell and stomata of the tetraploid plants were significantly observed when compared with the diploid plants. In conclusion, colchicine exposure time affected on ploidy level, morphological characters, and anatomical characters of *G. williamsiana* 'White Dragon'.

Marama, an orphan crop with potential for resource poor farmers, genome sequencing and analysis

Christopher Cullis
Case Western Reserve University

Marama bean (*Tylosema esculentum* (Burchell) A. Schreiber: Caesalpinioideae) is a perennial non-nodulating legume of southern Africa (Namibia, Botswana and South Africa), growing in poor, arid soils surrounding the western, southern and eastern Kalahari and is being developed as a possible crop for resource poor farmers in arid regions of Southern Africa. Marama produces large (2.5 g per seed without shell), protein- and oil-rich edible seeds, and extremely large (up to 200 kg) tubers, containing protein and carbohydrate. This species has been identified as an orphan crop. Whole genome sequencing using both Illumina and PacBio platforms have yielded a nuclear genome assembly, a complete chloroplast molecule and a mitochondrial genome. In addition to the whole genome sequence of one individual, lower coverage Illumina sequencing for 39 individuals across the range of Namibia and South Africa has been obtained. The genome assembly has been interrogated for the possible loss of nodulation genes as the reason for this species being non-nodulating. Also, since marama has a novel protease content, the genes for proteases and their inhibitors have also been identified. The chloroplast genome has been assembled from next generation sequencing using both Illumina and Pac-Bio data. The genome is of typical organization with a large single copy and a small single copy region separated by a pair of inverted repeats and covers 161,537 base pairs. The inverted repeat is expanded compared with other legumes and the small single copy region reduced. However, the marama chloroplast genome contains a unique inversion not present in any other legumes, even in the closest relatives for which the complete chloroplast genome is available, and two complete copies of the ycf1 gene. The sequencing of multiple individuals has identified variation in the chloroplast genomes of marama. The genomes from individuals collected in South Africa differ from those collected from Namibia. There is a more limited variation among the Namibian samples, than that between the South African and Namibian samples, but that which does occur appears appears to be geographically restricted. However, the sequence data form these individuals indicated that marama is heteroplasmic with respect to the chloroplast. The equivalent variation in the mitochondrial genome is also being characterized to determine if this is also heteroplasmic.

Living at the edge: Diversity of Chinese Dipterocarps

Tijana Cvetkovic[1], *Joeri Strijk*[1,2], *Damien Hinsinger*[1]
1. Plant Ecophysiology & Evolution Group, Guangxi Key Laboratory of Forest Ecology and Conservation, College of Forestry, Guangxi University, Nanning, Guangxi 530005, PR China
2. Plant Ecophysiology & Evolution Group, State Key Laboratory for Conservation and Utilization of Subtropical Agro-bioresources, Guangxi University, Nanning, Guangxi 530005, PR China

Tropical forests in the South-East Asia are one of the most important repositories of terrestrial biological diversity, providing both goods and services. Therefore, a better understanding and assessment of the biodiversity is essential for sustainable development in this region. From 2005-2015, total plywood production averaged more than 73 million m^3 in China, Indonesia and Malaysia. Among them, Dipterocarpaceae (with more than 550 species), as the economically most important native tree family for wood production, generated over 900 million US$ revenue for China alone. They form the dominant structural component of Asian tropical wet lowland forests, including both wide ranging and endemics species. Living dipterocarps *sensu lato* are spread over the tropical belt of three continents of Asia, Africa and South America. In China, Dipterocarpaceae are represented by five genera and 12 species; southern China also represents the northern limit for this solely tropical family. In spite of high diversity and ecological dominance of Dipterocarpaceae, very little is known about the genomic diversity and phylogenetic relationships within the family, and the diversity of the species that can be found in China. Here, we assembled a dataset comprising the 12 Dipterocarps species occuring in China, in addition to local suspected synonyms. Using N.G.S. and a genome skimming approach, we assembled the chloroplasts and the nuclear ribosomal cistrons for each species. In addition, we generated a genome-wide dataset of the repeats relative occurrences for these species and performed several diversity analyses to delineate the genomic features of these "edge" species. Our results indicate the genomic diversity is not evenly distributed among both the species and the chloroplasts sequence, different genes and genes families showing strikingly different substitution patterns. We will also discuss the phylogenetic diversity of the chinese species of Dipterocarps. Our research provides the scientific community with important resources for further studies on intraspecific, interspecific and intrageneric levels of genomic diversity in Dipterocarpaceae, as well as biodiversity, origin and evolution of Dipterocarpaceae and evolution of Asian tropical forests.

Charophyte algae as model systems

Charles Delwiche
University of Maryland

Genetic model systems are organisms that have been studied in great detail, and for which there are molecular genetic techniques and tools available. In their best application, model systems provide insights that can be extended to other organisms. Phylogenetic distance is one of several factors that influence such transferability; closely related organisms are more likely to share properties. Unfortunately, despite recent progress with gymnosperm and bryophyte model systems, the phylogenetic diversity of plant model systems remains relatively poor. Outside of the land plants, *Chlamydomonas* and *Volvox* stand out as enormously important model systems, but they diverged from land plants well over a billion years ago, and are substantially different in some important properties. In contrast, the charophyte green algae (basal streptophytes) are known to be much more closely related to land plants, and as such are potentially valuable for understanding fundamental plant properties and the origin of a terrestrial flora. Among the charophytes are several organisms that seem promising as model systems, but substantial development is still needed. Challenges include availability of high-quality cultures, techniques to consistently complete the life cycle in culture, methods for haploid genetics, and development of a diversity of molecular genetic tools.

Proteomic analysis of differentially expressed proteins of *Nicotiana benthamiana* triggered by INF1 elicitin from *Phytophthora infestans*

Juan Du[1], *Xiao Guo*[1], *Lin Chen*[2], *Conghua Xie*[1], *Jun Liu*[1]

1. Huazhong Agricultural University

2. South China Agricultural University

Pathogen-associated molecular pattern (PAMP)-triggered immunity (PTI) is considered to be durable, given that PAMPs are conserved in entire classes of microbes. Elicitins are structurally conserved extracellular proteins in oomycete species and are well characterized as having features of PAMPs. INF1 is an elicitin protein secreted by the late blight pathogen *Phytophthora infestans*. A cell surface receptor-like protein that mediates INF1 response was recently cloned in potato. In addition, some other genes are reportedly involved in INF1-triggered immune responses; however, the molecular mechanisms of INF1-triggered immunity remain poorly understood. Here, we used isobaric tags for relative and absolute quantification-based quantitative proteomics to analyze proteins involved in INF1-triggered cell death responses in *Nicotiana benthamiana*. Our approach identified 2964 proteins, 32 of which were significantly altered in abundance after INF1 induction. Two of eight selected upregulated proteins, namely, ATP-dependent transporter and 60S ribosomal protein L15 were shown to be essential in INF1-triggered cell death responses by virus-induced gene silencing analysis. This study represents the first proteomic analysis of INF1-triggered cell death responses in plants and provides the basis for further work to elucidate molecular mechanisms into oomycete PTI in host plants.

Genetic engineering of CymMV-resistant *Phalaenopsis*

Shuguo Fan

School of Chemistry and Life Sciences, Chuxiong Normal University

The orchid has been one of the most economic floricultural crops in China. Among them, *Phalaenopsis spp*. takes first place in commercial value in the orchid industry. However, viral infections result in the great reduction in both quality and quantity of flowers, hence becoming a limiting factor in the orchid industry. *Cymbididum mosaic virus* (CymMV) is one of the most prevalent plant viruses in orchids. The aim of this research is to generate CymMV-resistant *Phalaenopsis amabilis* overexpressing either the sense or anti-sense strand of the CymMV coat protein (CP) genes using particle bombardment. Hopefully, the transgenic orchids will be resistant against viral infection. Calli have been induced from *P. amabilis*. Plant regeneration system has been established from callus. The gene comprising the capsid proteins of CymMV has been constructed, optimum conditions for particle bombardment have been investigated. Resistant calli and transgenic plantlets have been screened on selection medium. The selection medium was optimized for shoot induction with L-methionine sulfoximine (MSO) added as selection agent. Selection was done in both solid and liquid medium. It was found that liquid media and experiment showed that selection in liquid medium was faster and more efficient. PCR amplification of the inserted CP genes were used for genotyping, and PCR Southern assay confirm the insertion of anti-sense strand of CymMV CP genes into several lines of *P. amabilis* transformants. Northern blot and Western blot have also been done for the putative transformed plants, and viral inoculation and detection will be performed on the transgenic *Phalaenopsis* when they grow to be big. Our results showed that the transgenic *P. amabilis* has been successfully created, and hopefully, the transgenic orchids will be resistant against viral infection.

Genetic engineering of ORSV-resistant *Phalaenopsis*

Shuguo Fan

School of Chemistry and Life Sciences, Chuxiong Normal University

Odontoglossum ringspot virus (ORSV) is one of the most prevalent plant viruses in orchids. The aim of this research is to generate ORSV-resistant *Phalaenopsis equestris* var. *alba* overexpressing either the sense or anti-sense strand of the ORSV coat protein (CP) genes using particle bombardment. In this research, calli have been induced from different explants of *P. equestris* var. *alba*. Plant regeneration system has been established from callus. The gene comprising the capsid proteins of ORSV has been constructed, optimum conditions for particle bombardment have been investigated. Resistant calli and transgenic plantlets have been screened on selection medium. The selection medium was optimized for shoot induction with L-methionine sulfoximine (MSO) added as selection agent. Selection was done in both solid and liquid medium. It was found that liquid media and experiment showed that selection in liquid medium was faster and more efficient. PCR amplification of the inserted *CP* genes were used for genotyping and PCR Southern assay confirm the insertion of anti-sense strand of ORSV *CP* genes into several lines of *P. equestris* var. *alba* transformants. Northern blot and Western blot have also been done for the putative transformed plants, and viral inoculation and detection will performed on the transgenic *Phalaenopsis* when they grow to be big. Our results showed that the transgenic *P. equestris* var. *alba* has been successfully created, and hopefully, the transgenic orchids will be resistant against viral infection.

Influential factors on *Phalaenopsis* transformation by biolistic bombardment

Shuguo Fan
School of Chemistry and Life Sciences, Chuxiong Normal University

Phalaenopsis equestris var. *alba* is a plant of the orchid genus *Phalaenopsis*. *Odontoglossum ringspot virus* (ORSV) is one of the two most prevalent viruses infecting orchids by mechanical transmission and no suitable control measurements are available thus far. Studies on various plants and viruses show that overexpression of a virus CP in plants makes the plants confers resistance against this virus and close-related viruses. In this study, *ORSV CP* gene was introduced into *P. equestris* var. *alba*'s genome, the factors affecting bombardment transformation of this *Phalaenopsis* species was investigated. *P. equestris* var. *alba.* was used in this study. Protocorm-like bodies (PLBs) were induced and proliferated in KC medium supplemented with 15% (v/v) coconut milk, 2% (w/v) sucrose and 3 mg/L BA. PLBs were subcultured into fresh medium every 2 weeks. The optimal concentrations of MSO for selection were determined by plating 150 wild-type *P. equestris* var. *alba.* PLBs onto the solid media without phytohormones, and with various concentrations of MSO (0.1,0.2,0.3,0.4,0.5,0.6,0.7,0.8,0.9 ,1.0 μM) added. To generate the vector *pORSV-CP* used for genetic transformation in this study, the coding region of *ORSV-CP* was cloned into a *pGreen 0229-35S* binary vector under the control of two CaMV 35S promoters. Phalaenopsis transformation was done by particle bombardment and putative transformants were selected with MSO. PCR and PCR southern have been done for the putative transformants. Gene transformation was performed by biolistic bombardment with a 3-day recovery period on MSO-free medium and two selection stages on media with increasing amounts of selection agent, using concentrations of 0.5 and 2 μM MSO. Helium gas pressure of 1350 psi and a distance of 9 cm from the stopping screen to orchid PLBs on plates were optimal parameters for biolistic bombardment of *P. equestris* var. *alba*, as transformation under these parameters gave the highest number of putative transformants after 3 months of MSO selection. Independent transgenic lines were obtained and the presence of the transgene was confirmed by PCR and PCR Southern blot analysis, respectively. A reliable protocol for *Phalaenopsis equestris* var. *alba* transformation by particle bombardment have been created.

Funding: This work was supported by grants from the program for Innovative Research Team (in Science and Technology) in University of Yunnan Province (IRTSTYN), Yunnan Province Universities Key Laboratory of Applied Biology, Applied and Basic Research Foundation of Yunnan Provincial Science and Technology Commission (2013FB061), and Key Discipline Construction of Yunnan Province and Chuxiong Normal University (05YJJSXK03).

Fine-mapping of quantitative trait loci (QTLs) by use of an ultra-large F_2 rice population

Laibao Feng[1], Aimin Ma[1], Bo Song[1], Sibin Yu[2], ***Xiaoquan Qi***[1]
1. Institute of Botany, Chinese Academy of Sciences, Beijing
2. Huazhong Agricultural University, Wuhan

Understanding the genetic basis of yield-related traits is important for rice breeding. Although many yield-related QTLs are detected, only a few have been cloned or fine-mapped. Construction of large traditional mapping populations, such as recombinant inbred lines and chromosome segment substitution lines, is costly and time-consuming. Here we genotyped ca. 1,500 F_2 progeny derived from two *indica* rice cultivars, Minghui 63 and Zhenshan 97 using genotyping-by-sequencing method. A genetic map containing 3,230 bin-markers was constructed, and 7 QTLs for plant height, 5 QTLs for heading date, 4 QTLs for grain length, 5 QTLs for grain width were detected respectively. Of them 16 QTLs have been previously reported or cloned. Three QTLs corresponding to *Hd1*, *GS3* and *GW5* were mapped in small intervals ~200 kb, ~350 kb and ~300 kb, respectively. Our study provides an efficient approach for rapid mapping QTLs with high resolution in a cost-effective manner.

Genome-wide comparison of *Picochlorum* (Chlorophyta, Trebouxiophyte) species

Fatima Foflonker[1]*, Hwan Su Yoon[2], Debashish Bhattacharya[1]*
1. Rutgers University
2. Sungkyunkwan University

Members of the *Picochlorum* genus are considered candidates for biofuel, nutraceutical, and wastewater applications due to their robustness, high biomass productivity, protein and lipid content. The genome of *Picochlorum sp.* strain SENEW3 was previously studied and found to have a small streamlined (13.5 Mb) genome characteristic of extremophiles. It also has an interesting genome organization with 'gene neighborhoods' of colocalized genes that were coexpressed under stress. Physiological, photosynthetic, and genomic differences were compared for five *Picochlorum* species. Difference in genome organization, gene family expansions, bacterial horizontal gene transfer, and evolution of salinity tolerance will be examined. Of these five species, closely related and highly salt tolerant species, *Picochlorum sp.* SENEW3 and *P. oklahomensis* were shown to have differences in genome size and the genomes will be compared for evidence of positive selection on genes to identify key functions that may be involved in adaption to each respective habitat.

Prevalence, mechanisms and importance of duplicate gene divergence in exon–intron structure

Xuehao Fu[1,2], *Hongyan Shan*[1], *Peipei Wang*[1,2], *Guixia Xu*[1], *Hongzhi Kong*[1]

1. State Key Laboratory of Systematic and Evolutionary Botany, CAS Center for Excellence in Molecular Plant Sciences, Institute of Botany, Chinese Academy of Sciences, Beijing 100093, China
2. University of Chinese Academy of Sciences, Beijing 100039, China

Gene duplication plays key roles in organism and genome evolution. Understanding how duplicate genes evolve and diverge through time is critical for elucidating the mechanisms underlying the origins of new characters and new organisms. Previous studies have shown that, at least in plants, some duplicate genes have diverged in the exon-intron organization, suggestive of structural divergence. However, because the species and gene pairs sampled were very limited, it is still unclear whether this phenomenon is widespread and, if yes, how prevalent it is. In this study, by conducting a genome-wide study on closely related duplicate genes from four representative species of plants (*Arabidopsis thaliana*), animals (*Drosophila melanogaster*), fungi (*Saccharomyces cerevisiae*), and protists (*Paramecium tetraurelia*), we found that structural divergence occurred prevalently in every examined species but with different proportions, ranging from 70.9% in *P. tetraurelia* to 91.9% in *A. thaliana*. Three mechanisms, including exon/intron gain/loss, exonization/pseudoexonization, and intra-exonic insertion/deletion, are detected to be responsible for structural divergence. Similar to non-synonymous substitutions, the probability of duplicate genes to diverge in structure increases with evolutionary time. We used Pearson correlation coefficient (PCC) and Euclidean distance (ED) to evaluate the difference of expression patterns between a pair of genes, and observed that PCC is lower and ED is higher in diverged than in undiverged duplicate genes, suggesting that structural divergence may be coupled with expression divergence. Using d_N/d_S values as a measurement of functional constraint, we found that duplicate genes with structural changes have higher d_N/d_S values, indicative of weaker functional constraint on these genes. This is in concordance with their lower expression levels. Further function enrichment analysis revealed that these genes are involved in unconserved biological processes, including biological regulation, signal transduction, and response to stimuli. Our findings show that the modes of structural divergence of duplicate genes are generally consistent in different eukaryotic species, implying that structural divergence is an important contributor to the evolution of duplicate genes.

Gray Herbarium Card Index: Then & now (historical perspective)

Kanchi Gandhi
Harvard University Herbaria

The Harvard University Herbaria made the nomenclatural contents of the *Gray Herbarium Card Index* (GCI) available online via a Gopher server in 1991. One website hailed this accomplishment as: “This grandfather of online checklists is a searchable database of names applied to the New World plant species.” The origins of GCI can be traced to Josephine Clark (1892), the librarian at the U.S.D.A., who published a compilation of newly described and renamed vascular plants under the title, “Systematic and Alphabetic Index of New Species of North American Phanerogams and Pteridophytes, in 1891.” Thus the progenitor of the GCI predates the Index Kewensis (IK; 1893). Clarke went on to collaborate with Mary Day, librarian at the Gray Herbarium, to extend coverage to the entire New World and include non-vascular plants. The names were printed on cards and distributed in sets. In late 1903 Clarke handed over the responsibility of the index to the Gray Herbarium. The initial scheme was to include all post-1885 names at the ranks of genus and below pertaining to the New World plants. Cards sets were usually issued every three months, and sets of cards with new names appeared within six months of publication. The indexing of non-vascular plant names was stopped in 1927 because of certain difficulties. In 1945 it was decided to include names of all vascular plant infraspecies published from 1753-1885 for the New World. The GCI served as a source of nomenclature with links to homotypic names. In contrast, from 1893 through 1965 the IK was published in book format and served as a global taxonomic source of seed plant species. Infraspecies names were added from 1970. After the first two volumes published in 1893 and 1895, supplements were issued every five years, and a total of 21 supplements were issued from1902 through 2002. The production of GCI transitioned from cards to microfiche in 1986 to save on costs. Using both the cards and microfiche together to have full access of the GCI data often posed problems. As access to computers and programming became more widespread, it was decided to put the entire content into a database system. The complete index was digitized in 1991, and the Harvard University Herbaria website was established in 1993 to make the GCI content available. The new scheme allowed to record type data. Similar to the GCI’s effort, the IK’s content was issued as a CD-ROM in two editions (1: coverage 1753-1992 ; 2: coverage 1753-July 1996). In mid-1990s, GCI and the IK agreed to collaborate to avoid duplication and make the indexing process more efficient. The *Australian Plant Name Index* was also invited to join this venture. All the three indices merged their data together to constitute as single database and launched it online in 2000: the International Plant Names Index (IPNI).

Main regulatory pathways, key genes, and microRNAs involved in flower formation and development of moso bamboo (*Phyllostachys edulis*)

Wei Ge, Ying Zhang, Zhanchao Cheng, Dan Hou, Xueping Li, ***Jian Gao***
International Centre for Bamboo and Rattan

Moso bamboo is characterized by infrequent sexual reproduction and erratic flowering habit; however the molecular biology of flower formation and development is not well-studied in this species. We studied the molecular regulation mechanisms of moso bamboo development and flowering by selecting three key regulatory pathways: plant-pathogen interaction, plant hormone signal transduction, and protein processing in endoplasmic reticulum at different stages of flowering in moso bamboo. We selected *PheDof1*, *PheMADS14,* and six microRNAs involved in the three pathways through KEGG pathway and cluster analysis. Subcellular localization, transcriptional activation, western blotting, *in situ* hybridization and qRT-PCR were used to further investigate the expression patterns and regulatory roles of pivotal genes at different flower development stages. Differential expression patterns showed that *PheDof1*, *PheMADS14* and six miRNAs may play vital regulatory roles in flower development and floral transition in moso bamboo. Our research paves way for further studies on metabolic regulatory networks and provides insight into the molecular regulation mechanisms of moso bamboo flowering and senescence.

The origin and diversity of tarap (*Artocarpus odoratissimus*, Moraceae), an underutilized tree crop from Borneo: Insights from HybSeq and SSRs

Elliot M. Gardner[1,2]*, Joan T. Pereira*[3]*, Aida Shafreena Ahmad Puad*[4]*, Nyree J.C. Zerega*[1,2]
1. Northwestern University
2. Chicago Botanic Garden
3. Forest Research Centre, Sabah Forestry Department
4. Universiti Malaysia Sarawak

Target enrichment sequencing (HybSeq) is applicable to a wide range of questions and sample types. Here, we present insights from HybSeq-based phylogenomic analyses and nuclear SSRs into a question at the intersection of phylogenetics and population genetics: the origin and diversity of tarap (*Artocarpus odoratissimus,* Moraceae), an underutilized tree crop from Borneo. We combine a HybSeq data set of ca. 450 nuclear genes based on fresh and herbarium samples from across the species range with SSR analysis of more densely-sampled populations in Sabah and Sarawak. We discuss strategies for library construction and hybridization for degraded samples up to 100 years old. Phylogenomic analyses and population structure analyses shed light on the relatioship of cultivated tarap to morphologically diverse wild forms. Results elucidate the genetic diversity, intra-species relationships, and domestication history of this locally prized but underutilized crop.

Identification and characterization of microRNAs at different flowering developmental stages in moso bamboo (*Phyllostachys edulis*) by high-throughput sequencing

Jian Gao[1]*,* ***Wei Ge***[1]*, Ying Zhang*[1]*, Zhanchao Cheng*[1]*, Long Li*[1]*, Dan Hou*[1]*, Chenglin Hou*[2]
1. International Centre for Bamboo and Rattan
2. Capital Normal University

Researching moso bamboo (*Phyllostachys edulis*) flowering has been difficult because of its unknown flowering interval and the rarity of florescent samples. To identify microRNAs (miRNAs) and study their expression patterns during the flower developmental process of moso bamboo, small RNAs from non-flowering leaves and four flower developmental periods were sequenced using Illumina technology. In total, 409 known miRNAs and 492 differentially expressed novel miRNAs were identified in moso bamboo. Of the known miRNAs that were differentially expressed between non-flowering and flowering samples, 64 were predicted to have a total of 308 targets. Among the miRNAs, seven known and five novel miRNAs were selected, as were four of their target genes, and their expression profiles were validated using qRT-PCR. The results indicated that the miRNA expression levels were negatively correlated with those of their targets. The research comprehensively revealed that the differentially expressed miRNAs and their targets participated in diverse biological pathways and played significant regulatory roles in moso bamboo flowering. The data provide a significant resource for understanding the molecular mechanisms in moso bamboo flowering and senescence, and serve as the primary foundation for further studies on metabolic regulatory networks that involve miRNAs.

Production of red flower rapeseed by ectopic expression of *OvPAP2* from *Orychophragmus violaceus*

Wenqin Fu[1]*, Daozong Chen*[1]*, Qi Pan*[1]*, Fengfeng Li*[1]*, Zhigang Zhao*[2]*,* ***Xianhong Ge***[1]*, Zaiyun Li*[1]
1. Huazhong Agricultural University
2. Qinghai University

Oilseed rape is both an important oleaginous crop and agriculture sightseeing crop whereas has relatively scanty flower color (yellow flowers). As natural flavonoids, anthocyanins are responsible for the attractive red, purple, and blue colors of various tissues in higher plants. One *Brassica napus-Orychophragmus violaceus* disomic addition line (M4) obtained previously exhibits red petals. Transcriptome analysis of M4, *B. napus* (H3), *O. violaceus* with purple (OvP) and white petals (OvW) revealed that most of structural genes for anthocyanin synthesis were up-regulated in both M4 and OvP. Reads assembling and sequence alignment indicated that one of unigenes identified as *PAP2* in M4 was from the transcript of *O. violaceus* (*OvPAP2*). Overexpression of *OvPAP2* via CaMV35S promoter in *A. thaliana* leads to different levels of red/purple pigments accumulation in most of organs, including petals. However, overexpressed *B. napus* exhibited restricted accumulation of anthocyanins primary in stamens. Interesting, when driven by the petal-specific prompter XY355, transgenetic plants of *B. napus* showed both red anthers and petals. RT-PCR analysis indicated that the relative expression values of *OvPAP2*, which influenced by different promoters and genetic background, are closely related to the expression of *DFR* and *ANS* as well as the red color formation in different organs. Metabonomics analysis found abundance and specific anthocyanins accumulated in red petals of M4 and XYP3 transgenic plants. Present study gives a successful case for flower color modification of the agriculture sightseeing rapeseed and provided materials for further expounding the regulation of anthocyanin biosynthesis in petals of *Brassica*.

Profiling of plant lncRNA encoded polypeptide and their functions under stresses

***Sisi Geng**, Zhi Lu*
MOE Key Laboratory of Bioinformatics, Center for Plant Biology, School of Life Sciences, Tsinghua University

Recent studies have found that plant long non-coding RNAs (lncRNAs) play many roles in important biological processes such as development, flowering, biotic and abiotic stress responses. With the development of high-throughput sequencing technology, more and more studies have accumulated large amounts of unannotated plant lncRNA. However, except for several studies that unfolded the detailed molecular mechanisms of several lncRNAs, functions of most lncRNAs remain elusive. Studies on lncRNAs using ribosome profiling and sequencing (Ribo-Seq) technique in both animals and plants indicate that lncRNAs have similar translational efficiency when compared to protein-coding mRNAs. But only a few lncRNA encoded polypeptides have been detected so far either due to limitations in detection methods or because they are degraded quickly. This work integrates Ribo-Seq and proteomics based on liquid chromography coupled mass spectrometry (LC-MS) optimized for short peptide detection to study the coding potential, as well as the change of lncRNA coding potential under stress conditions to demonstrate the function of lncRNAs encoded polypeptides in plants under stresses.

Foliar stomatal movement is critical for regulating plant water status and gas exchange. Elevated carbon dioxide (CO_2) is known to induce stomatal closure, and vice versa, low CO_2 induces stomatal opening. However, current knowledge on CO_2 signal transduction in stomatal guard cells is limited. Here we report metabolomic responses of *Brassica napus* guard cells to different CO_2 concentrations using a hyphenated metabolomics approach. During the one-hour CO_2 treatment, the metabolome showed a generally increasing trend under elevated CO_2, and a decreasing trend under low CO_2. This may be explained by the availability of carbon source. Interestingly, jasmonic acid (JA) biosynthesis was significantly increased under elevated CO_2 treatment. Yet under low CO_2, a branching pathway of JA biosynthesis leading to green volatiles and traumatic acid production was induced. Together with results obtained from JA biosynthesis and signaling mutants as well as CO_2 signaling mutants, we discovered that jasmonic acids partially mediates high CO_2 induced stomatal closure, but not low CO_2 induced stomatal opening. Under low CO_2, we observed other phytohormones including cytokinins, auxins, brassinosteroids, as well as melatonin increased at early time points, indicating possible roles of these hormones in mediating stomatal opening under low CO_2. Sucrose, malate, mannitol, citric acid, as well as some other organic acids were found to be significantly altered under both high and low CO_2 treatments, and their trends correlate well with the osmotic changes during stomatal opening or closure. In addition, proteomic level changes are currently under investigation to reveal how enzyme amount or modification changes may relate to metabolite changes in guard cell responses to different CO_2 levels.

Heterogeneous plant phenotyping big-data aggregation for crop breeding with diverse data-acquiring platforms and technologies

Liang Gong
Shanghai Jiao Tong University

It plays an important role for high-throughput phenotyping in cutting-edge crop breeding field, and this automation generates heterogeneous measuring data for subsequent meta-analyses, modeling, and ground-truth dataset building. However, data-processing problems arise due to the lack of an effective data modeling technique and tool to manage and scale them. In order to quantitatively use the phenotyping data for crop breeding, a data aggregation methodology is proposed to tackle the heterogeneous data obtained by means of digital text, image, or point cloud. First, plant organ-specific phenotyping parameter index sets for crop breeding are optimally determined, and corresponding phenotyping instrumentation are introduced. Second, an entity-relationship data aggregation model is built to organize and present the phenotyping big data; Third, a paradigm of creating a phenotyping database is proposed to facilitate crop breeding. Finally, a formal paradigm for constructing a crop breeding phenotyping database is established, which highlights the plant morphometric data retrieval and data mining. This data aggregation scheme provides an effective tool and exemplary template for dealing with big plant phenotyping data acquired by different devices and equipment under user-defined resolution. The case study for creating a GEOP phenotyping database is step-by-step investigated to show the feasibility and effectiveness of plant phenotyping big-data aggregation.

Tissue- and stage-specific processes in plant fiber development: View from the level of transcriptome

Tatyana Gorshkova, *Tatyana Chernova, Natalia Mikshina, Oleg Gorshkov*

Kazan Institute of Biochemistry and Biophysics, Kazan Scientific Center, Russian Academy of Sciences

Plant fibers are the most widely spread cell types in mechanical tissues of vascular plants. For the plant itself, fibers are important as a source of mechanical support, in defense from herbivores, and in some cases as elements with contractile properties, resembling those of muscles. Being the structural components of timber and the final product of fiber crops, plant fibers constitute one of the most important renewable resources. The major distinguishing features of fibers are the extreme cell length that can reach many centimeters and thickened cell wall. Correspondingly, the especially important stages of fiber development are cell elongation and cell wall thickening. Fiber elongation is mainly performed by intrusive growth - the type of plant cell enlargement characterized by the excessive rate of a cell elongation as compared to the surrounding tissues. During intrusive elongation, a cell splits the middle lamellae of the cells on the way and squeeze in between the surrounding tissues. Intrusive growth is very important both for the development of plant organism architecture and for the yield and quality of plant fibers, because this very process provides the extreme length to the individual fibers and also forms the cell surface for the subsequent thickening of the cell wall. However, the data on the intrusive growth are extremely scarce, since intrusive elongation occurs within the depth of plant tissues, making it extremely difficult to isolate fibers at this stage of development in quantities sufficient for wet biochemical analysis. We have isolated the intrusively growing fibers from flax stem by laser microdissection and performed the RNA-Seq analysis to obtain the transcriptome landscape. Similar type of analysis was applied for fibers isolated at advanced stage of specialization – deposition of G-layer. There are two types of plant fibers differing in design and properties. One, developing seconadary cell wall, provides static reinforcement, helping to stabilize the organism and its parts in space. The other develops contractile properties that may permit to move the plant parts and as such can be considered as plant “muscles”. The latter deposits fiber-specific G-layer (tertiary cell wall). As distinct from the secondary cell wall that consists of several layers of helicoidally oriented cellulose microfibrils interlaced with xylan and lignin, G-layer contains mainly of axially oriented cellulose microfibrils and specific version of rhamnogalacturonan I. To characterize the general picture of specialized plant cell during its development in planta and to reveal the genes specifically expressed at key stages of fiber development we compared the whole transcriptome portraits of fibers during intrusive elongation and G-layer deposition and of the surrounding tissues in several stem parts. Besides, the obtained results were compared to the published data on transcriptome landscapes during wood development in tree species. Transcriptome analysis permitted to elucidate the important players involved in the key stages of fiber development, like transcription factors, ion transporters, glycosyltransferases, cell wall proteins, and provided a solid basis for the in-depth analysis of fibre-specific processes. The work was supported by the grant from Russian Scientific Foundation (project #16-14-10256).

Numerous foreign mobile elements shape the mitochondrial genome of the fern *Gleichenia dicarpa*

Felix Grewe[1], *Andan Zhu*[2], *Prisca Viehoever*[3], *Bernd Weisshaar*[3], *Volker Knoop*[4]

1. The Field Museum, Chicago
2. University of Lincoln-Nebraska
3. University of Bielefeld
4. University of Bonn

Largely due to their size and complexity, only two complete fern mitochondrial genome sequences are available to date, both from early diverging eusporangiate species. To gain more insight into the evolution of the mitogenome of ferns, we sequenced the mitochondrial genome of the leptosporangiate fern *Gleichenia dicarpa* by a hybrid fosmid sequencing and high-throughput genome skimming approach. The assembled fern mitochondrial genome is very repetitive and characterized by a high frequency of integrated foreign mobile elements, such as promiscuous DNA from the plastid and nuclear genome, DNA and RNA polymerases derived from linear mitochondrial plasmids and mitoviruses, a recent intron transposition from the *rpl2* gene into the *rps1* gene, and many highly conserved fragments of retroelements. In addition, Fosmid cloning identified identical fragments of the mitochondrial genome integrated into the nuclear genome of *G. dicarpa*. Some of these nuclear mitochondrial regions were disrupted by retroelements indicating a recent massive expansion of retroelements in the nuclear genome. Therefore, the sequencing of *G. dicarpa* demonstrates how mobile elements can strongly shape mitochondrial genome patterns in addition to their effect on the nuclear genome.

Cytogenetic relationships among *Citrullus* species inferred from rDNA distribution patterns

Yonghua Han

Jiangsu Normal University

Background: Comparative mapping of 5S and 45S rDNA by fluorescent *in situ* hybridization (FISH) technique is an excellent tool to determine cytogenetic relationships among closely related species. Results: In this study, the number and position of 5S and 45S rDNA loci in all *Citrullus* species and subspecies were determined. The cultivated watermelon (*C. lanatus* subsp. *vulgaris*), *C. lanatus* subsp. *mucosospermus, C. colocynthis* and *C. naudinianus* (or *Acanthosicyos naudinianus*) had two 45S rDNA loci and one 5S rDNA locus which was located syntenic to one of the 45S rDNA loci. *C. ecirrhosus* and *C. lanatus* subsp. *lanatus* had one 45S rDNA locus and two 5S rDNA loci, each located on a different chromosome. *C. rehmii* had one 5S and one 45S rDNA locus positioned on different chromosomes. The distribution of 5S and 45S rDNA in several species belonging to other genera in Benincaseae tribe was also investigated. The distribution pattern of rDNAs showed a great difference among these species. Conclusions:The present study confirmed evolutionary closeness among cultivated watermelon (*C. lanatus* subsp. *vulgaris*), *C. lanatus* subsp. *mucosospermus* and *C. colocynthis*. Our result also supported that *C. lanatus* subsp. *lanatus* was not a wild form of the cultivated watermelon instead was a separate crop species. In addition, present cytogenetic analysis suggested that *A. naudinianus* was more closely related to *Cucumis* than to *Citrullus* or *Acanthosicyos*, but with a unique position and may be a link bridge between the *Citrullus* and the *Cucumis*.

Dissecting grass genome organisation at the cytomolecular level using the model genus *Brachypodium*

Robert Hasterok[1], *Alexander Betekhtin*[1], *Natalia Borowska-Zuchowska*[1], *Agnieszka Braszewska-Zalewska*[1], *Karolina Chwialkowska*[2], *Marta Hosiawa-Baranska*[1], *Dominika Idziak-Helmcke*[1], *Arita Kus*[1], *Jolanta Kwasniewska*[1], *Miroslaw Kwasniewski*[2], *Joanna Lusinska*[1], *Ewa Robaszkiewicz*[1], *Magdalena Rojek*[1], *Rakesh Sinha*[1], *Aleksandra Skalska*[1], *Marta Sowa*[1], *Elzbieta Wolny*[1], *Karolina Zubrzycka*[1]

1. Department of Plant Anatomy and Cytology, Faculty of Biology and Environmental Protection, University of Silesia in Katowice

2. Department of Genetics, Faculty of Biology and Environmental Protection, University of Silesia in Katowice

In contrast to animals, the organisation of plant genomes at the cytomolecular level is still relatively poorly studied and understood. However, the *Brachypodium* genus in general and *B. distachyon* in particular represent exceptionally good model systems for such study. This is due not only to their highly desirable 'model' biological features, such as small nuclear genome, low chromosome number and complex phylogenetic relations, but also to the rapidly and continuously growing repertoire of experimental tools, such as large collections of accessions, whole genome sequence information, large insert (bacterial artificial chromosome; BAC) libraries of genomic DNA, *etc*. Advanced cytomolecular techniques, such as fluorescence *in situ* hybridisation (FISH) with evermore sophisticated probes, empowered by cutting-edge microscope and digital image acquisition and processing systems, offer unprecedented insight into chromatin organisation at various phases of the cell cycle. A good example is chromosome painting which uses pools of chromosome-specific BAC clones, and enables the tracking of individual chromosomes not only during cell division but also during interphase. Here we outline our current projects and their future prospects, using *Brachypodium* species for research on various aspects of grass genome organisation using cytomolecular approaches and focuses on following topics: (i) karyotype structure and evolution, (ii) distribution of chromosome territories and domains within the interphase nucleus, (iii) dynamics of epigenetic modifications of chromatin during embryo development and cell differentiation, (iv) true nature of selective rRNA gene inactivation in some *Brachypodium* allopolyploids, (v) intraspecific epigenetic variation in natural populations of *B. distachyon*, (vi) instability of a small grass genome subjected to mutagenic treatments, and (vii) meiosis and chromosome pairing control in *B. hybridum*. Financial support from the National Science Centre Poland (grants no. 2012/04/A/NZ3/00572,2014/14/M/NZ2/00519 and 2015/18/M/NZ2/00394) is acknowledged.

4. Finnish Museum of Natural History and Department of Biosciences, University of Helsinki

Colonization of terrestrial habitats by plants is one of the most important events in the history of life on Earth. Extant embryophytes (land plants) share a common ancestor with a grade of freshwater charophyte green algae (basal streptophytes). A range of features of charophyte green algae have been shown to be orthologous to those found in embryophytes, and bryophyte-grade plants share a common ancestor with polysporangiophytes. However, many key questions regarding the origin of embryophytes, transition from a single-celled zygote to a multicellular embryo, and development of alternating life cycles, have remained ambiguous. Challenges surrounding these questions are for example the paucity of the fossil record, the depth of phylogenetic divergence of streptophytes, as well as the limited genome-scale data of bryophytes and charophytes. We aim to sequence complete genomes of a simple thalloid liverwort *Blasia pusilla* and a charophyte *Coleochaete orbicularis* and establish them as model species for further, more detailed studies. These two species occupy a critical position in the streptophyte evolution. We aim to conduct a comparative study on the evolution of streptophytes, particularly on the molecular mechanisms underpinning the origin and success of the embryophytes. We will present our preliminary data on the axenic cultures, techniques to complete the life cycle in laboratory conditions, and the NGS techniques we are planning to use in whole genome sequencing.

SINEs in Solanaceae – SINE family characteristics, gene association and utilization as molecular markers

Kathrin M. Seibt[1], *Torsten Wenke*[1], *Katja Muders*[2], *Bernd Truberg*[2], ***Tony Heitkam***[1], *Thomas Schmidt*[1]

1. TU Dresden, Institute of Botany

2. Norika GmbH, Groß Lüsewitz

Short interspersed nuclear elements (SINEs) are non-autonomous retrotransposons widespread in the plant kingdom. SINEs are short in length, non-coding and contain promoter motifs derived from cellular RNAs, primarily tRNA. Due to their lack of coding domains and high sequence heterogeneity, SINEs are difficult to identify and annotate. We identified ten Solanaceae SINE families and subfamilies using our SINE-Finder tool which enables the targeted identification based on the few structural characteristics of SINEs. Using five Solanaceae reference genome sequences including potato, tomato, and pepper, we annotated 82,900 SINEs. The copy numbers per genome of the SINE families range from tens to over eight thousand. An analysis of the sequence divergence in comparison to reference sequences revealed different age structure of the SINE family populations. The presence of highly similar copies indicates a recent activity of some SINE families in potato. Fluorescence in situ hybridization and mapping along the assembled chromosomes showed that SINEs are dispersed across all chromosomes with a preference for distal euchromatic regions similar to the distribution of the annotated genes in the genome assemblies. Our analysis revealed a strong association of some SINE families with genes. 10% of the annotated Solanaceae genes contain up to 16 SINE copies, mainly in introns and untranslated regions. SINEs can contribute splice sites, start and stop codons as well as exons to genes. Moreover, 2% of the SINEs occur in tandem-like organization and SINEs are involved in the transduction of genomic sequences across the genome. Based on the analyzed Solanaceae SINEs, a PCR-based marker system called inter-SINE amplified polymorphism (ISAP) for genotyping potato varieties was developed for applications in breeding and genebank management. Our results indicate the particular suitability of high copy number families with recent activity as the derived markers are highly polymorphic enabling us to discriminate a collection of 364 European varieties and breeding lines with only two primer combinations.

Golden SusPtrit - a well transformable accession to study barley nonhost resistance

Goetz Hensel[1], *Freddy Yeo*[2], *Rients Niks*[2], *Jochen Kumlehn*[1]
1. Leibniz Institute of Plant Genetics and Crop Plant Research (IPK)
2. Wageningen University and Research Centre

Plant-microbe interactions could be roughly divided into host- and nonhost resistance mediated by different mechanisms of which most are not yet well understood. Candidate genes are at best examined in a genotype which is either resistant or susceptible for the type of resistance under study. Consequently, the genotype ‘SusPtrit’ would be the line of choice in studies on nonhost and partial resistance in barley-rust fungus interactions. Seedlings of this experimental line have an extraordinary high susceptibility to rust fungi to which barley is normally a nonhost. Unfortunately, this line is not amenable to *Agrobacterium*-mediated genetic transformation. To combine susceptibility to non-adapted rust fungi of ‘SusPtrit’ with high transformability of the model cultivar ‘Golden Promise’, doubled haploids (DHs) were created from hybrids between these two accessions. Four DH lines showing a level of non-adapted rust infection similar or higher than that of ‘SusPtrit’ were selected and tested for transformation efficiency using a construct that harbours the *gfp* reporter gene under control of the maize *UBIQUITIN-1* promoter. DH line SG062N, designated ‘GOLDEN SUSPTRIT’, proved to be almost as transformable as ‘Golden Promise’. Also, copy numbers, expression and inheritance of the transgene were well comparable with results obtained in other transformable barley accessions. ‘GOLDEN SUSPTRIT’ is deemed highly valuable for the functional validation of genes putatively involved in plant-fungus interactions.

Production of an anti-human immunodeficiency virus antibody in the barley endosperm

Goetz Hensel[1], *Doreen M. Floss*[2], *Twan Rutten*[1], *Udo Conrad*[1], *Jochen Kumlehn*[1]
1. Leibniz Institute of Plant Genetics and Crop Plant Research (IPK)
2. Heinrich-Heine-University

Molecular Farming is a useful option for the production of valuable recombinant proteins. As a major prerequisite, highly efficient and cost effective expression systems are required. The cereal grain is an attractive vehicle for producing recombinant proteins, because its evolution as a protein storage organ assures an environment in which proteins accumulate to high abundance and remain stable over long periods without any need for refrigeration or aseptic conditions. The anti-Human Immunodeficiency Virus antibody 2G12 is a well-studied model which had been used in many different expression systems including plants. Here, the 2G12 antibody was used to demonstrate that the endosperm of barley grains is a particularly valuable Molecular Farming platform.

The first DNA genes and their ubiquitous modern derivatives: Reverse Transcriptase enabling catalytic and self-assembling RNA to become stable and regulated

Js (Pat) Heslop-Harrison, *Trude Schwarzacher*
University of Leicester

The first catalytic and self-assembling molecules were almost certainly based on RNA. In the transition to DNA, some 3.5 billion years ago, reverse transcriptase functions must have been involved. We see the likely signature of this primitive enzyme as a motif including three aspartic acid residues -D-n-D-D- (where n is a run of other amino acids and D is an aspartic acid residue) in retrotransposons, retroviruses and telomerase in modern plants. Now, retrotransposons (Class I transposable elements) and their reverse transcriptase genes, often degenerate, are the most abundant component of many genomes. Using high-throughput sequence raw-read and assembled sequence data from various crops and wild plants, with novel informatic analyses to extract motifs, we will discuss the nature of reverse-transcriptase genes, including those found in pararetroviruses, LTR- and non-LTR retrotransposons and the telomerase enzymes in plants. We will also show data from examination of their evolutionary modes including evidence for horizontal transfer at various phylogenetic levels, and their distribution, amplification, loss and homogenization in chromosomes and related genomes or plant families.

Comparative genomics and phylogenetics of the moonseed genus (*Menispermum*, Menispermaceae)

***Faiza Hina**, Yao Chen, Pan Li*

Laboratory of Systematic & Evolutionary Botany and Biodiversity, College of Life Sciences, Zhejiang University, Hangzhou 310058, P. R. China

Menispermum L. (moonseed) is a small genus of deciduous climbing woody vines in the moonseed family (Menispermaceae). There are three species in this genus, namely *M. canadensis* L., *M. dauricum* DC., and *M. mexicanum* Rose. They exhibit a unique eastern Asia-eastern North America-Mexico disjunct pattern (one species each in these three areas, respectively). *M. mexicanum* is thought to be the same species of *M. canadensis* by some authors, whereas some other botanists think it is a synonym of *M. dauricum* instead. The rhizomes of *M. dauricum* ("Bei-Dou-Gen") have been used as Traditional Chinese Medicine (TCM) for a long time, to treat sore throat, colitis, dysentery and rheumatic arthralgia, while some Native American tribes used *M. canadensis* medicinally as dermatological, gastrointestinal, gynecological, and venereal aids, and as remedies for various other complaints. Although *Menispermum* species have medicinal and horticultural uses, studies related to species identification and molecular phylogenetic analysis of this genus have not been reported. Here, we report the complete nucleotide sequences of two *Menispermum* chloroplast (cp) genomes (*M. canadensis* and *M. dauricum*) using Illumina paired-end sequencing technology. We aim to: (1) characterize and compare the cp genomes of two *Menispermum* species in order to gain insights into their evolutionary patterns; (2) screen and identify the most rapidly evolving cpDNA regions and polymorphic SSR markers of the *Menispermum* genome for species identification and future phylogeographic studies of the genus; (3) resolve the phylogenetic relationships within *Menispermum* using these novel markers.

Genetic polymorphism for *Dreb 1* loci in bread wheat varieties with different drought resistance

***Anastasiia Honcharova**, Olga Kolesnyk*

Plant Breeding and Genetics Institute – National Center of Seed and Cultivar Investigation

Drought is a major problem throughout the world, which seriously affects crop yield and quality. *Dreb* genes are transcription factors. Their active expression can lead to the regulation of the entire series of genes controlled by them. There is evidence that *Dreb* genes are involved in the formation of resistance to a number of stresses, including drought. The aim of our work was to detect the polymorphism in *Dreb 1* genes for wheat varieties of home and foreign breeding and associate this polymorphism with drought resistance of wheat varieties. To determine the genetic polymorphism for *Dreb 1* genes there was performed DNA isolation from home bred wheat varieties that are highly drought-resistant: Odes'ka napivkarlykova, Al'batros odes'kyy, Bezosta 1, Stepnyak, Odes'ka 16, Zastava, Antonivka, Dal'nyts'ka, Odes'ka 132, Hoduval'nytsya, Vatazhok, Chayka, Viktoriya; from home bred varieties of wheat that are low drought-resistant: Hostianum 237, Odes'ka 3, Karlyk 1. As material with potentially low drought resistance there were used wheat varieties and lines of foreign breeding: Dromos, Florus, Faqus, Ortequs, Platin, 114013, WW4734, Armada, Alhambra, Ascott, Artagnen, Anapurna, T153, T154, T158, LCS News, LCS 3114. The study was performed with use of PCR analysis according to recommendations of Wei *et al.,* Husyeynova observed that 717 bp amplification product was detected in the PCR analysis of DNA drought-resistant variety Barakatli-95, and indicates the presence of the *Dreb 1* gene in B genome. But 717 bp amplification fragment was not found for other drought-resistant varieties studied by Husyeynova. We have detected 717 bp amplification product of *Dreb 1B* locus for the following varieties and lines: Odes'ka napivkarlykova, Al'batros odes'kyy, Bezosta 1, Stepnyak, Odes'ka 16, Zastava, Antonivka, Dal'nyts'ka, Odes'ka 132, Hoduval'nytsya, Vatazhok, Chayka, Viktoriya, Hostianum 237, Odes'ka 3, Karlyk 1, Dromos, Florus, Faqus, Ortequs, Platin, Ascott, Artagnen, Anapurna, T154, LCS 3114. In varieties and lines Alhambra, Armada, T153, T158 and LCS News there was found amplification fragment of 715 bp for *Dreb 1B* locus. Thus, the 717 bp amplification product is present both in the drought-resistant varieties and in the varieties which are low drought-resistant. For *Dreb 1D* locus there was detected amplification fragment of 1193 bp for the following varieties and lines: Odes'ka napivkarlykova, Al'batros odes'kyy, Bezosta 1, Stepnyak, Odes'ka 16, Zastava, Antonivka, Dal'nyts'ka, Odes'ka 132, Hoduval'nytsya, Vatazhok, Chayka, Viktoriya, Hostianum 237, Odes'ka 3, Karlyk 1, Dromos, Florus, Faqus, Ortequs, Platin, Ascott, Artagnen, Anapurna, T154, LCS 3114. Additionally amplification fragment of 1191 bp was found in varieties and lines: Alhambra, Armada, T158 and LCS News. According to our research amplification fragment of 1193 bp was detected for both drought-resistant varieties and for those varieties which are not drought-resistant.

Comparative transcriptome analysis of *Klebsormidium nitens* NIES-2285 between solid and liquid culture.

***Koichi Hori**[1], Hiroyuki Ohta[1,2]*

1. Tokyo Institute of Technology, School of Life Science and Technology

2. Tokyo Institute of Technology, The Earth-Life Science Institute

The colonization of land by plants was a key event in the evolution of life, making the modern terrestrial environment habitable by supplying various nutrients and sufficient atmospheric oxygen. During the colonization of land, the transition species of aquatic algae must have acquired a range of adaptive mechanisms to cope with the harsh features of terrestrial environments, such as drought, high-intensity light, and UV radiation. It is generally accepted that the ancestor (s) of current terrestrial plants was closely related to present-day charophytes. The charophyte algae *Klebsormidium* is an early diverging lineage of charophytes, and usually consist of multicellular and non-branching filaments without differentiated or specialized cells. *Klebsormidium* species therefore have primitive body plans, and most species that have adapted to land also can survive in fresh water. We provided 17,060 revised gene models (Version 1.1) including UTR sequences of *Klebsormidium nitens* NIES-2285 (formerly identified as *K. flaccidum*) based on new Illumina RNA sequence data. In this presentation, we report RNA-seq data of *K. nitens* NIES-2285 in solid and liquid culture. We will discuss the factors involved in adaptation to land environments.

Geophytic Organisms — Ontogeny & Phylogeny (GOOP)

Cody Coyotee Howard[1,2], *Nico Cellinese*[1,2]
1. Florida Museum of Natural History
2. University of Florida

Geophytes are a fascinating group of plants that can spend a large part of their lives underground, hidden from dangers such fire or unfavorable weather. This ability to withstand unconducive growth conditions by retreating underground has allowed species with this capability to inhabit landscapes across the globe ranging from deserts to alpine regions. Their belowground structures come in a wide array of morphological forms and include types such as bulbs, corms, tubers and rhizomes, and taxa exhibiting these structures can be found throughout the plant tree of life. While researchers have focused on select geophytic groups of interest from across the globe, the combined efforts of interested scientists would greatly increase our overall knowledge of these diverse, curious taxa. We hope to bring together the geophytophiles of the world with the Geophytic Organisms-Ontogeny & Phylogeny (GOOP) working group. The main goal of presenting at IBC is to interact with interested researchers and gauge the scienctific community's interest in collaborative research on geophytes in order to broadly investigate their complex evolution and development.

Linked and co-expressed QTLs in syntenic genomic regions for resistance to *Sclerotinia* stem rot and flowering time in *Brassica napus*

Fengqi Zhang[1,2], ***Junyan Huang***[1,3], *Mingxing Cheng*[1], *Xiaohui Cheng*[1], *Yueying Liu*[1], *Chaobo Tong*[1,3], *Jianguo Chen*[3], *Shengyi Liu*[1,3]
1. Oil Crops Research Institute of CAAS, Key Laboratory of Biology and Genetic Improvement of Oil Crops, Ministry of Agriculture
2. Cereal Crops Research Institute, Henan Academy of Agricultural Sciences
3. Hubei Collaborative Innovation Center for Green Transform

Sclerotinia sclerotiorum stem rot is a major disease in *Brassica napus* oilseed rape worldwide, particularly in China where annual yield loss is more than 10%. A close association of disease incidence with flowering time is widely observed in oilseed rape fields or germplasm. Up to now there are no reports on cloning of resistant QTLs and its definition of the association. To reveal the genetic relationship between the two traits, we investigated QTLs of both traits in a recombinant inbred line population derived from a cross between 888-5 (a susceptible and early flowering line) and M083 (a highly resistant and later flowering line). The population was genotyped by employing a *B. napus* 60K SNP array which produced a high density genetic map comprising 9,278 SNPs and spanning 4,071 cM of the genome. QTL mapping was conducted with phenotypic data of stem lesion size of artificial inoculation and both the disease index and flowering time which were evaluated in eight environments. A total of 31 QTLs for resistance were detected. Of them, the major QTL *qSSE2-1* in A2 explained 10.50%-27.30% of the phenotypic variation across the eight environments, but with no interactions with environments. For flowering time, 21 putative QTLs were found. Of them, the stable major QTLs *qFTE2-1* and *qFT2-6*, contributing to 16.40%-34.50% of the phenotypic variation in six environments, co-located with stable major QTLs *qSSE2-1* and *qSS2-9* in a narrow A2 region, but they are closely linked, rather than pleiotropy of a single gene. A syntenic analysis approach was used to search co-expressed QTLs in syntenic regions between the subgenomes A and C. Of syntenic regions found, *qSS2-10* in the A2 region is syntenic to *qSS12-1* in a C2 region and within the two QTL regions, two pairs of orthologous genes (in total, five genes and of them, two are tandem duplicates) were identified as preferential candidates which were annotated as hormone biosynthesis and transcription factor, respectively. Our results on the linked QTLs and the co-expressed syntenic QTLs will promote their fine mapping and help improve efficiency of breeding for *Sclerotinia* resistance and early maturation in oilseed rape.

The population genetics of *SODA1* indicated a possible divergent selection in two closely related wild rice—*Oryza rufipogon* and *O. nivara*

Lei Huang[1], *Yi Ren*[1], *Song Ge*[2]
1. College of Life Science, Shaanxi Normal University
2. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences

Ecological speciation accentuates the role of divergent selection in the process of two species adapting to different habitats. Identifying the candidate genes which may be the target of divergent selection or play a key role in ecological speciation is of great importance in evolutionary researches. *Oryza rufipogon* and *O. nivara* are two incipient species at the early stage of speciation with distinct differences in morphology, life history traits and habitat preference. Previous studies showed that *O. rufipogon* and *O. nivara* were good model of ecological speciation. In this study, we identified a candidate gene-*SODA1* by outlier approach based on whole genome re-sequencing data. The F_{ST} was very high in *SODA1* and we found 15 highly differentiated SNPs in this gene between *O. rufipogon* and *O. nivara*. In this study, we sampled six pairs of sympatric natural populations to verify the genetic differentiation of *SODA1* and carried out neutrality tests to detect possible selection signals in gene full length, 3 kb upstream and 3 kb downstream. In the 120 individuals sequenced, we identified a total of 36 highly differentiated SNPs in all six species pairs, and 3 SNPs were in coding region while 2 SNPs were nonsynonymous mutations. Interestingly, the two nonsynonymous mutations were found in all six species pairs, in contrast with other highly differentiated SNPs which were detected only in part of samples. Secondly, the average F_{ST} was relatively higher in *SODA1* gene region than those in upstream or downstream. The neutrality tests showed that *SODA1* gene might undergo positive selection in gene region. However, the selection signals were not detected in either upstream or downstream region. This indicated that the two nonsynonymous mutations would be more likely to the target of positive selection, and divergent selection might drive the genetic differentiation between *O. rufipogon* and *O. nivara* on *SODA1*. Previous gene function researches proved that *SODA1* was induced by drought and salinity stress. Since *O. nivara* adapted to seasonally dry environment from deep water habitat of *O. rufipogon*, the divergent selection of *SODA1* provided us new insights into the ecological speciation of *O. rufipogon* and *O. nivara*. Further work on the gene function may help us uncover the puzzle of how the divergence of *SODA1* is related to the speciation process. Furthermore, the different pattern of genetic differentiation on *SODA1* in 6 species pairs implied multiple origins of *O. nivara*, which was in accordance with previous studies.

Using CALUX bioassay to determine the dioxins in the effluent and the sludge of the pulp and paper enterprises in Guangxi Province, China

Ning Huang

Guangxi Environmental Monitoring Center

Chemical activated luciferase gene expression (CALUX) could be utilized for quantification of dioxins, and possesses advantages over high resolution gas chromatography/high resolution mass spectrometer (HRGC/HRMS) for short testing period, low testing cost, large quantities of samples analyzed in parallel and the total toxic potency of samples determining. It is applied specially for large-scale high throughput screening of large quantities of samples. In order to collect data for the "China-dioxins reduction from the pulp and paper industry project" sponsored by the global environmental facility (GEF), both samples of the effluent and the sludge collected from processing departments of several pulp/paper production enterprises in Guangxi Province were analyzed with CALUX bioassay. Water samples were collected at 40 L, and net weights of sludge samples 20 g. The analyzed results demonstrated that (1) The value of toxic equivalent quantities of dioxins in the effluent were within the range of 3.0 ~ 167 pg-TEQ/L, while the value of toxic equivalent quantities of dioxins in the sludge were within the range of 3.3 ~ 5.8 pg-TEQ/g. (2) Most dioxins content in processing effluent discharged by the pulp/paper production enterprises was higher than the discharged control limit value 30 pg-TEQ/L referenced as the discharge standard of water pollutants for pulp and paper industry (GB3544-2008), while the levels of dioxins in sludge were relative lower. (3) The dioxins content in the factory applied for chlorine bleaching process was higher than that for elemental chlorine-free bleaching process. This work was first conducted in effluent and sludge for the pulp/paper industries in Guangxi Province, and the testing results can provide valuable data for the treatment of dioxin pollution to the government of Guangxi.

Polyploids are not the genetic and ecological additivity of their progenitors

Stella Huynh[1], *François Felber*[1,2], *Olivier Broennimann*[3], *Antoine Guisan*[3], *Christian Parisod*[1]

1. Laboratory of Evolutionary Genetic, University of Neuchâtel

2. Musées et jardins botaniques cantonaux vaudois

3. Laboratory of Spatial Ecology, University of Lausanne

Polyploid organisms contain the chromosome sets of their progenitors and are therefore expectedly characterized by the additivity of their genetic backgrounds and ecological properties. Previous studies have long rejected this assumption, showing genome restructuring and ecological niche shifts following polyploidy. However, evolutionary processes shaping parental subgenomes in polyploids and their influence on the polyploid success remain unclear. We investigated here four diploids *Aegilops* species that differentially combined in four derivative tetraploids with 361 representative accessions that were genotyped at 35 single-copy nuclear loci. Amplicon sequencing with overlapping paired-end reads provided individual haplotypes which dosages were inferred based on their proportions. All four polyploids showed genome composition that is coherent with their selfing reproductive system, with homologs usually homozygous while heterozygosity is mostly fixed among homeologs. Some loci however presented alleles from only one of the parental subgenomes, highlighting asymmetrical genome reorganization with only part of the genetic diversity present in the diploid progenitors being retained in polyploids. To address whether this asymmetry is reflected in species ecological requirements, the niche of polyploid species was further compared to the addition of their diploid progenitors. Niche modeling based on 5821 georeferenced occurrences and 20 bioclimatic factors supported parallel ecological shifts with niche expansion towards moister and colder environments for three polyploids but substantial niche retraction for the last one. Niche comparisons between polyploids and their respective diploid ancestors show a symmetrical overlap with their progenitors for two polyploids while two others present asymmetrical overlap toward their common progenitor species. The reported non-additivity of *Aegilops* polyploids is thus characterized by asymmetrical changes of genetic and ecological traits, providing new insights on processes driving long-term evolution following polyploidy.

What have we learnt about plant drought tolerance mechanisms from high throughput phenotyping platforms?

Puertolas Jaime, *Ryan Annette C, Rothwell Shane A, Davies William J, Dodd Ian C*

Lancaster Environment Centre. Lancaster University

Selecting drought tolerant genotypes is one of the main research targets to increase crop yield under limited water availability, but plant responses to water deficit are complex and the traits controlling those responses can have different impacts depending on the drought scenario. Technologically advanced high-throughput screening platforms equipped with automated irrigation systems can measure a wide range of morpho-physiological variables in a large number of genotypes, to link phenotype to gene. At Lancaster, we have installed a “water use efficiency” phenotyping platform within our greenhouses, comprising 200 balances that continuously monitor crop water use. Maize plants (comprising 100 different genotypes) were grown with well-watered conditions under naturally varying atmospheric vapour pressure deficit (VPD), and transpirational responses to VPD and whole plant water use efficiency (WUE, defined as the accumulation of above ground biomass per unit of water used) were measured. While some genotypes showed a linear response of transpiration to VPD, others showed a non-linear response with a pronounced change point. Variation in the transpiration response to VPD was linked to genotypic ranking for WUE. When plants were grown under water-limited conditions, the response of xylem ABA concentration (a measure of soil water availability) was not uniquely related to transpiration rate or stomatal conductance according to the irrigation technique. At the same whole pot soil water content, maintaining sub-optimal soil water by frequent irrigation resulted in larger soil water content gradients, lower root and xylem ABA concentrations, along with higher transpiration rates or stomatal conductance, compared to plants from which water was withheld. Since physiological responses to soil drying depend on the irrigation method, genotypic variation in “drought tolerance” derived from phenotyping platforms must be carefully interpreted.

Phenotyping from the lab to the field and back

Marcus Jansen
LemnaTec GmbH

Plant phenotyping activities frequently originated from laboratory test, but since plants strongly respond to the environment, field based measurements gained high importance in recent times. At the same time, demand for gaining physiological data together with the morphometric properties came into play. Physiological measurements frequently are more complex than measuring plant dimensions, so that the laboratory environment gained importance for driving the development of new tools for physiological phenotyping. Physiological processes, as part of the development or in response to the environment or other organisms, cause changes in the plants that can be detected by means of non-invasive sensing. LemnaTec approaches such challenges by improved image and data processing for measuring disease and stress responses and by establishing tools for measuring early stages of plant development. Involving wavelengths beyond the visible spectrum as well as spectrally resolved images these developments will allow new insights in plant physiology and help to address new types of phenotypic data that complement classical laboratory analyses.

Research on gene clone and its expression, function in *E. coli* of *PseIF5A* from peony

Changhua Jiang[1,2], *Yan Gao*[1,2], *Kan Ye*[1,2], *Yao Song*[1,2], *Guangqi Zhao*[1,2], *Shucheng Feng*[1,2]
1. Shanghai Botanical Garden
2. Shanghai Engineering Research Center of Sustainable Plant Innovation

Eukaryotic translation initiation factor 5A (eIF5A) is the only cellular protein known to contain the unusual amino acid hypusine. It is a highly conserved protein found in all eukaryotic organisms. Although originally identified as a translation initiation factor, recent studies suggest that eIF5A is mainly involved in translation elongation, mRNA turnover and decay, cell proliferation, and programmed cell death. *RceIF5A* cloned from *Rosa chinensis* expression is up-regulated in *Rosa chinensis* under high temperature, and oxidative and osmotic stress conditions. In this research, *PseIF5A*, a gene induced by heat stress, had been cloned from ‘*Fengdanbai*’, one heat-tolerance variety of *Paeonia suffruticosa* under 38 ℃ /3h high temperature and its ORF has 480bp, with high homology comparison of nucleotide and amino acid sequence in *VveIF5A* from grape and *MaeIF5A* from *Mongolian ammopiptanthu*. Recombinant *PseIF5A* had detected in recombine *E. coli* BL21 by SDS-PAGE and western blot and its expression had made recombinant *E. coli* increase the abiotic stresses, such as high temperature (50℃), low temperature (4℃), heavy metal (300mM LiCl and 350mM $CdCl_2$), salt (550mM NaCl), high Ph (15mM Na_2CO_3) and oxidation (400um H_2O_2). So, this research result had indicated *PseIF5A* can response to various abiotic stresses.

Mysterious beauty: Evolution of R2R3-MYB transcription factors in plants

Chen-Kun Jiang, *Jing-Dan Han, Guang-Yuan Rao*
School of Life Sciences, Peking University, Beijing 100871, China

R2R3-MYB proteins are one of the largest groups of paneukaryotic transcription factors (TFs) in plants. Although many studies have made the classification of plant R2R3-MYB proteins using phylogenetic approaches, there is no consensus on the classification system due to lack of reliable and robust criterion in the identification of homologous sequences. More importantly, little attention was paid into deep phylogenetic relationships among R2R3-MYB TFs, which means that the origin and evolution of plant R2R3-MYB proteins remain unclear. In this study, we establish a new criterion to identify R2R3-MYB proteins, and use genome sequences from 38 species of algae and land plants to explore the relationships between these sequences. Phylogenetic analyses indicate that land plant R2R3-MYB proteins constitute nine subfamilies, and eight of them present in all of the major lineages, including bryophytes, lycophytes, gymnosperms and angiosperms. No member of R2R3-MYB subfamilies is identified in glaucophytes, rhodophytes and chlorophytes, whereas a stepwise increase in the number is found in streptophytes before terrestrialization of embryophytes. The subsequent increase of R2R3-MYB TFs in seed plants mainly result from the diversification of subfamily VIII, the largest subfamily. Interestingly, our study shows that DNA binding profiles are highly variable within subfamily VIII, while DNA binding profiles of other subfamilies are relatively conserved. We conclude that the R2R3-MYB TFs specific to land plants emerged in early embryophytes, and their diversification is attributed into intrinsic features of subfamily VIII MYB proteins as well as increasing complexity of biological processes.

ODE reconstruction of high-dimensional genetic networks through game theory with application to dissecting tree salt tolerance

Libo Jiang[1], *Rongling Wu*[1,2]
1. Beijing Forestry University
2. The Pennsylvania State University

Ordinary differentiation equations (ODE) have proven to be powerful for reconstructing precise and informative gene regulatory networks (GRNs) from dynamic gene expression data. However, joint modeling and analysis of all genes, essential for the systematical characterization of genetic interactions, are challenging due to high dimensionality and a complex pattern of genetic regulation including activation, repression and antitermination. Here, we address these challenges by unifying variable selection and game theory through ODE. Each gene within a GRN is co-expressed with its partner genes in a way like a game of multiple players, each of which tends to choose an optimal strategy to maximize its "fitness" across the whole network. Based on this unifying theory, we designed and conducted a real experiment to infer salt tolerance-related GRNs for Euphrates poplar, a hero tree that can grow in the saline desert. The pattern and magnitude of interactions between several hub genes within these GRNs were found to determine the capacity of Euphrates poplar to resist to saline stress.

Transcriptome analysis reveals the morphological difference of *Opisthopappus* Shih.

Juan He, Wei Chen, ***Yiling Wang***
College of Life Science, Shanxi Normal University

Opisthopappus (Asteracceae) were consisted of *Opisthopappus longilobus* shih and *Opisthopappus taihangensis* (Ling) Shih. Deepen our understanding of phylogenetic relationships ultimately assist morphological difference of the *O. longilobus* and *O. taihangensis* through molecular methods. However, the molecular methods are lack of genomic resource; it only provided limited information on full-length genes to compare the *O. longilobus* and *O. taihangensis* on the phylogenomics analysis. In our study, samples of *O. longilobus* and *O. taihangensis* were collected and sequenced, from which total RNA were ready for RNA-Seq. The transcriptome library was constructed, and first strand cDNA and second strand cDNA were synthesized. As result of sequence, average 35 million clean 150 bp-paired-end reads were obtained from three *O. Longilobus* and *O. taihangensis* tissue libraries, generated a total of 12.9 giga-bases (Gb) of sequences. A average 306,839,788 clean reads was obtained from 319,668,420 raw reads with percent of 99.99% To annotate the Trinity-assembled unigenes, the 33,974 unigenes were subjected to Blastx searches against six public databases. Based on the protein annotation results from the NR database homology search, 7,533 unigenes (Biological process: 5,231 unigenes; Cellular component: 4,689 unigenes; Molecular function: 6198 unigenes) could be assigned to 50 GO groups. The number of reads mapped back to the orthologous region of each gene in proper pairs were 45,161,366 (71.54%) and 47,663,788 (69.42%) in the *O. taihangensis* and *O. longilobus*, respectively. To validate gene expression, 52 DEGs related to somatic embryogenesis were selected for qRT-PCR analysis. Totala 3410 differentially expressed transcripts were detected, with 1925 up-regulated and 1485 down-regulated genes. The conclusion showed that the information obtained in this study will undoubtedly provide genomic resource and insights into the molecular mechanisms of leaf forms diversity of *Opisthopappus* Shih.

A specialised information service for biodiversity research, involving large-scale data mobilisation by mining German biodiversity literature

Gerwin Kasperek[1], *Marco Schmidt*[2]
1. University Library Johann Christian Senckenberg
2. Senckenberg Gesellschaft für Naturforschung

Biodiversity research heavily relies on recent and older literature, and the data contained therein. Despite great effort, large parts of the literature and the data it holds are still not available in appropriate formats needed for efficient compilation and analysis. As a part of the current funding strategy of the German Research Council (Deutsche Forschungsgemeinschaft, DFG), and resulting from an extensive dialogue with the scientific community in Germany, a "Specialised Information Service" (Fachinformationsdienst, FID) for Biodiversity Research will be established with the objective of making further segments of literature about biodiversity available in up-to-date formats. This project, starting 2017, is conducted by the University Library Johann Christian Senckenberg (Frankfurt/Main, Germany) together with the Senckenberg Gesellschaft für Naturforschung and the Text Technology Lab of the Goethe University (Frankfurt/Main). The new Specialised Information Service for Biodiversity Research (FID Biodiversitätsforschung) comprises four core elements: An essential focus is on the mobilisation of biodiversity data from the literature via a text mining approach which encompasses advanced text technologies and a large body of 20th century literature (Module 1). The aims of this module are twofold: to mobilise data on selected keystone groups (vascular plants, butterflies, birds) in the Central European literature, and, to develop reusable text mining tools which are adapted to the domain-specific contents and formats of the biodiversity literature. The chosen approach involves integration of botanical, zoological and ecological ontologies (such as PO, FLOPO, ENVO) as well as ontology development, maintenance and enhancements. The digitisation of German literature (Module 2) provides a significant part of the text corpus which is a necessary prerequisite for Module 1. The online availability of 20th century literature regarding the selected keystone groups will be substantially improved. Furthermore, Module 2 provides a basis for the journal platform (Module 3). A platform für Open Access journals (Module 3) will be established as a long-term service for biological academic societies and not-for-profit editors. This service also comprises the transfer of print-only titles into digital formats. The acquisition of specialised print literature (Module 4), combined with efficient services for document delivery, ensures nation-wide availability for researchers in Germany, with delivery also available to other countries. Built on the foundation of the comprehensive holdings of biological literature supported by the DFG for decades, this service encompasses the entire bandwidth of biodiversity literature.

Identification of novel QTLs for tea quality traits in black tea (*Camellia sinensis*)

Kipyegon Robert Koech
University of Pretoria

The tea plant is indigenous to southern and eastern Asia and has been cultivated in China since ancient times. Tea, a product made up from the leaf and buds of the plant *Camellia sinensis*, is one of the most widely consumed beverages in the world, and has become an important agricultural product. Tea being a popular beverage, has attracted attention of both the consumers and the scientific community because it contains a number of bioactive compounds, such as the flavonoids, caffeine, L-theanine and γ-aminobutyric acid (GABA). It has been demonstrated to have a wide variety of pharmacological properties including antioxidant, anti-inflammatory, anticancer, antidiabetic, neuroprotective effects. These health benefits associated with tea intake have led to high consumption of tea products in regards to tea extracts in pharmaceutical, food and beverage and cosmetic industries. In addition, to these health benefits, tea quality is a complex phenomenon and depends mainly on the biochemical components that determine colour, aroma and taste, attached to the tea infusions. Tea quality is a complex and subjective trait, and breeding for this trait is time consuming and depends on knowledge of the genetics of its components. In a study conducted in Kenya, we have developed an integrated genetic map of tea (*Camellia sinensis*) using DArTseq platform on a segregating 251 F_1 population derived from a reciprocal cross between two highly heterozygous commercial tea cultivars (TRFK 303/577 and Gw Ejulu). High-density linkage maps of both parents were constructed based from the F_1 population that was taken from cross-pollinated population using integrated approaches (regression algorithm). The map consisted of 14 linkage groups that spanned 1,162.80 cM with mean interval of 1.2 cM between markers. A total of 15 phenotypic traits were assessed in the two tea plant populations. Both interval and multiple QTL mapping revealed a total of 33 putative QTLs in the 14 LGs associated with tea quality at a significance genome-wide threshold of 5%. In total, six caffeine QTLs, 23 catechins QTLs, three theaflavins QTLs and one QTL for liquor brightness were detected. Of these 33,13 major QTLs were identified for five traits in three main regions on LG01, LG03, LG11, LG12 and LG13. QTLs associated with individual catechins, caffeine and individual theaflavins were mostly located clustered in LG01 and LG03 but in different regions of the map. The population variability explained by each QTL was predominantly at moderate-to-high levels and ranged from 5.5% to 56.6%, with an average of 10.7%. The identification of QTLs that are tightly linked to these markers at the seedling stage and using UPLC technique coupled with genetic markers would greatly accelerate development of elite tea cultivars. These will also contribute to development of marker-assisted selection (MAS) for tea quality improvement.

Molecular genetic polymorphism of bread wheat varieties and associations of microsatellite loci alleles with agricultural valuable traits

Olga Kolesnyk*, Andrii Venger*
Plant Breeding and Genetics Institute – National Center of Seed and Cultivars Investigations (PBGI)

The executed researches are devoted to estimation of allelic diversity of microsatellite loci, differentiation and identification of modern bread wheat varieties (*Triticum aestivum* L.) originated in Plant Breeding and Genetic Institute and registered in State Register of plant varieties suitable for dissemination in Ukraine during different years. There were analyzed the intravarietal heterogeneity and distribution of allele frequencies of microsatellite loci that have selective and adaptive value for the South region of Ukraine. Based on the results of SSR analysis of studied varieties, molecular genetic registration certificates of all varieties were created. To ensure the unambiguous differentiation and identification of modern bread wheat varieties with a common origin from a single breeding center there were created the minimally required working sets of microsatellite markers that have close differentiating abilities and consist of six-eight microsatellite loci. Determining of specific genomic regions which control important agronomical traits is considered to be one of the main wheat breeder’s goals. The detection of significant associations between microsatellite markers and such traits as heading time, plant height, awn size, colour and size of ears, which can be used for applying in plant molecular breeding to improve the efficiency of marker assisted selection (MAS) for finding important quantitative trait loci (QTLs). 34 marker trait associations (MTAs) for heading time, 37 for plant height, 32 for awn size, 18 for ear colour and 8 for size of ears were proved to be stable and significant in all growing seasons. The SSR markers *Xgwm186-5A* and *Xgwm3-3D* were significantly associated with all analyzed traits and showed stability in all four years for plant height. Analysis of microsatellite markers associated with grain colour was performed in order to identify the important regions involving in this trait. As a result, 36 MTAs were found to be significant in one-three growing seasons, of which 19 MTAs were significantly associated with the lighter grain colour (CI_g) while 17 MTAs showed association with the darker CI_g. Among studied 17 microsatellite markers we have found alleles of *Xgwm357-1A*, *Xgwm18-1B*, *Xtaglgap-1B*, *Xgwm155-3A*, *Xgwm389-3B*, *Xgwm3-3D*, *Xgwm186-5A*, *Xgwm190-5D*, *Xgwm325-6D*, *Xgwm577-7B*, *Xgwm44-7D* and *Xwmc405-7D* associated with the value of CI_g. During the analysis of microsatellite markers associated with 1000 kernel weight (TKW) 26 MTAs were found to be significant in one – three growing seasons, of which 12 MTAs were significantly associated with the larger value of TKW while 14 MTAs showed association with the smaller value of TKW. Among studied 17 microsatellite markers we have found alleles of *Xgwm18-1B*, *Xgwm095-2A*, *Xgwm389-3B*, *Xgwm3-3D*, *Xgwm165-4A*, *Xgwm186-5A*, *Xgwm408-5B*, *Xgwm325-6D* and *Xwmc405-7D* associated with TKW. Microsatellite markers which showed significant associations and stability in different seasons can be useful and suitable for improving the efficiency of MAS in Ukrainian wheat breeding programs.

Cytogenetic and epigenetic analysis of rDNA Loci in invasive *Spartina anglica* allopolyploid and the homoploid *S. × townsendii* hybrid

Alena Kuderová[1]*, Ilia Leitch*[2]*, Dalibor Húska*[1]*, Julie Ferreira De Carvalho*[3]*, Andrew R. Leitch*[4]*, Malika Ainouche*[4]*, Aleš Kovařík*[1]

1. Institute of Biophysics, Academy of Sciences of the Czech Republic, Královopolská 135, 612 65 Brno, Czech Republic

2. Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey TW9 3AB UK

3. 3UMR 6553 ECobio Université de Rennes 1, Bât. 14A Campus de Beaulieu, France

4. Queen Mary University of London, School of Biological and Chemical Sciences,, Mile End Road, London E1 4NS, UK

Interspecific hybridisation between the hexaploid *Spartina alterniflora* (♀, 2n=6x=62, genomic composition AA) from North America and the native British hexaploid *S. maritima* (♂, 2n=6x=60, genomic composition MM) produced the largely infertile homoploid hybrid *S.* × *townsendii* (2n=6x=62, genomic composition AM) first collected in 1870 at Hythe, Southampton, UK. The derived fertile allopolyploid *Spartina anglica* C.E. Hubbard dodecaploid (2n=12x=120-124), genomic composition AAMM) is thought to have formed by spontaneous duplication of chromosome sets soon after the hybridisation event. Invasive *S. anglica* has rapidly expanded in distribution and occurs on several continents. In evolutionary ecology, *S. anglica* has become recognized as a model system of recent allopolyploid speciation. Cytogenetically it represents a difficult object due to a large number of chromosomes and limited availability of tissues containing mitotic cells. Samples were also collected from 11 French (mostly Brittany) and 3 British (Southampton water) populations of *Spartina.* The localities were repeatedly visited during 2011-2016. The ploidy levels were determined by flow cytometry. Real-time RT-PCR using locus-specific primers allowed us to quantify homeologous 35S rRNA transcripts. rDNA loci were visualized on chromosomes by fluorescent *in situ* hybridization (FISH) in four individuals collected from the British populations using the 18S and 5S rDNA probes. The *S.* × *townsendii* hexaploid hybrid inherited two sites of each 35S and 5S rDNA. The derived *S. anglica* dodecaploid (two individuals) inherited four sites of each 35S and 5S rDNA. However, the third *S. anglica* individual from the same locality (Ealing Marchwood, UK) harboured only two 35S sites, and Southern blot hybridisation analysis revealed that the M-genome loci were lost. At the expression level, large survey of more than 60 individuals collected from English and French populations revealed: (i) The A-genome genes were always expressed and frequently dominant. (ii) The M-genome genes were silenced in most populations except of two populations from Southern Brittany where codominance was observed. (iii) *S.* × *townsendii* and *S.* × *neyrautii* (independent hybrid from the south of France) exhibited strong silencing of M-genome units indicating that interspecific hybridisation is sufficient to trigger epigenetic inactivation of rDNA homeologs. Despite large number of chromosomes and high ploidy levels (up to 12x) *Spartina* allopolyploids tend to keep diploid numbers of rDNA loci. This is explained by rapid locus loss following polyploidisation events. Though most *S. anglica* individuals we analysed here retain locus and gene additivity we identified one individual that lost the M-genome locus suggesting that the process of rDNA “diploidisation” may have already started in these recently formed allopolyploids. We hypothesize that locus inactivity may eventually lead to its elimination. Thus, there might long-term genetic consequences of immediate and directional epigenetic changes triggered by interspecific hybridisation.

P1213

Multicolour FISH-based analysis of mutagen-induced micronuclei in *Brachypodium distachyon*

Arita Kus*, Jolanta Kwasniewska, Robert Hasterok*

Department of Plant Anatomy and Cytology, Faculty of Biology and Environmental Protection, University of Silesia in Katowice

Higher plant bioassays are well established systems for screening and monitoring environmental genotoxicity. *Brachypodium distachyon* is an internationally accepted model grass, which possesses numerous, highly desirable ‘model’ biological features, such as one of the smallest (~350 Mb) nuclear genomes described to date in Poaceae with low (x = 5) chromosome number. This grass is also characterised by a small stature, self-fertility, short life cycle and undemanding growth requirements. Due to well-studied organisation of the *B. distachyon* nuclear genome both at the molecular and cytogenetic level, we used this species as a reference organism, which would be a convenient system in mutagenesis to analyse “hot spots” of DNA damage in a small genome grass. The advances in molecular biology enabled the progress in methods of the detection and estimation of genotoxicity of different agents. Here, we quantitatively analyse the maleic hydrazide (MH)-induced micronuclei in order to examine the involvement of specific chromosomes or chromosome fragments in their formation. Fluorescence *in situ* hybridisation (FISH) with four different and used simultaneously DNA probes (5S rDNA, 25S rDNA, *Arabidopsis*-type (TTTAGGG)n telomeric sequence and *Brachypodium* originated centromeric BAC (Bacterial Artificial Chromosome) clone CB33J12 was applied in the quantitative and qualitative analysis of the micronuclei. The results allowed to distinguish ten different types of micronuclei, which were characterised by the presence or absence of specific FISH signal (s). We demonstrated that the most of the MH-induced micronuclei originated from the distal regions of chromosomes. Furthermore, for the detailed analysis of mutagen-induced genome changes we used FISH with selected single-copy chromosome-specific BAC clones. Our findings demonstrate a promising potential of *B. distachyon* to be a valuable model to analyse the effects of various genotoxic agents on the plant nuclear genome stability. This work was supported by the National Science Centre, Poland (grant no. 2012/04/A/NZ3/00572).

Transcriptome analysis of *Michelia maudiae* petals: Putative

genes associated with flower colour formation

Xiaoan Lang[1,2,3], *Lingfei Li*[3], *Leilei Yang*[3], *Jianhua Qi*[1], *Tiecheng Cui*[2], *Shouzhou Zhang*[3]
1. Southwest Forestry University
2. Zhaoqing University
3. Fairylake Botanical Garden, Shenzhen & Chinese Academy of Sciences.

Michelia maudiae Dunn is one of the most highly valuable medicinal and ornamental plants with white colour flowers. However, in the wild there also exist another mutant *M. maudiae* Dunn var. *rubicunda* Yi et J. C. Fan, whose flowers can be naturally pink, thus it provides an opportunity to unravel the complex regulation networks of colour formation in Magnoliaceae. White petals cDNA library of *M. maudiae* and pink petals cDNA library of *M. maudiae* var. *rubicunda* in two individual developmental stages were used for transcriptome sequencing using Illumina HiSeq 2500 platform. Among all 109,729 uni-transcripts isolated. A total of 60,538 unigenes were annotated by comparison with non-redundant National Center for Biotechnology Information (NCBI) protein (Nr), non-redundant NCBI nucleotide (Nt), Gene Ontology (GO), and Kyoto Encyclopedia of Genes and Genomes (KEGG) databases. Nr annotation results revealed that the squences of *Michelia* showed more similarity to Nymphaeaceae than to other families, with 37.64% match to *Nelumbo nucifera*. Total 41,231 differential experssion genes (DEGs) were identified by comaprison between different groups. GO term enrichment analysis of these DEGs showed that ATP binding, intergral component of membrane, and metabolic process were dominant; KEGG pathway enrichment analysis revealed they were mainly involved in spliceosome, starch and sucrose metabolism, biosynthesis of amino acids. Futhermore, total 258 unigenes were identified as putative homologues of colour-related genes in other species, of which 142 showed differential expression between white and pink petals, account for 55.0%. Interestingly, *4CL*, *F3H*, *DFR*, *UFGT* showed low expression in white while high expression in pink petals which could be the direct reason led to transtion of petals from white to pink, although the detail mechanism still need to clarify. This study will provides a new theoretical basis and novel gene resources for tree breeding.

Cis-regulatory variations of a single copy gene associate with root growth adaptation to high iron levels in *Arabidopsis thaliana*

Baohai Li, *Wolfgang Busch*
Gregor Mendel Institute, Austrian Academy of Sciences, Vienna Biocenter, 1030 Vienna, Austria

The geographic distribution of heavy metals in soils is a critical factor that determines the diversity and population size of plant species in a local region. Heavy-metal tolerance in plants is therefore important for local adaptation. While, Iron (Fe) is the most important transition metal in all living organisms, it is highly toxic to cells when present in excess. In past decades, several important molecular components involved in Fe uptake, transport and homeostasis have been identified, however, which genes and mechanisms are responsible for the natural genetic variation of plant sensitivity to Fe toxicity are largely unknown. Here, we conducted genome-wide association studies (GWAS) in 319 *Arabidopsis thaliana* accessions using root growth responses to a high level of Fe. We identified one single copy gene, encoding for an alcohol dehydrogenase that is highly conserved among different species to be the major locus responsible for the variation of root growth responses to high Fe in the *Arabidopsis* population used for the GWAS. Compared with the reference (Col-0) allele, the variant is associated with increased root sensitivity to high Fe and a low expression level. Interestingly, the lowly expressed variant occurs predominantly in accessions derived from areas with a higher soil pH; a growth environment with decreased Fe bioavailability. In agreement with the hypothesis that activity of this gene is important for growth under high Fe, the root growth of a knockout mutant line is negatively correlated with the Fe level supplied in growth medium, and an overexpression line displays enhanced resistance to high Fe. As the variation of its expression level seems key for its role in natural variation, we aimed to map the expression quantitative trait loci that underlie this expression variation, by making use of a GWAS with its transcript levels in 665 *Arabidopsis* accessions. Our analysis revealed that natural variation of our candidate gene's expression is mainly due to cis-regulatory variation in multiple independent SNPs in its promoter region. In summary, we have identified cis-regulatory elements that most likely confer intraspecies expression variation of an otherwise highly conserved alcohol dehydrogenase that according to its expression level modulates root growth in response to high Fe levels. This suggests that the modulation of enzyme levels counteracts the detrimental effects of high Fe may be an important adaptation to high Fe environments in *Arabidopsis*.

2. Bioinformatics Center, National Key Laboratory of Crop Genetics and Germplasm Enhancement, Nanjing Agricultural University, Nanjing 210095
3. Department of Biological Sciences, Michigan Technological University, Houghton, MI 49931

Although the molecular basis of carpel fusion in maize ovary development remains largely unknown, increasing evidence suggests a critical role of microRNAs (miRNAs). Here, a combination of miRNA sequencing, degradome and physiological analysis was used to characterize carpel fusion development in incompletely fused carpels (IFC) ovary and completely fused carpels (CFC) ovary in maize. A total of 162 known miRNAs distributed across 33 families were identified, of which 20 were differentially expressed. In addition, 53 miRNA candidates were identified, and 10 of them were found to be differentially expressed in IFC and CFC ovaries. In degradome analysis, a total of 113 and 11 target genes were predicted for known and novel miRNAs, respectively. Thereinto, 24 (60%) target genes of the differentially expressed known miRNAs were found to code transcription factors, including auxin response factors (ARF), TB1-CYC-PCFs (TCP), APETALA2 (AP2), growth regulating factor (GRF), MYB, NAC, NF-YA and so on, which have been proved to have roles on regulating carpel fusion development. Correlation analysis of differentially expressed known miRNAs and their targets to phytohormone signals revealed that either of the miRNA or of its target had a significant correlation to at least one phytohormone signal, the main regulator of carpel fusion development. These results suggested that incomplete carpel fusion is partly the result of differential expression of certain miRNAs and their targets. Taking together, the findings improve our knowledge about the effect of miRNA regulation on target expression, providing a useful resource for further analysis of the interactions between miRNAs, target genes and phytohormones during carpel fusion development in maize.

Comparative study on the complementary distribution of simple sequence repeats and intron polymorphism in plant

Yi Wang[2], ***Huayang Li***[1], *Long Yang*[1]
1. Agricultural Big-Data Research Center, College of Plant Protection, Shandong Agricultural University
2. Beijing Key Laboratory of Grape Science and Enology and Key Laboratory of Plant Resource, Institute of Botany, Chinese Academy of Sciences

Molecular marker is an important tool in the study of comparative genomics. Due to the rapid development of biotechnology, it is more urgent need some new and efficient markers that with high polymorphism, high cover rate or functional. In this study, we large-scale developed two kinds of markers, simple sequence repeats (SSRs) and intron polymorphism (IP) in 259 plants' genome. Using a pipeline program by Perl script, we had developed a total of 1,715,915 SSR, 1,232,445 IP and 2,326,806 PIP. Among all the markers, 1,063,896 SSR and all IP were based on the model plants. The overlap rate of SSR and IP markers in all species was in a very lower level. The moss had the highest overlap rate (9.41%), and most of others were less than 5%, even 1 or 2 percent minimum. That's mean that SSR and IP is complementary distribution in plant. PSID (Plant SSR and IP Database) is a platform that provides SSR and IP markers and other related information of most sequenced plants to the biologist. It is freely available on the web (http://biodb.sdau.edu.cn/psid/home.html). The result would cause a revolution that the combined utility of SSR and IP markers in the area of molecular plants.

Physiological and epigenetic analyses of *Brassica napus* seed germination in response to salt stress

Jian Li, *Yujie Fang, Youping Wang*
Yangzhou University

Salinity stress significantly affects plant growth and development because of osmotic stress, ion toxicity, and nutrient imbalance. Therefore, salinity stress becomes a serious threat to rapeseed production in agriculture. Epigenetic regulations, including DNA methylation and histone modification, play a major role in tuning gene expression into plant response to environmental stimuli. Although many progresses have been reported in plant response to salt stress, the epigenetic changes in *Brassica napus* under salt stress are far from being understood. A series of physiological parameters, including water content, proline content, malondialdehyde content, electrolyte leakage, and antioxidant enzyme activities, under different concentrations (0, 25, 50, and 100 mM) of NaCl treatment in "Yangyou 9" was determined at the germination stage. Immunofluorescent staining and high-performance liquid chromatography-assisted quantification were conducted to analyze the level and distribution patterns of DNA and histone methylation under salt stress. Results of morphological and physiological analyses under salt stress indicated that 25 mM NaCl treatment promoted the growth of "Yangyou 9" seedlings, whereas 50 and 100 mM NaCl treatments inhibited the growth of "Yangyou 9" seedlings. Epigenetic investigations showed that 25 mM NaCl mediated the enrichment of H3K4me3, as well as decreases in H3K9me2 and 5-methylcytosine (5-mC), whereas 50 and 100 mM NaCl induced increases in H3K9me2 and 5-mC and a decrease in H3K4me3. Overall, this study offers new insights into the epigenetic changes in salt stress response in rapeseed, and this information would be propitious to engineering crops for salt tolerance.

A new variety breeding and study of purple V-marking white clover

Jinbo Li
ShenZhen Techand Ecology & Ennironment CO., LTD

White clover (*Trifolium repens* L.), perennial and creeping, is a kind of good leguminous forage and ideal flowering and foliage cool-season turfgrass, belonging to family Leguminosae and genus *Trifolim*. One hundred and eighteen accessions of white clover samples around the world were collected. a mutant strain with distinguishing purple V-marking on leaves was obtained from 118 accessions of white clover samples around the world collected. Through years of breeding, the new variety of purple V-marking white clover, which was the first variety used of turf and forage, approved by the Inner Mongolia Committee of Grass Variety examination in 2015, filled the gap of lawn with white clover breeding in China. Relationship analysis showed that it originated from "QZH2004-3" and genetic analysis showed that purple is controlled for single gene. Then, the purple candidate gene *TrMYB1* was determined through the RNA-seq transcriptome sequencing and pH differential method. The main results we got are as follows. 1. One hundred and eighteen accessions of white clover samples around the world were collected to build a germplasm nursery, based on this nursery, we evaluated the white clover germplasm resources and bred new variety. After selfing and hybridization using mutant strain, a new landscaping variety of white clover integrated ornamental, covering and turf value with a distinguishing purple V-marking on leaves was obtained. This variety approved by the Inner Mongolia Committee of Grass Variety examination in 2015, widely used in the production. 2. The results of genetic diversity of ISSR and ITS using cluster analysis revealed that white clovers showed a relatively regional distribution law: the samples from Asia, Oceania and America have a relatively close relationship, while the European and Western Asia ones in relationship were near. purple v-marking white clover built a separate branch with QZH2004-3 from Guizhou, China in cluster, suggesting that they have close relationship, and the former is probably a mutant of the latter. 3. RNA-sequencing was proceed in both QZH2004-3 and purple V-marking white clover. In the new variety many differential expression gene about purple V-marking were identified. To provide candidate of V-marking related gene, the gene involved in KEGG pathway and those differential expression gene were mutual authenticated, and 6 candidate genes were further studied. 4. pH-differential method were used in the qualitative and quantitative analysis of anthocyanin in purple V-marking white clover. The results were remarkalbe, the specific metabolites of white clover with purple V-marking is anthocyanin, and the content reached 5.43mg/100g. Conserved sequence of MYB were used to design primers and the transcription factor *TrMYB1* gene regulated the anthpcyanin biosynthesis was isolated and homology-based cloned, the genetic and corresponding protein structure were also analysed.

Drought-induced gene expression changes in tissues of loblolly pine clones

Jingjia Li[1], *Jason West*[1], *Carol Loopstra*[1], *Tom Byram*[1], *Jean-Christophe Domec*[2], *Jeff Puryear*[1], *Matthew Smith*[1], *Claudio Casola*[1]

1. Texas A&M University

2. Bordeaux Sciences Agro

Loblolly pine plantations represent a major economic and ecological resource in the Southeastern United States, a region bound to sustain a dryer and warmer climate in the near future. In this study, we combine physiological and transcriptome measurements to 1) identify variation in sensitivity of loblolly pine clones to low water availability; 2) identify genes involved in drought tolerance in needle and root tissues. This study takes advantage of a greenhouse experiment with seedlings from several loblolly pine clones grown under control and low-water treatments. Several traits related to water use were measured in these seedlings to determine physiological responses to water stress. One of two clones used for transcriptomic analysis exhibited drought-tolerance physiological responses in preliminary experiments, although the same two clones showed no significant difference in subsequent analysis of seedlings response to low water availability. To investigate on the genetic basis of drought tolerance, RNA was extracted from needles and roots of seedlings from these two clones under control and low water treatments. Analyses of the RNA-Seq data showed 71,600 expressed genes, of which ~92% were transcribed in both tissues, although root samples exhibited higher transcription levels and more expressed genes than needles. Using the DESeq2 we identified 560 up-regulated genes and 2,173 down-regulated genes in tissues from low-water treatment seedlings compared to control plants. Gene Ontology analyses revealed a functional enrichment for genes involved in response to stimulus in both groups of genes, and a specific abundance of up-regulated transcripts involved in response to abscisic acid and potassium transmembrane transport. Additionally, we identified 7,817 genes with differential expression between the two clones. Ongoing analyses will point to the genetic networks involved in drought tolerance across the examined tissues and clones of loblolly pine. These results will be integrated with the physiological measurements to provide novel insights into the genetic architecture of traits implicated in drought response in loblolly pine.

RNA polymerase III dependent *AtR8* long non-coding RNA relate with *WRKY53* and *WRKY70* on plant defense in *Arabidopsis*

Shuang Li[1], *Saraswati Nayar*[2], *Sanjay Kapoor*[2], *Juan Wu*[3], *Yasushi Yukawa*[1]

1. Grad. Sch. Nat. Sci., Nagoya City Univ.,

2. Dept. Plant Mol. Biol., Univ. Delhi South Camp.,

3. Alkali Soil Nat. Env. Sci. Cent., Northeast Forestry Univ.,

An *AtR8* RNA transcribed by RNA polymerase III (Pol III) was discovered as a highly abundant long non-coding RNA (lncRNA) in *Arabidopsis*. The AtR8 RNA is a 260 nt lncRNA observed in root tips and localized in cytosol. And in *atr8* mutant, early flowering-stalk elongation was observed. In the previous study, this RNA was responsive to hypoxic stress and salicylic acid (SA) treatment. SA is one of plant hormone that play important roles in responses to environmental conditions. Microarray assay with *atr8* mutant showed some WRKY transcription factor (FT) genes were up regulated. WRKY TFs are one of the largest families among transcriptional factors in plants. When WT, *atr8*, *wrky53* and *wrky70* mutant were growing in the medium with or without SA (20 μM), different root elongations were observed. And then each RNA accumulation levels were assayed by real time RT-PCR. *WRKY53*, *WRKY70* mRNA and *AtR8* RNA expression levels were also quite immediately elevated by plant pathogen *Pseudomonas syringae* infection. To sum up, *AtR8* RNA expression could relate with *WRKY53* and *WRKY70* expressions through plant defense.

Transcriptome analysis provides insights into wood formation during larch tree aging

Wan-Feng Li[1], *Wen-Hua Yang*[1], *Shou-Gong Zhang*[1], *Su-Ying Han*[2], *Li-Wang Qi*[1]

1. State Key Laboratory of Tree Genetics and Breeding, Research Institute of Forestry, Chinese Academy of Forestry

2. State Key Laboratory of Tree Genetics and Breeding, Research Institute of Forest Ecology, Environment and Protection, Chinese Academy of Forest

Tree age affects wood formation and yield. However, the underlying mechanisms are poorly understood, particularly at the molecular level. In this study, we investigated the transcriptomic changes of the uppermost main stems of *Larix kaempferi* in an entire rotation period using the RNA-Seq method. In total, ~151 million reads were obtained from the stems of 1-, 2-, 5-, 10-, 25-, and 50-year-old *L. kaempferi* trees. Combining these with the published Illumina sequencing reads, 299,637 assembled transcripts were generated, of which 161,232 were annotated. 12,927 transcripts were identified as differentially-expressed genes (DEGs) by time-series expression profiling; function enrichment analysis of these DEGs showed that 459 gene ontology terms in the biological process category were enriched. These terms were associated with the processes of wood formation, such as cell differentiation, growth and death, and its hormonal regulation. Based on the expression patterns of *L. kaempferi* homologues of genes associated with ethylene, calcium, and cell-wall expansion and synthesis, the regulatory network of tracheid growth was outlined. Altogether, the comparative transcriptomic analysis reported here demonstrated the molecular aspects of aging effects on *L. kaempferi* wood formation. The identification of genes involved in the regulatory network of tracheid growth provides a means of investigating the regulation of wood formation in gymnosperm trees and also offers potential targets for genetic manipulation to improve the properties of xylem fibers.

Gene duplicability of core genes is highly consistent across all angiosperms

Zhen Li[1,2], *Jonas Defoort*[1,2], *Setareh Tasdighian*[1,2], *Steven Maere*[1,2], *Yves Van De Peer*[1,2, 3], *Riet De Smet*[1,2]
1. VIB
2. Ghent University
3. University of Pretoria

Gene duplication is an important mechanism for adding to genomic novelty. Hence, which genes undergo duplication and are preserved following duplication is an important question. It has been observed that gene duplicability, or the ability of genes to be retained following duplication, is a nonrandom process, with certain genes being more amenable to survive duplication events than others. Primarily, gene essentiality and the type of duplication (small-scale versus large-scale) have been shown in different species to influence the (long-term) survival of novel genes. However, an overarching view of "gene duplicability" is lacking, mainly due to the fact that previous studies usually focused on individual species and did not account for the influence of genomic context and the time of duplication. Here, we present a large-scale study in which we investigated duplicate retention for 9,178 gene families shared between 37 flowering plant species, referred to as angiosperm core gene families. For most gene families, we observe a strikingly consistent pattern of gene duplicability across species, with gene families being either primarily single-copy or multicopy in all species. An intermediate class contains gene families that are often retained in duplicate for periods extending to tens of millions of years after whole-genome duplication, but ultimately appear to be largely restored to singleton status, suggesting that these genes may be dosage balance sensitive. The distinction between single-copy and multicopy gene families is reflected in their functional annotation, with single-copy genes being mainly involved in the maintenance of genome stability and organelle function and multicopy genes in signaling, transport, and metabolism. The intermediate class was overrepresented in regulatory genes, further suggesting that these represent putative dosage-balance-sensitive genes.

P1225

A new factor containing WD-40 domain positively regulated the primary miRNAs processing in *Arabidopsis thaliana*

Chao Liang[1], *Qiang Cai*[1], *Beixin Mo*[1], *Xuemei Chen*[1,2]
1. Shenzhen University
2. University of California, Riverside

MicroRNAs (miRNAs) are a class of 20-24 nucleotide (nt) non-coding RNAs, which negatively regulate gene expression through cleaving their target RNA or repressing translation. We have chosen a genetic screening for *Arabidopsis* miRNA biogenesis pathway mutants, utilizing vein beaching phenotype caused by phloem specific expression of an artificial miRNA (amiR-SUL) targeting *CH42* gene as a visible selection marker, and isolated a suppressive mutant named *ab57*. Both exogenous amiR-SUL and the endogenous miRNAs levels are reduced in *ab57* seedlings, along with the decrease of their primary transcripts. Chromatin Immunoprecipitation (ChIP) result shows that the occupancy of RNA polymerase II (Pol II) at *MIR* promoters is reduced in *ab57*. Here we report the *ab57* mutant which is defective in a WD-40 domain protein. The WD-40 proteins are evolutionarily conserved in plants. We reveal that this WD-40 domain protein interact with DICER LIKE 1 (DCL1) which is efficient for miRNAs generation from pri-miRNAs. Besides, we further reveal the interaction between the WD-40 domain protein and CDC5, which regulates the *MIR* transcription and the pri-miRNAs processing. Based on the results, we propose this WD-40 domain protein links transcription of *MIR* genes by Pol II to processing of pri-miRNAs by DCL1.

Phylogenomics of Lauraceae: Complete chloroplast genome sequence of *Neolitsea sericea* (Blume) Koidz. and clarifying the phylogenetic position of *Neolitsea*, an important Asian tree genus

Xijian Liang[1], *Damien D. Hinsinger*[1], *Joeri S. Strijk*[1,2]
1. Plant Ecophysiology & Evolution Group, Guangxi Key Laboratory of Forest Ecology and Conservation (under state evaluation status), College of Forestry, Nanning, Guangxi,
2. State Key Laboratory for Conservation and Utilization of Subtropical Agro-bioresources

Genomic, evolutionary and biogeographical studies of complex, diverse and widely distributed plant groups are hampered by a number of technical and practical difficulties. This is especially true for major plant families in the tropics, which are often characterised by amorphic and widespread tropical genera supported by weak taxonomical and nomenclatural frameworks. This has major consequences for our efforts to understand, study and conserve tropical biodiversity. Unlike most other Magnoliids, Lauraceae are highly species rich with over 3000 species worldwide, making it one of the dominant plant families encountered in predominantly warm temperate and tropical regions. This makes them an important structural and evolutionary component of wet tropical forests. Many species are locally and commercially used for their wood, fruits and high concentration of essential oils which are valued for spices and perfumes. The loss of untouched habitat in tropical regions, coupled with overexploitation of commercially attractive species has put many species in danger of extinction, as evidenced by the growing number of Lauraceae on the IUCN Red List. The Red List currently holds 295 species, with the majority (72%) in the top three categories and the most important threat reported being logging and wood harvesting. Regrettably, despite their abundance and widespread occurrence, Lauraceae remain poorly known and difficult to identify, primarily due to the absence of clear vegetative characters that can aid in successful identification. This absence of diagnostic characters perturbs also into a poor delimitation of genera, prohibiting the construction of congruent classifications and the continued existence of large paraphyletic and polyphyletic genera in Lauraceae to this day. The genus *Neolitsea* consists of nearly 100 species distributed widely from Indo-Malaysia to East Asia and Australia. They occur mostly as small shrubs and trees, forming an important component of low- and mid-elevation forests. China is a centre of diversity for the genus with nearly 50 species distributed across the southern provinces. Little is known about the internal relationships of the genus or its exact position in the family, as higher generic relationships in Lauraceae remain unclear. In our study we aim to resolve internal relationships by employing whole chloroplast sequencing, enriched with additional sequencing of portions of the nuclear genome. Here we present the first complete plastome for the genus *Neolitsea*. The chloroplast of *N. sericea* showed the structure and composition usually found in angiosperm (LSC, IRa, SSC, IRb ; GC = 37.8%), and contained 129 genes (29 tRNA, 8 rRNA, 92 coding genes). Using complete chloroplasts for 15 related genera produced by our ongoing project, we clarified the position of the genus *Neolitsea* in Lauraceae and confirmed its inclusion in the Laureae group. We also provided a first estimate of its genomic divergence from the rest of family. As demonstrated by our study, the use of complete chloroplasts opens exciting opportunities to address evolutionary questions in Lauraceae. Finally, better knowledge of this ancient family, successfully facing major environmental changes since its origin, will help us to face the ongoing global climatic changes.

Genomic imprinting and DNA methylation in dicotyledonous seeds with persistent endosperms

Wei Xu, ***Aizhong Liu***

Kunming Institute of Botany, Chinese Academy of Sciences

Genomic imprinting causes parent-of-origin specific differential expression of maternally and paternally inherited alleles. Triploid endosperm tissue is the main place where gene imprinting occurs. In this study, we inspected genomic imprinting in castor bean endosperm where gene imprinting persists throughout seed development using high throughput RNA sequencing. Total, we identified 209 genes with potential parent-of-origin specific expression, including 200 maternally expressed genes (MEGs) and nine paternally expressed genes (PEGs) in reciprocal endosperms, and seven MEGs and three PEGs in the embryos. To dissect the potential molecular mechanism underlain gene imprinting arise in endosperms, we comprehensively analyzed the distribution of genomic DNA methylation between embryo and endosperm tissues, we uncovered 1) a significant hypodemethylation in the endosperm and an enrichment of DMRs around the earlier identified imprinted genes; 2) the CHH methylation levels in endosperm and embryo were, unexpectedly, substantial higher than known plants; 3) the endosperm hypodemethylation was caused by the global reduction in the CG and CHG methylation level relative to its embryo, but the CHH methylation occurring in endosperm did not exhibit a significant reduction; 4) combining with the expression profiles of DNA methyaltion-related genes in endosperm and embryo, we proposed a novel genomic DNA methylation pattern. Taken together, we discussed that emergence of gene imprinting, biological interests and its potential driver power of DNA methylation. This study might add new insights into understanding the genomic imprinting and DNA methylation occurring in dicot seeds.

SNP genotyping by exome-seq localized 9.5K genes for development of a high density genetic map in limber pine (*Pinus flexilis* James)

Jun-Jun Liu[1], *Anna W. Schoettle*[2], *Richard A. Sniezko*[2], *Fupan Yao*[1], *Benjamin Rancourt*[1], *Hao Chen*[1], *Arezoo Zamany*[1]

1. Canadian Forest Service

2. USDA-FS

Limber pine is one of keystone conifer species of high elevation forest ecosystems in North America. Many of its populations are seriously impacted by the invasive, exotic fungal pathogen *Cronartium ribicola*, which causes white pine blister rust (WPBR) on five-needle pines of the subgenus Strobus. Genetic maps with localization of functional genes at the genome level provide essential knowledge for understanding genetic resistance and local adaptation to changing climates in all living organisms. Because limber pine possesses a huge genome (~30.5Gbp), exome-seq was used to explore genetic variations such as single nucleotide polymorphisms (SNPs) and genotype two seed families with 91 and 99 individuals. About 14 K unique gene sequences from a limber pine reference transcriptome de novo assembled in a previous study (Liu *et al.,* BMC Genomics, 2016) were targeted by probe design to enrich the exome. Analysis of exome-seq data found that a total of 87,374 SNPs from 12,389 genes (~85% of total genes selected for exome enrichment) segregated at least in one mapping seed family with an expected segregation ratio. A consensus limber pine genetic map was constructed with localization of 9,510 expressed genes (including >600 NBS-LRR and >200 RLK genes) on 12 linkage groups (LGs), corresponding to the number of chromosomes in *Pinus* species. The total genetic distance was calculated at 2,043 cM with ~4.6 genes per cM. Of all genes co-segregated with phenotypic traits, we identified functional candidates that putatively control host resistance against WPBR. Syntenic relationships among *Pinus* species were further determined, revealing both conservative and divergent regions in genome structure among *Pinus* species. Using genome sequences of two other *Pinus* species released recently, we investigated how genetically co-localized genes are distributed across the genome sequence scaffolds. This high density genetic map provides genomic resource and practical tools for application in breeding and genetic conservation programs, and will facilitate final characterization of functional genes contributing to adaptive traits and help sequencing and assembly of the full-length genomes in limber pine and related *Pinus* species.

Genomics study of five-needle pine major gene resistance to white pine blister rust

Jun-Jun Liu[1], *Anna Schoettle*[2], *Richard Sniezko*[3]
1. Canadian Forest Service
2. USDA Forest Service, Rocky Mountain Research Station
3. USDA Forest Service, Dorena Genetic Resource Center

Molecular breeding incorporates efficient tools to increase rust resistance in five-needle pines. Susceptibility of native five-needle pines to white pine blister rust (WPBR), caused by the non-native invasive fungus *Cronartium ribicola* (J.C.Fisch.), has significantly reduced wild populations of these native conifers in North America. Four five-needle pine species have been found with major gene resistance against specific avirulent pathotypes. In this study we screened genic SNP markers by comparative transcriptome and genetic association analyses. Saturated SNP linkage maps were constructed for the *R* (*Cr2* and *Cr4*) loci in western white pine (*Pinus monticola*, Douglas ex D. Don) and limber pine (*Pinus flexilis* E. James). Comparative SNP mapping among *Pinus* species anchored *P. monticola Cr2* locus and *P. flexilis Cr4* locus on the Pinus consensus linkage group1 (LG1) and LG8, respectively. GO annotation identified a set of NBS-LRR and other resistance-related genes as *R* candidates in five-needle pines. Practical molecular tools for marker-assisted selection (MAS) were developed by association genetics of non-synonymous SNP loci of the NBS-LRR genes, which will shorten the breeding cycle of resistance screening and aid in the restoration and management of WPBR-disturbed and threatened forest ecosystems.

Profiling methyl jasmonate-responsive transcriptome for understanding induced systemic resistance in whitebark pine

Jun-Jun Liu[1], *Williams Holly*[1], *Xiao Rui Li*[1], *Anna W. Schoettle*[2], *Richard A. Sniezko*[2], *Michael Murray*[3], *Arezoo Zamany*[1], *Hao Chen*[1]
1. Canadian Forest Service
2. USDA-FS
3. Ministry of Forests, Lands and Natural Resource Operations, BC Government

Whitebark pine is an endangered conifer species due to its high susceptibility to mountain pine beetle and white pine blister rust fungus. Resistance mechanisms, such as induced systemic resistance (ISR), are not well characterized in conifers, hindering forest conservation and resistance breeding programmes. Exogenous jasmonates are well known to trigger ISR by manipulating the plant immunity system through regulation of global gene expression to the production of chemical defense compounds. In the present study whitebark pine transcriptomes were profiled post methyl jasmonate (MJ) treatment using RNA-seq. MJ-responsive transcriptome was *de novo* assembled and sequent transcriptome profiling identified a set of differentially expressed genes (DGEs) in response to MJ application, revealing 1,421 up- and 999 down-regulated transcripts with at least two-fold-changes (FDR corrected p <0.05), respectively. GO analysis revealed that these MJ-responsive DEGs have putative functions in plant defense signalling, transcription regulation, biosyntheses of secondary metabolites, and other biological processes. Comparison with MJ signalling in model plants detected whitebark pine lineage-specific defense-related genes. It was further found that MJ-triggered transcriptome re-programming highly overlapped with the defenses responses against either herbivore or fungal pathogen as reported in close Pinus species, suggesting that MJ has potential application to improve whitebark pine resistance/tolerance to MPB and WPBR. Our study provides new insights into molecular mechanism and metabolic pathways involved in whitebark pine ISR. The candidate genes for improving resistance may benefit genetic dissection of genomic variation contributing to host immunity and breeding selection of elite genotypes with better adaptive fitness to environmental stresses in this endangered tree species.

Study the function of *AtFbox* on flowering time in *Arabidopsis*

Wei Zhu, *Zhixue Dong, Junyan Huang, Shengyi Liu*
Oil Crops Research Institute, Chinese Academy of Agricultural Sciences

Plants react to flower formation controlled by complicated molecular pathway, and have many alternative splicing variants (ASVs) in these genes controlling flowering time. However, why there are so many ASVs and whether there is function differentiation involved in traits such as flowering time are unclear. Here we characterize a alternatively splicing variants gene controls flowering time and its protein interacts with AtFbox2, named *AtRDR* producing two splicing variants of *AtRDR1* and *AtRDR2* which promote flowering. Through yeast library screening and yeast two hybridization, we identified one candidate protein AtFbox whose function is unknown and whose gene *AtFbox* that produced 4 ASVs was chosen to study its function and further check whether specific interactions occur between ASVs of the *AtRDR* and *AtFbox* . The BIFC (bimolecular fluorescence complementation) identified that AtRDR1 and AtRDR2 interacted with AtFbox2 respectively in cell membrance and cell nuclei, but did not detected for interaction with AtFbox1. AtFbox2 has been identified to regulate photoperiod-responsive growth by integrating the clock with light perception pathways through modulating daily phyB-signaling. *AtFbox* belongs to the F-box family, and produces three extra transcripts *AtFbox2*, *AtFbox3* and *AtFbox4* as well as a normal full length transcript *AtFbox1*. *AtFbox2* only contains the first two exons and lacks the sequence encoding the F-box functional domain required for protein ubiquitination in different functional pathways. Genetic analysis showed that negative regulation of *AtFbox* on flowering time, and over-expressed *AtFbox1* and *AtFbox2* in *Arabidopsis* wild type exhibited later flowering and shorter hypocotyl compared to WT. The T-DNA insertion mutant *fbox* was earlier flowering and longer hypocotyl, which is consistent to the SAMs of *fbox* differentiated earlier than WT. The *fbox* mutant will be partially recovered WT phenotype by over-expression of *AtFbox1* or *AtFbox2* in the genetic complementation test.

Linked and co-expressed QTLs in syntenic genomic regions for resistance to *Sclerotinia* stem rot and flowering time in *Brassica napus*

*Fengqi Zhang[1,2], **Junyan Huang**[1,3], Mingxing Cheng[1], Xiaohui Cheng[1], Yueying Liu[1], Chaobo Tong[1,3], Jianguo Cheng[3], Shengyi Liu[1,3]*

1. Oil Crops Research Institute of CAAS, Key Laboratory of Biology and Genetic Improvement of Oil Crops, Ministry of Agriculture, Wuhan, China.

2. Cereal Crops Research Institute, Henan Academy of Agricultural Sciences, Zhengzhou, China.

3. Hubei Collaborative Innovation Center for Green Transformation of Bio-Resources, Hubei University, Wuhan, China

Sclerotinia sclerotiorum stem rot is a major disease in *Brassica napus* oilseed rape worldwide, particularly in China where annual yield loss is more than 10%. A close association of disease incidencewith flowering timeis widely observedin oilseed rape fields or germplasm. Up to now there are no reports on cloning of resistant QTLs and its definition of the association. To reveal the genetic relationship between the two traits, we investigated QTLs of both traits in are combinant inbred line population derived from a cross between 888-5 (a susceptible and early flowering line) and M083 (a highly resistant and later flowering line). The population was genotyped by employing a *B. napus* 60K SNP array which produced ahigh density genetic map comprising 9,278 SNPs and spanning 4,071cM of the genome. QTL mapping was conducted with phenotypic data of stem lesion size of artificial inoculation and both the disease index and flowering time which were evaluated in eight environments. A total of 31 QTLs for resistance were detected. Of them, the major QTL *qSSE2-1* in A2 explained 10.50%-27.30% of the phenotypic variation across the eight environments, but with no interactions with environments. For flowering time, 21 putative QTLs were found. Of them, the stable major QTLs *qFTE2-1* and *qFT2-6*, contributing to 16.40%-34.50% of the phenotypic variation in six environments, co-located with stable major QTLs *qSSE2-1* and *qSS2-9* in a narrow A2 region, but they are closely linked, rather than pleiotropy of a single gene. A syntenic analysis approach was used to search co-expressed QTLs in syntenic regions between the subgenomes A and C. Of syntenic regions found, *qSS2-10* in the A2 region is syntenic to *qSS12-1* in a C2 region and within the two QTL regions, two pairs of orthologous genes (in total, five genes and of them, two are tandem duplicates) were identified as preferential candidates which were annotated as hormone biosynthesis and transcription factor, respectively. Our results on the linked QTLs and the co-expressed syntenic QTLs will promote their fine mapping and help improve efficiency of breeding for *Sclerotinia* resistance and early maturation in oilseed rape.

Dissecting QTLs for plant height in a set of dwarf and semi-dwarf *Brassica napus* mutants

***Chuanji Zhao**, Junyan Huang, Chaobo Tong, Khorshed Alam Muhammad, Yueying Liu, Xiaohui Cheng, Shengyi Liu*

Key Laboratory of Biology and Genetic Improvement of Oil Crops, the Ministry of Agriculture, Oil Crops Research Institute of CAAS, Wuhan 430062, China.

Oilseed rape (*Brassica napus*) in the Changjiang valley is a tall crop and mechanized management such as chemical spray in the crop late growth stage and mechanical harvestare difficult, and furthermore its harvest index is rather low. An ideal plant architecture should be developed to meet mechanization requirement and to increase harvest index. To this end, understanding controlling genes of plant height is one of crucial elements. In this project, five lines of four dwarf and one semi-dwarf (*dwf* and *s-dwf*) mutants and one taller mutant, all derived from a bulk of EMS mutagenized seeds of *B. napus* cv. zhongshuang9 (ZS9), has been investigating. In the mature stage, in comparison with ZS9, the height of the *dwf* and *s-dwf* was respectively reduced by about 58% and 30% evaluated in multiple years in fields. For genetic analysis of the two mutants, we constructed two F_2 populations from the ZS9×*dwf* and ZS9×*s-dwf*, which showed an expected Mendelian inheritance ratio of 7:9 and 15:1 (tall-dwarf plants, $\chi^2 < \chi^2_{0.05} = 3:84$; $P < 0.05$), indicating that the phenotype of the two mutants was respectively controlled by two gene loci. Allelic test showed the loci are not allelic between the two mutants. Genome wide SNP profiling byre-sequencingof BSA pools from theF_2 populations identified two significant genomic regions, one on A04 (3.3 Mb) and another on A04 (0.1 Mb) controlling dwarf. Similarly, two significant genomic regions, one on C03 (7.6 Mb) and another on C03 (1.5 Mb) were identified for semi-dwarf. Further studies are in progress.

Arabidopsis BREVIPEDICELLUS interacts with the SWI2/SNF2 chromatin remodeling ATPase BRAHMA to regulate *KNAT2* and *KNAT6* expression in control of inflorescence architecture

*Minglei Zhao, **Xuncheng Liu***

South China Botanical Garden, Chinese Academy of Sciences

BREVIPEDICELLUS (BP or KNAT1), a class-I KNOTTED1-like homeobox (KNOX) transcription factor in *Arabidopsis thaliana,* contributes to shaping the normal inflorescence architecture through negatively regulating other two class-I *KNOX* genes, *KNAT2* and *KNAT6*. However, the molecular mechanism of BP-mediated transcription regulation remains unclear. In this study, we showed that BP directly interacts with the SWI2/SNF2 chromatin remodeling ATPase BRAHMA (BRM) both *in vitro* and *in vivo*. Loss-of-function *BRM* mutants displayed inflorescence architecture defects, with clustered inflorescences, horizontally orientated pedicels, and short pedicels and internodes, a phenotype similar to the *bp* mutants. Furthermore, the transcript levels of *KNAT2* and *KNAT6* were elevated in *brm-3*, *bp-9* and *brm-3* *bp-9* double mutants. Increased histone H3 lysine 4 tri-methylation (H3K4me3) levels were detected in *brm-3*, *bp-9* and *brm-3 bp-9* double mutants. Moreover, BRM and BP co-target to *KNAT2* and *KNAT6* genes, and BP is required for the binding of BRM to *KNAT2* and *KNAT6*. Taken together, our results indicate that BP interacts with the chromatin remodeling factor BRM to regulate the expression of *KNAT2* and *KNAT6* in control of inflorescence architecture.

Mitochondrial genome of mycoheterotrophic *Hypopitys monotropa*: unusual structure and extensive RNA editing.

Maria Logacheva[1], *Mikhail Schelkunov*[2], *Viktoria Shtratnikova*[1], *Aleksey Penin*[1]
1. Lomonosov Moscow State University
2. Institute for Information Transmission Problems

The capability to photosynthesis is the distinctive feature of plants, which is of highest importance for biosphere. However, there are plants, including several thousands of flowering plant species that obtain organic substances from sources other than photosynthesis. These plants get the organics either from associated fungi (myco-heterotrophy), or by parasitising on other plants. While plastid genomes of non-photosynthetic plants are well characterized, little is known about mitochondrial genomes. We report the structure of mitochondrial genome in *Hypopitys monotropa*, a mycoheterotrophic member of Ericaceae, and the expression of mitochondrial genes. In contrast to highly reduced plastid genome, the mitochondrial genome of *H. monotropa* is larger than that of its photosynthetic relative *Vaccinium macrocarpon*, its complete size is ~ 810 Kb. We found an unusual long repeat-rich structure of chondriome that suggests the existence of linear fragments. Despite this unique feature, gene content of *H. monotropa* chondriome is typical for flowering plants. Notably, we did not found any acceleration of substitution rates in mitochondrial genes, in contrast to previous observations on non-photosynthetic plants. Transcriptome sequencing revealed trans-splicing of several genes and extensive RNA editing.

De novo assembly and characterization of the root transcriptome of two traditional chinese medicine species, *Scrophularia ningpoensis* and *S. burgeriana* (Scrophulariaceae)

Jocelyn Losh, *Chengxin Fu, Chuan Chen*
Zhejiang University

Scrophularia ningpoensis (Ningpo figwort) and *Scrophularia buergeriana* (Buerger's figwort) occur throughout southern and northern China, respectively. While *Scrophularia ningpoensis*' roots are used extensively in Chinese medicine to treat arthritis and inflammation, *S. burgeriana*'s roots are less-commonly used, even though modern studies have shown that the species contains the same bioactive compounds. The diversity between the two species is not yet fully understood due to the lack of genome and SSR data. Here we report the results of *Scrophularia ningpoensis* (XS-L) and *S. buergeriana*'s (XS-3Y) *de novo* root transcriptome sequencing, characterization, and a comparative transcriptome analysis between the two species. Our goals were to create a foundation of genome sequence data and to identify genes potentially expressed differently between the root transcriptomes of these two economically important species. In this study, the sequencing of cDNAs resulted in a total of 46,918,622 (*XS-L*) and 48,007,868 (*XS-3Y*) clean reads. These clean reads were assembled into 58,893 and 56,235 unigenes, respectively. These unigenes were annotated through comparison with known protein databases NR, Swiss-Prot, KEGG and COG. For XS-L, 50,161 (85%) were annotated, and for XS-3Y, 49,988 (89%) were annotated. Based on NR annotation, 32,093 unigenes from XS-L and 32,396 from XS-3Y were assigned gene ontology (GO) with 14,034 shared functional terms. We performed transcriptome sequencing of *S. ningpoensis* and *S. buergeriana* and generated 6724 orthologous genes. To find the differently-expressed genes (DEGs), we employed the RPKM method to compare the transcriptomes. The differently expressed genes between *S. ningpoensis* and *S. buergeriana* result in up-regulation or down-regulation of various biological processes such as in metabolism or response to stimuli, as well as in differing cellular components and molecular functions. However, the greatest percentage of DEGs (14.72%) relate to metabolic pathways the result of differential expression of genes can be varying levels of secondary compounds such as cinnamic acid, harpagoside, angroside C, and acteoside, important factors in *Scrophularia*'s medicinal effects. Additionally, we developed EST-SSR molecular markers from single nucleotide polymorphisms (SNPs) in the unigenes. The unigenes were searched for SSRs using the MISA program and primers were designed using the Oligo 7 software. Around 50 primers were successfully designed with polymorphic amplicons. To validate the markers, 12 *S. ningpoensis* individuals (10 wild, 2 cultivated), 2 *S. buergeriana* individuals (1 wild, 1 cultivated) and one individual each from the closely-related *S. kakudensis* and *S. yoshimurae* were tested for amplification. The markers may be used in the future for phylogenomic studies of the *Scrophularia* genera. This study provides valuable resources for the field of Traditional Chinese Medicine as well as for future phylogenomic endeavors.

Genome-wide survey reveals transcriptional differences underlying the contrasting trichome phenotypes of two sister desert poplars

Jianchao Ma, *Xiaodong He, Xiaotao Bai, Zhimin Niu, Bingbing Duan, Ningning Chen, Xuemin Shao, Dongshi Wan*
State Key Laboratory of Grassland Agro-Ecosystem, School of Life Sciences, Lanzhou University, Lanzhou 730000, China

Trichomes, which are widely used as an important diagnostic characteristic in plant species delimitation, play important roles in plant defense and adaptation to adverse environments. In this study, we used two sister poplar species, *Populus pruinosa* and *Populus euphratica*, which have, respectively, dense and sparse trichomes to examine the genetic differences associated with these contrasting phenotypes. The results showed that 42 and 45 genes could be identified as candidate genes related to trichomes in *P. pruinosa* and *P. euphratica* respectively; most of these genes possessed high degrees of diversification in their coding sequences but they were similar in intron/exon structure in the two species. We also found that most of the candidate trichome genes were expressed at higher levels in *P. pruinosa*, which has dense trichomes, than in *P. euphratica*, where there are few trichomes. Based on analyses of transcriptional profiles, a total of 195 genes, including many transcription factors, were found to show distinct differences in expression. The results of gene function annotation suggested that the genes identified as having contrasting levels of expression level are mainly associated with trichome elongation, ATPase activity and hormone transduction. Changes in the expression of these and other related genes with high sequence diversification may have contributed to the contrast in the pattern of trichome phenotypes between the two species.

Constitutive over expression of *HSP24.4* gene for the development of salt tolerance in cultivated tomato

Upender Mahesh[1], *Mamidala Praveen*[2], *Rao Pjm*[3], *Hari Yadla*[3], *Kirti P.B.*[1], *Ramaswamy Nanna*[2], *Aragao Francisco Jl*[4]
1. University of Hyderabad
2. Kakatiya University
3. Prof. Jayashankar State Agricultural University
4. National Centre for Genetic Resources and Biotechnology

Tomato (*Solanum lycopersicum* L.) is sensitive to high salt conditions at almost all the stages of its growth and development. Considering the important role of heat shock proteins in imparting tolerance against high salt to the cells and tissues, for the first time, we isolated small *HSP24.4 (MasHSP24.4)* cDNA from wild banana (*Musa accuminata*) and introduced into the cultivated tomato cv PKM1 via *Agrobacterium tumefaciens* Stable integration and expression of the transgene in the tomato genome was demonstrated by southern, northern and western blot analyses. The genetic analysis of the transgenic T_2 tomato lines showed the Mendelian ratio in transgene segregation. The *MasHSP24.4* showed expression in root, shoot and stem tissues at 200mM and 300mM NaCl treatments and conferred tolerance to high salt stress by showing increased seed germination, healthy vegetative growth and normal fruit and seed setting. The transgenic tomato plants showed significantly the best growth performance in the recovery phase following the stress could be due to over expression of *HSP24.4* gene. Thus, the development of transgenic tomato plants for high salt tolerance could provide advantage to use the semi-arid tropics and also drought-prone areas in a better way.

Computational approach to study the role of active site amino acid in thermostability of alpha amylases

Arooma Maryam, *Abdul Rauf Siddiqi*
COMSATS Institute of Information Technology (CIIT), Islamabad-45550

Pakistan experiences a huge production cost in detergent, textile processing and leather industry due to import of alpha amylases. This study provides insight into the structural determinants of thermostability in alpha amylase family to aid the process of protein engineering. We have undertaken a comparative sequence and structural study on seven homologous mesosphilic and thermophilic microbial species to decipher the thermostability features in alpha amylase family. Sequence Analysis and Molecular docking studies revealed presence of charged residues in primary structure and strong network of ionic and stacking interactions within the active site and disulphide bridges involving cysteine residues (Cys153, Cys154, Cys388, Cys432) as main factors of thermostabilityof *Pyrococcusfuriosus* alpha amylase as compared to its prokaryotic and eukaryotic homologues. One of the promising factors contributing to the thermostability in *Pyrococcusfuriosus* that was deficient inits homologs is presence of numerous charged residuesin the active site of thermo tolerant alpha amylases. These charged residues are making strong hydrogen bonds and vander wall interactions with the substrates. Among non-covalent interactions aromatic interactions (arene- arene&arenecations) interactions seems a determinant factor for the overall stability in this enzyme family. Analysis of protein protein interactions in hyperthermostable *Pyrococcusfuriosus* had shown the involvement of residues from neighbouring domain to stabilize its catalytic domain. These structural features might be helpful for in house-production of thermo stable enzymes for industrial application.

A defence pathway linking plasma membrane to chloroplasts is co-opted by a virus to suppress salicylic acid signaling

Laura Medina-Puche, *Tabata Rosas-Diaz, Liping Wang, Tamara Jimenez-Gongora, Dan Zhang, Xue Ding, Chanhong Kim, Yuanyuan Zhang, Shanshan Lv, Renyi Liu, Rosa Lozano-Duran*
Shanghai Center for Plant Stress Biology, Chinese Academy of Sciences, Shanghai

Plant pathogens need to suppress plant defence responses in order to establish a successful infection. RNA silencing is considered the main plant anti-viral defence; in recent years, however, it has become increasingly clear that plants have additional strategies against viral invasion, which include production of defensive hormones such as salicylic acid (SA) and jasmonic acid. C_4 is a small protein encoded by *Tomato yellow leaf curl virus* (TYLCV) which is essential for infectivity, but of which the molecular function remains obscure. Our results indicate that C_4 is localized in two different subcellular compartments, namely plasma membrane and chloroplasts. This double localization correlates with the presence in the C_4 protein of two targeting signals, an N-myristoylation motif required for plasma membrane localization, and a chloroplast transit peptide. Interestingly, we have found that these two targeting signals are present in a number of pathogen effectors, as well as in a subset of plant proteins, many of which play a role in defence. These data suggest that a pathway may exist in plants linking plasma membrane and chloroplasts to regulate defence, and that this putative pathway is hijacked by plant pathogens, presumably to suppress these responses. Strikingly, transcriptome analysis of transgenic *Arabidopsis* plants expressing C_4 shows a clear repression of SA biosynthesis and responses. Treatments with pathogen-associated molecular patterns (PAMPs) to activate defence trigger a re-localization of C_4 from plasma membrane to chloroplasts, and production of SA in response to this treatment is halved in plants expressing C_4 or a non-myristoylable version of C_4, which localizes to chloroplasts exclusively. Given that the biosynthesis of this defensive hormone occurs in the chloroplast, our current hypothesis is that activation of plant defence leads to the re-localization of C_4 from plasma membrane to chloroplasts, where it inhibits SA biosynthesis to promote the viral infection.

Genetically encoded FRET-based biosensor for *in vivo* monitoring of glycine betaine in living cells

Mohammad Ahmad[1], *Tariq Omar Siddiqi*[1], *Altaf Ahmad*[2]
1. Jamia Hamdard
2. Aligarh Muslim University

Glycine betaine (GB) accumulates in the cell at exceedingly high level under the conditions of high salinity and plays a crucial role in the maintenance of osmolarity of the cell without affecting the physiological processes. Since, analysis of stress-induced physiological conditions in living cells requires real-time monitoring of cellular GB level. A genetically encoded FRET-based biosensor has been developed in this study that allows the real-time monitoring of GB levels inside living cells. GB binding protein (ProX) was sandwitched between the cyan fluorescent protein (CFP) and yellow fluorescent protein (YFP), which are known as Förster resonance energy transfer (FRET) pair. This trimeric sensor protein was named as Glycine Betaine Optical Sensor (GBOS). Conformational change in ProX, which was used as sensory domain, reported the change in the level of this compatible solute under *in vitro* and *in vivo* conditions. Binding of the GB to the sensory domain fetches close to both the fluorescent moieties that result in the form of increased FRET ratio. So, any change in the concentration of GB is correlated with change in FRET ratio. This biosensor also reported the GB cellular dynamics in real-time in *Escherichia coli* cells after the addition of its precursor, choline. GBOS was also expressed in yeast and mammalian cells and live cell imaging was performed to monitor the intracellular GB level, quantitatively. Therefore, the GBOS represents a unique FRET-based nanosensor which allows the non-invasive ratiometric analysis of the GB in living cells.

Comparative organellar genomics of the European Calypogeiaceae

Kamil Myszczyński[1], *Monika Ślipiko*[1], *Katarzyna Buczkowska*[2], *Alina Bączkiewicz*[2], *Monika Szczecińska*[1], *Jakub Sawicki*[1]
1. University of Warmia and Mazury in Olsztyn
2. Adam Mickiewicz University

Calypogeiaceae is liverwort family distributed worldwide, primarily in subtropical and tropical climates. Nowadays only a few chloroplast and mitochondrial genomes of liverworts have been completely sequenced. Further neither plastome nor mitogenome sequence of Calypogeiaceae have been revealed. In this study we present phylogenomic analyses of sequenced chloroplast and mitochondrial genomes of all known European Calypogeiaceae species. The plastome and mitogenome of Calypogeiaceae display the typical structure of most liverworts, however few exceptions were found including introns loss. SNP and indels were also identified among analyzed species. Comparative genomics analyses of the species were conducted with main focus on possible reasons of differences in reproductive morphology of Calypogeiaceae. Identification of differences between monoecious: *Calypogeia integristipula* and *C. neogea* and dioecious: *C. arguta* and *C. suecica* revealed that presence of one or both sex organs is not due to chloroplast or mitchondrial genomes diversity.

Molecular and chemical evidences for the poisoning of a duck by Anatoxin-a, Nodularin and Cryptophycin at the coast of the ShoorMast Lake (Mazandaran province)

Bahareh Nowruzi
Department of Biology, Science and Research Branch, Islamic Azad University, Tehran, Iran

The toxic cyanobacteria in aquatic ecosystems are a big concern especially in warm summer months. Animals are incapable of avoiding toxic blooms near the shore and might get poisoned. There have been many cases, when ducks, sheep, cows and dogs have died for poisoning caused by cyanobacteria. In this study the aim was to find a cause of death for a duck found near the coastal area of the ShoorMast Lake. Cyanotoxin poisoning was suspected as the cause of fatalities, as a result, the water samples were collected and examined with phenotypic and genotypic analyses in order to find if the duck is poisoned by the toxic cyanobacteria. Different molecular and chemical methods such as phylogenetic analysis based on 16S rRNA gene sequence, polymerase chain reaction (PCR), disc diffusion bioassays and liquid chromatography-mass spectrometry (LC-MS) were used. Based on the results, three different cyanobacteria strains were found in duck´s stomach and three diverse groups of potentially bioactive compounds (Anatoxin-a, Nodularin and Cryptophycin) might account for the death of this animal. The cyanobacteria strains were identified and registered under DDBJ as *Anabaena* sp. BN KY303913, *Nodularia* sp. BN KY303914 and *Nostoc* sp. BN KY303912. This case is the first documented incident of toxicity from fresh water cyanobacteria related intoxication in Iran.

Primitive auxin response without TIR1 and Aux/IAA in the charophyte alga *Klebsormidium nitens*

Kinuka Ohtaka[1], *Koichi Hori*[2], *Yuri Kanno*[3], *Mitsunori Seo*[3], *Hiroyuki Ohta*[1,2,4,5]
1. Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology
2. School of Life Science and Technology, Tokyo Institute of Technology
3. Center for Sustainable Resource Science, RIKEN
4. Japan Science and Technology Agency (JST), Core Research for Evolutional Science and Technology (CREST) program
5. Earth-Life Science Institute, Tokyo Institute of Technology

The phytohormone auxin regulates many aspects of growth and development in land plants; however, the origin and evolution of auxin signaling and response mechanisms remain largely unclear. Auxin research in more primitive plants is therefore essential to address these issues. The charophyte alga *Klebsormidium nitens* is an intermediate organism between green algae and land plants, and its draft genome revealed some putative genes involved in auxin response (Hori *et al.,* 2014).We detected auxin (indole-3-acetic acid, IAA) in *K. nitens* by hormonome analysis. In this study, we aimed to clarify primitive auxin response in *K. nitens*. Exogenous IAA treatment inhibited growth of *K. nitens*. Therefore, we analyzed cell division and cell elongation with exogenous IAA treatment in detail. The results suggested that IAA affected on not only cell division but also cell elongation. Furthermore, we tested for auxin mediated-regulation of gene expression by analyzing *K. nitens* transcriptome. Here, we discuss primitive auxin response in *K. nitens* based on these results.

In Silico Comparative Analyses of *Phytochelatin Synthase* (*PCS*) Genes in Selected Plants: Employing Bioinformatics Approaches

Ibrahim Ilker Ozyigit[1], *Ertugrul Filiz*[2], *Recep Vatansever*[1]
1. Marmara University, Faculty of Science and Arts,
2. Duzce University, Department of Crop and Animal Production, Cilimli Vocational School

Heavy metal-based environmental pollution in soil and water damages to living organisms related to its toxicity and accumulation. Toxic heavy metals displace endogenous metal cofactors from their cellular binding sites, react with thiol groups of proteins and induce reactive oxygen species formation. There are several defense strategies in plants to mitigate the negative effects of heavy metals and re-establish the metal balance. Like algae and fungi, higher plants also overcome heavy metal stress by increasing the synthesis of sulfur containing defense compounds called cysteine, glutathione (GSH) and phytochelatins (PCs). Phytochelatins promote the vacuolysosomal sequestration of heavy metals like As, Ag, Cd, Cu, Hg, Pb and Zn, and also contribute to their detoxification. Although phytochelatins are activated by several heavy metals, Cd is one of the most effective activator for them.

In this study, 14 PCs homologs were identified from the genomes of selected 10 plant species by using bioinformatics tools. PCSs were seen as polypeptides of 452-545 residues and characterized both phytochelatin and phytochelatin_C domains. C-terminal site of proteins was less preserved while N-terminal site was highly conserved. Additionally, earlier reported full-conserved Cys-residues in heavy metal binding were identified. In association with metal binding, other preserved cysteines, with minor substitutions Cys (C) or Ser (S) or Tyr (Y) or Trp (W) were also identified in PCS sequences. Cys56, His162 and Asp180, characterized catalytic triad residues from *Arabidopsis thaliana* were conserved in respective sites of PCSs. As a result of phylogenetic analysis, a clear monocot/dicot separation was revealed and further corroborated by exon-intron organizations of *PCS* genes. *Cis*-regulatory motif, miRNA, *co*-expression network and GO term analyses showed the complex and dynamic organization of *PCSs*. In addition to metal detoxification, data showed their roles in different metabolic pathways such as signaling, defense and stress. Furthermore, protein structure variations were also implicated to confer the functional divergence in PCS proteins.

Transcriptomic and expression analysis indicate involvement of NO in *Camellia sinensis* pollen tube growth at low temperature

Junting Pan[1], *Weidong Wang*[2], *Zaifa Shu*[1], *Xiaoli Ye*[1], *Yuhua Wang*[1]
1. Nanjing Agricultural University
2. Northwest A&F University

Nitric oxide (NO) functions as a critical signaling molecule in the low-temperature stress responses in plants, including polarized pollen tube growth in *Camellia sinensis*. We investigate alterations to gene expression in *C. sinensis* pollen tubes exposed to low-temperature stress and NO using RNA-Seq technology, in order to find the potential candidate genes related to the regulation of pollen tube elongation by NO under low-temperature stress. We produced three libraries from pollen tubes under control (CK), low-temperature stress (LT) and NO stress (NO), including a dataset containing 45,432 unigenes from the *C. sinensis* pollen tube transcriptomes using paired-end and *de novo* sequencing with the Illumina HiSeq^{TM}2000 platform. Among these unigenes, 36,097 were annotated with descriptions from the NR, NT, Swiss-Prot, KEGG, COG and GO databases. Our dataset includes comprehensive analysis in sequence and DEGs profiling data that provide a dynamic perspective on transcriptomic variations caused by NO and low-temperature in *C. sinensis* pollen tube elongation. Many DEGs were simultaneously found in both the CK-VS-LT and CK-VS-NO libraries in different functional pathways, such as plant hormone signaling (ABA, BRs, ET and auxin), TFs (MYB, ZFP, CAMTA and MADS-box), vesicle polarized trafficking and cell wall biosynthesis (PI4K and COBRA-like), the ubiquitination machinery of the ubiquitin system (E3s, 26S proteasome, U-box and BTB/POZ) and caffeine and theanine biosynthesis (caffeine synthase and glutamate receptor). Combining our findings and previous reports, we propose a crosstalk network which may indicate the probable mechanisms underlying NO mediating *C. sinensis* pollen tube growth during the response to low-temperature stress. Plant hormone signaling pathways (ABA, BRs, ET and auxin) respond to pollen germination and tube elongation at low temperature, and then TFs (MYB, ZFP, CAMTA and MADS-box) modulated relevant proteins expression. Moreover, the UPS (E3s, 26S proteasome, U-box and BTB/POZ) probably involves in affecting pollen germination and tube growth in response to low-temperature stress by modulating the activity, localization or stability of different proteins. Additionally, Ca^{2+} gradient, vesicle polarized trafficking as well as cell wall biosynthesis might participate in pollen tube elongation under low-temperature stress through the NO signaling pathway by CAMTA, PI4K and COBRA-like. Taken together, these findings offer a more profound understanding of the candidate genes employed by *C. sinensis* pollen tubes to integrate low temperature signals and finely tune their tolerance responses, present a fundamental transcriptomic resource to further explore the molecular mechanisms of reproductive tissue tolerance to low-temperature.

The complete chloroplast genome sequence of Korean endemic species *Corydalis filistipes* Nakai (Papaveraceae: Fumarioideae)

Kyu Tae Park, *Seonjoo Park*
Department of Life Sciences, Yeungnam University

Corydalis is a large genus of approximately 470 species in Papaveraceae .and mainly native to temperate Northern Hemisphere. Most species of genus *Corydalis* are diverse in China and the Himalayas. One of this genus, *Corydalis filistipes*, is endemic species in Korea. *C. filistipes* is restricted only to Uleng island. And the genetic and molecular data is deficient. Therefore we conducted analysis through NGS and determined the complete chloroplast genome sequence of *C. filistipes*. The chloroplast genome of *C. filistipes* is a circular molecule of 155,782bp containing two single copy regions and two inverted repeat regions, a large single copy region (LSC, 86,884bp) and a small single copy region (SSC, 18,348bp), separated by inverted repeat regions (IRs, 25,275bp each). In addition, the chloroplast genome of *C. filistipes* has 40.6% GC content and contains 129 genes, of which 83 are protein-coding, 38 are transfer RNA, and four are ribosomal RNA. A phylogenetic analysis based on 71 protein coding genes indicate that *Corydalis* is related to Papaveroideae species.

Acknowledgments: This study was supported by grants from Scientific research (KNA1-2-13.14-2) of Korea National Arboretum.

DNA-binding domains of dehydration responsive element binding proteins of bread wheat (*Triticum aestivum* L.)

Svitlana Proskurina[1], ***Olga Kolesnyk***[2], *Andrii Venger*[1], *Anastasiia Honcharova*[2]
1. International Humanitarian University
2. Plant Breeding and Genetic Institute

Drought is a common adverse environmental condition that significantly influences plant growth and productivity worldwide. In the last years there has begun the intensive study of the functions of genes encoding transcription factors (TFs), which can be directly or indirectly involved in the regulation of processes of plants resistance in response to drought. Dehydration responsive element binding (DREBs) are important plant transcription factors that regulate the expression of many stress-inducible genes and causes a strong influence in improving the abiotic stress tolerance of plants by interacting with a DRE/CRT cis-element present in the promoter region of various abiotic stress-responsive genes. According to structural characteristics, DREBs proteins are subdivided into six subgroups (A-1-A-6), which may perform different functions. The precise study of domains of different DREB subgroup proteins will give the opportunity to compare their functions in order to understand the mechanism of response to stressful conditions. However at the moment the function of DREBs proteins of bread wheat are studied insufficiently. The purpose of this research was to compare the domains of 6 subgroups of DREBs proteins in order to reveal similarities and differences in their functional features as these proteins are associated with the mechanisms of response to stressful conditions. Protein sequences of DREBs proteins (accession number of DREB1 is AAL01124.1; DREB2 − ADM89078.1; DREB3 − AAX13277.1; DREB4 − AAX13283.1; DREB5 − AAX13286.1; DREB6 − AAX13289.1) were taken from National Centre of Biotechnology Information and were aligned according to database of protein sequences using online program “BLAST” by Smith-Waterman algorithm. Protein domains and biochemical properties of DREBs were figured out by Domain Enhanced Lookup Time Accelerated BLAST online program. Consequently according to delta-BLAST online program each of six subgroups of DREBs proteins consists of three domains: 1) AP2 (accession number cd00018)-DNA-binding domain found in transcription regulators in plants such as APETALA2 and EREBP (ethylene responsive element binding protein). In EREBPs the domain specifically binds to the 11bp GCC box of the ethylene response element (ERE), a promotor element essential for ethylene responsiveness. EREBPs and the C-repeat binding factor CBF1, which is involved in stress response, contain a single copy of the AP2 domain. APETALA2-like proteins, which play a role in plant development contain two copies of the AP2 domain. 2) AP2 (accession number smart00380)-DNA-binding domain in plant proteins such as APETALA2 and EREBPs. 3) AP2 domain (accession number pfam00847). This 60 amino acid residue domain can bind to DNA and is found in transcription factor proteins. The mentioned domains of different subgroups of DREB proteins differ by the number of amino acid residues as well as they are located in different parts of the DREB protein which means that although they have partially similar structure these proteins may have the functional peculiarities. The presence of different subgroups of DREB genes in the genotypes of bread wheat varieties of South Ukraine makes it possible to lead to different ways of plant response to drought conditions.

Using a chloroplast genome reference library for the identification of cultivated peanut

Caroline Puente-Lelievre, *Sara Handy, Ning Zhang, Anne Eischeid*
US Food and Drug Administration

The advancement of high-throughput sequencing technologies has expedited the progress of plant genomics, particularly chloroplast genomics. To date, the National Center for Biotechnology Information (NCBI) organelle genome database harbors more than 300 chloroplast genomes from crops and trees. These genome data have been used mainly for studies in phylogenetics, breeding, domestication, and conservation; but could also be used to develop specific DNA markers to identify allergenic plants such as peanuts. Domesticated peanut (*Arachis hypogea*, Fabaceae) is one of the most consumed legumes in the world, and is widely cultivated in the tropics and subtropics (annual production of ~46 million tons). While peanuts have a key role in human nutrition, they are one of the most common allergy-causing foods in the United States. Food allergy reactions can be fatal and are a leading cause of anaphylactic events. Consumers with food allergies must rely on correct food labeling to identify the presence of allergens. To help protect consumers in the U.S., the Food Allergen Labeling and Consumer Protection Act of 2004 requires the presence of any of the major food allergens (including peanut) be declared on the label. It is critical for the enforcement of this regulation to have reliable analytical methods that accurately identify and detect these plant allergens. DNA markers have become increasingly common and effective tools to achieve this goal. The *Ara h 2* and *Ara h 3* (allergenic protein) genes and the internal transcribed spacer (ITS) have traditionally been used for peanut identification, but their level of sensitivity has been limited so far. The number of copies of nuclear markers in the cell is inherently lower than the number of plastid copies, which significantly restricts their use for reliable peanut identification in processed samples that often contain small DNA concentrations. We propose an alternative application of chloroplast genomes as a source of unique DNA markers to identify domesticated varieties of peanut. We are building a chloroplast genome reference library of economic crops to support the development of highly sensitive DNA-based assays to detect the presence of peanuts in a broad range of commercial products. We also compare and discuss the effectiveness of these newly developed chloroplast markers against nuclear markers previously published.

Genetic programming based models as an alternative to the traditional statistical methodology in plant research

Meenu R.M., *Ashalatha S. Nair*
Department of Botany, University of Kerala, Kariavattom

In this paper we compared the efficacy of observation based modelling approach using genetic algorithm with the usual statistical analysis as an alternative methodology in plant research. The preliminary experimental data pertaining to *in vitro* rooting in *Wrightia tinctoria* was taken for this study; with an aim to understand the effect of activated charcoal (AC) and naphthalene acetic acid (NAA) on successful rooting. The two variables were also optimized for maximum result. Observation based modelling as well as traditional approach could identify the presence of charcoal in the culture medium along with NAA as a critical factor in rooting and survival of the plantlets under the experimental conditions employed. The results suggested that NAA has a significant positive effect on rooting provided AC is present in the medium. In the present study AC had a positive and stimulatory effect in rooting of shoots by reducing basal callus. Thus absence of callus initiation enhanced rooting in auxin containing medium. However, with traditional statistics, estimating the combination/s of both variables that producing the best results can not be achieved. Symbolic regression analysis using the software employed here, optimized the treatments studied and was successful in identifying the complex non linear interaction among the variables with minimalistic preliminary data. It provides both optimum model function as well as the optimum variable values in the model. Such an approach is advantageous for establishing in vitro culture protocols as these models will have significant potential for saving time and expenditure in plant tissue culture experiments at commercial level laboratories.

Establishment of a consensus map for fatty acids and oil content QTLs, identification of candidate genes for seed oil alteration in *Brassica napus*.

Nadia Raboanatahiry
Huazhong University of Science and Technology

Introduction: Deciphering the molecular architecture of a species is a good way to understand its evolutionary history, but also to tailor its profile for breeding elite cultivars with desirable traits. Combining diverse populations in one consensus map and utilizing it as a basis for multiple analyses assure a stronger accuracy to understand the genetic system that works on a given phenotype. In this study, we unraveled the genetic architecture of fatty acid (FA) and triacylglycerol (TAG) biosyntheses in rapeseed *Brassica napus*. *B. napus* (AACC, 4n = 38) is a well-known source of vegetable oil and is the preferred oil crop for biodiesel production in Europe, it was produced from hybridization of *Brassica rapa* (AA, 2n = 20) and *Brassica oleracea* (CC, 2n = 18), and both of them are closely related to the model plant *Arabidopsis thaliana*. Our objectives were to establish a consensus map for FA and oil content QTLs in *B. napus*, and identify potential candidate genes for seed oil alteration.

Methods: The genes involved in FA biosynthesis and TAG formation in *Brassica* were identified based on homology with *A. thaliana* genes. A comparative study of these genes were performed to highlight a brief evolution synopsis among this tribe. Then, a consensus map representing oil content QTLs (OC-QTLs) and fatty acids QTLs (FA-QTLs) was built based on the QTLs identified in nine populations: *DY, KN, M201xM202, PT, RNSL, SG, SO, TN* and *Z5*. The physical positions of the markers were determined by using of E-PCR. Finally, potential candidate genes underlined by these QTLs were identified, and their genetic network interaction and pathway were analyzed.

Results: A total of 438 genes involved in the FA and TAG biosyntheses were identified in *B. napus*, they were homologous to 224 genes of *B. rapa* and 173 genes of *B. oleracea*. Synteny analysis of these genes was made. Compared to parents *B. rapa* and *B. oleracea, B. napus* genome showed mix of loss and insertion. While settling the QTLs for oil content and 10 fatty acids traits identified from *DY, KN, M201xM202, PT, RNSL, SG, SO, TN* and *Z5* on the physical map of *Darmor-bzh,* the map was covered by 217 molecular markers and 335 FA-QTLs and OC-QTLs could be highlighted ; 101 QTLs were co-localized, and 78 among them were OC-QTLs. Chromosome C6 hosted the highest amount of co-localized QTLs (27) and C3 contained a total of 22 co-localized QTLs with all trait studied unless for C18:3. Co-localized QTLs were found in populations with similar environments. Besides, 218 candidate genes were identified in 162 QTL intervals, 77 among them were underlined by 61 co-localized QTLs, and they were majorly potential candidate genes for oil content. FAE genes represented potential genes that might affect all traits unless C18:3. Analysis of network interaction and pathway of these candidate genes indicated ten genes that strongly interacted with the other genes and might affect them. Traits might be affected by these genes in multilevel of oil biosynthesis.

Conclusion: Our findings provide new information on genetic characteristics of *B. napus*. New track showing genes that might alter seed oil are now accessible, and might be suitable for breeding improvement purpose.

Heterologous expression of *Lolium perenne* antifreeze protein confers chilling tolerance in transgenic tomato

Sathishkumar Ramalingam, ***Balamurugan Srinivasan***
Bharathiar University

Being sessile in nature, plants constantly encounter several abiotic and biotic stresses that adversely affect plant growth, development and survival. Among them, abiotic stresses are serious, as they are uncontrollable and unpredictable. The low temperature stress imposed on plants has huge impact on agriculture in particularly in the tropical or sub-tropical plants, which will potentially limit plant survival leading to reduced yield. Antifreeze proteins (AFP) are produced by certain plants, animals, fungi and bacteria that enable them to survive during chilling conditions. Perennial rye grass, *Lolium perenne* was reported to possess AFP, which protect them from cold environment. Here, we isolated *AFP* gene from *L. perenne* and expressed in tomato, the second most consumed chilling sensitive vegetable crop to confer chilling tolerance. The T_1 transgenic tomato lines were subjected to molecular, biochemical and physiological studies. Stable integration and transcription of *LpAFP* in the host genome was confirmed by Southern blot hybridization and RT-PCR, respectively. Physiological analyses under chilling conditions showed that the chilling stress induced physiological damage was observed in wild type lines, while the transgenics remained healthy phenotypically. Total sugar content was increased gradually in both WT and transgenics throughout the stress period. Interestingly, transgenics exhibited remarkable alterations in terms of relative water content and electrolyte leakage index than that of WT during the chilling treatment. Relative water content was increased significantly by 3-fold and the electrolyte leakage was reduced by 2.6-fold in transgenics than WT. Overall, these findings demonstrate that *LpAFP* gene confers chilling tolerance in transgenic tomato plants by upholding the membrane integrity. Hence, we propose *LpAFP* could be a potential candidate to extrapolate the chilling tolerance on other chilling sensitive food crops. The outcome will significantly help the high altitude farming of economically important food crops in long term.

Patterns of cyto-nuclear disequilibrium and the influence of heteroplasmy in wild carrot, *Daucus carota* (Apiaceae)

Adam Ramsey[1], *Dviti Mody*[2], *David Mccauley*[2], *Massimo Iorizzo*[3], *Philipp Simon*[4], *Jennifer Mandel*[1]
1. University of Memphis
2. Vanderbilt University
3. Plants for Human Health Institute
4. USDA-Agricultural Research Service

Cyto-nuclear linkage disequilibrium (LD) is the non-random association of alleles in the nuclear and cytoplasmic organellar genomes (cpDNA or mtDNA). Patterns of cyto-nuclear LD can indicate admixture of divergent populations or of two species, positive or negative cyto-nuclear selection, inheritance of organelles in a non-traditional fashion, or the occurrence of more than one mitochondrial or plastid genome within an individual (heteroplasmy). Cyto-nuclear interactions have been shown to play a role in cytoplasmic male sterility (CMS) which occurs in gynodioecious plant species. These species are also implicated in instances of paternal inheritance of organelles. We used the gynodioecious species, Daucus carota ssp. carota, or wild carrot, to investigate cyto-nuclear LD. We genotyped a total of 255 individuals from two North American regions, 129 from the Olympic Peninsula, Washington State, and 126 from Nantucket Island, Massachusetts. We used 15 nuclear microsatellites, two mitochondrial SNPs and one plastid insertion-deletion (indel) to calculate nuclear-nuclear LD, cyto-nuclear LD and LD between organelles both among regions and within regions. We were further able to identify over 100 individuals heteroplasmic for one of the mitochondrial SNPs and over 30 individuals heteroplasmic for the plastid indel. Thus we were able to calculate the same sets of cyto-nuclear LD values for individuals that are heteroplasmic and homoplasmic (non-heteroplasmic) for the mitochondrial SNP. Differences were found between several of the LD values between the heteroplasmic and homoplasmic groups.

Solving the puzzle: Using DNA barcoding and chemical analysis for authenticating *Pelargonium* species in commercial herbal products

Ryan Rattray[1], *Michelle Van Der Bank*[1], *Alvaro Viljoen*[2]
1. University of Johannesburg
2. Tshwane University of Technology

Several *Pelargonium* species indigenous to South Africa are highly valued for their horticultural value and medicinal properties. For hundreds of years various ethnic groups have used root extracts of *P. sidoides* DC as a remedy to treat coughs, upper respiratory tract irritations and gastrointestinal conditions. An ethanolic extract is used in the proprietary herbal tincture known as Umkaloabo® that is currently successfully marketed in Germany with sales that have escalated over 700%. The use of commercial herbal products (CHP) have surged globally in recent years and as a result the phytomedicine industry is under immense pressure to develop rapid, accurate and economical methods for quality control, especially for the positive identification of raw materials. The taxonomic delimitation of the two taxonomic allies *P. sidoides* and *P. reniforme* Curt. has been debated in literature. Most consumer products explicitly refer to the botanical active as *P. sidoides* posing quality control concerns as *P. sidoides* and *P. reniforme* have not been proven to be pharmacologically equipotent. Here, we used DNA sequence information generated through standardized DNA barcoding techniques for the authentication of *Pelargonium* sidoides products. Furthermore, a DNA barcode reference library for the section Reniformia was added to the Barcode of Life Database and several herbal medicines tested, showed not to contain DNA material of *Pelargonium* species, indicating adulteration of the said products. Results as well as recommendations from the study will be presented.

Genomic diversity in *Vaccinium vitis-idaea* and its association with environmental conditions and biochemical variables

Zobayer Alam, Lourdes Peña-Castillo, ***Julissa Roncal***
Memorial University of Newfoundland

Partridgeberry (*Vaccinium vitis-idaea* L.) is rich in nutrients and biochemical properties beneficial for human health, and is one of the least studied crops of the *Ericaceae* family. The cultivation of this fruit crop is popular in Europe, in early development in the United States, but in Canada harvesting for local consumption and exportation is from the wild. Genetic markers are needed to facilitate the selection of berries with desirable agronomic and nutritious characteristics to start a cultivation program. In this study, we estimated the total phenolic content (TPC) and antioxidant capacity (AC) of 56 partridgeberry fruit samples collected from different regions in Newfoundland and Labrador, the province with the largest amount of export in Canada. We applied next generation sequencing technology, specifically the genotyping-by-sequencing method to discover single nucleotide polymorphisms (SNPs) across the 56 samples. We identified 1,586 high-quality putative SNPs using the UNEAK pipeline available in TASSEL. To search for an association between adaptation to environmental conditions and population-level genetic diversity, we obtained the correlation of each of the identified SNPs with eight environmental variables. We also searched for an association between the identified SNPs and TPC and AC. We found 260 SNPs likely to be associated with at least one of the environmental and biochemical variables. The functional annotation of the 260 SNP-containing sequences, based on BLAST similarity searches, identified 128 genes with functional roles likely to be related to phenolic compound biosynthesis, transcription regulation, transport, and drought. The SNP markers discovered in this study might provide a useful resource for future molecular genetic studies, such as high-density quantitative trait locus analysis, and association mapping. The identified candidate genes containing the SNPs need further studies on their adaptation ability in partridgeberry.

Genetic dissection of agronomic performance, yield and quality of durum wheat through genome-wide nested association mapping

Yuefeng Ruan[1]*, Bianyun Yu*[2]*, Wentao Zhang*[2]*, Prabhath Lokuruge*[2]*, Peng Gao*[2]*, Christine Sidebottom*[2]*, Janet Condie*[2]*, Ron Knox*[1]*, Richard Cuthbert*[1]*, Curtis Pozniak*[3]*, Andrew Sharpe*[2]*, Pierre Fobert*[2]
1. Swift Current Research and Development Centre, Agriculture and Agri-Food Canada
2. Aquatic and Crop Resource Development, National Research Council Canada
3. Crop Development Center, College of Agriculture and Bioresources, University of Saskatchewan

Durum wheat is an important crop in Canada. The rate of genetic gainin yield and quality traits in Canadian durum cultivars have been achieved greatly in the past 50 years. However, Climate change and an increasing world population pose challenges to the yield with current rate of genetics gain.Recently, advances in genomic assisted breeding provide promising technologies to meet these challenges and to speed up the genetic gain on Canadian durum wheat. The efficiency of such an approach relies on the precision of QTL mapping and robust molecular markers linked to the trait. However, most important crop traits are complexly inherited and controlled by multiple genes with minor effects. Current mapping strategies - linkage mapping or association mapping alone has less statistical power to detect these minor alleles and less precision to estimate their position and effects. Nested association mapping (NAM), combining the advantages of both linkage analysis and association mapping has recently been proved as a promising approach to address these challenges with current mapping strategies on complex traits. To explore the usefulness of this NAM based approach in improving the genetics gain on Canadian durum wheat, a durum NAM panel comprised of 14 sub-populations with a common reference parental line “Strongfield” crossed with 14 other durum cultivars was assembled. Each sub-population has 50 lines, resulting in a total of 700 inbred lines. The NAM population, parents and checks were grown and evaluated forагronomic traits, yield and yield components, protein content and foliar disease leaf spot in two growing seasons at two locations. The Illumina infimum wheat 90K SNP chip was used to genotype the NAM population. Combining the genotypic data with field data, genome wide association study is being carried out to detect QTL for each trait with NAM based mapping approach. The efficiency, precision, effectiveness and usefulness of NAM approach to capture the multiple alleles with minor effects underling these complex traits in Canadian durum wheat will be discussed.

Rhopalocnemis phalloides possesses one of the most reduced and mutated plastid genomes known

Mikhail Schelkunov[1,2]*, Maxim Nuraliev*[2,3]*, Maria Logacheva*[1,2]
1. Institute for Information Transmission Problems
2. Lomonosov Moscow State University
3. Joint Russian–Vietnamese Tropical Scientific and Technological Center

Holo-heterotrophic plants are plants, completely incapable of photosynthesis - instead they feed by parasitizing on fungi or other plants. Several hundreds of holo-heterotrophic plants are known, representing several dozen cases of independent transition from autotrophic to holo-heterotrophic lifestyle. Their plastid genomes (“plastomes”) are usually highly reduced, mainly due to loss of genes with functions related to photosynthesis. To date, only one higher plant is supposed to have lost its plastid genome completely - *Rafflesia lagascae*. This work is dedicated to an analysis of a plastome of *Rhopalocnemis phalloides* (family Balanophoraceae) - a plant which we initially suspected to have also lost a plastome. Instead, deep sequencing has shown that, in fact, it possesses a plastome, but its sequencing coverage was depressed due to an extremely high AT-content of 87% - the highest among all sequenced plant plastomes. The plastome has a length of 18 622 base pairs and contains a gene set typical for holo-heterotrophic plants, with most of retained genes encoding ribosome components. Although all of the retained genes are likely functional, they have accumulated an enormous amount of mutations, with proteins encoded by some genes having sequence identity of about 25% to the closest homologs in GenBank. Due to the high AT-content, sequences of several genes converged with sequences of genes from Apicomplexa, which also have AT-rich plastomes. To sum up, *Rhopalocnemis phalloides* represents one of the most extreme cases of plastid genome reduction.

Identification and characterization of N-alpha acetylated proteins in *Ostreococcus tauri*

Rashmi Shakya[1], *Thierry Lebihan*[2]
1. Miranda House, University of Delhi
2. The Institute of Quantitative Biology, Biochemistry and Biotechnology, SynthSys-Systems and Synthetic Biology, School of Biological Sciences, University of Edinburgh

Protein Nα-acetylation is one of the most common modifications found in living organisms and plays a significant role for the fate of proteins in terms of stability and activity. In spite of being so abundant these modifications remain poorly described and badly characterized, especially in plants. Recent advances in N-terminal positional proteomics have made it possible to unravel the nature of N-terminal modifications. By employing N-terminal enrichment and no enrichment-based strategies we have identified 228 non-redundant Nα-acetylated peptides in the smallest known eukaryote, *Ostreococcus tauri,* and showed that the effect of penultimate amino acid on the efficiency of methionine cleavage is conserved. Proteome-wide comparison has revealed that bias for serine residue at ultimate and aspartic residue at penultimate position seems to be a characteristic of Nα- acetylome in *O. tauri*. Analysis of experimentally identified Nα-acetylome has led to the prediction of four methionine amino peptidases (MAPs) and seven N-acetyltransferases (NATs) orthologs which probably play a crucial role in N-terminal processing mechanisms. In agreement with higher eukaryotes, NatA was found to be the most abundant NAT followed by NatB and NatC. We report redundancy in terms of NATs orthologs predicted in *O. tauri* protein sequence database. Based on proteogenomics analysis of 48 downstream Nα-acetylated (dNAA) peptides which had methionine residue before them, it has been suggested that probably 12 proteins (corresponding to these 12 dNAA peptides) have not been annotated correctly. Finally, we report a possibility of 103 novel proteins in *O. tauri* (which are found in *O. lucimarinus*) as indicated by proteomics data.

Identification of potential genes that contributed to the variation in the taxoid contents between two *Taxus* species (T*axus media* and *Taxus mairei*)

Chunna Yu[1], *Hong Guo*[1], *Yangyang Li*[1], *Erxu Pi*[1], *Lei Zhang*[2], ***Chenjia Shen***[1]
1. Hangzhou Normal University
2. Washington State University

Taxol is currently a valuable anticancer drug; however, the accumulated mixture of taxoids can vary greatly among *Taxus* species. Genomic information for the genus *Taxus* is currently unavailable. Thus, transcriptome analysis is a powerful approach to explore the different regulatory mechanisms underlying taxoid biosynthesis pathways in *Taxus* species. First, we quantified the variation in the taxoid contents between *Taxus media* and *Taxus mairei* using an high-performance liquid chromatography-tandem mass spectrometry method. Then, the transcriptome profiles of *T. media* and *T. mairei* were analyzed to investigate the altered transcripts. From six complementary cDNA libraries, ~350.1 million short reads were generated, and 88,194 unigenes were found. A total of 20,704 significantly differentially expressed genes (DEGs), including 9,865 unigenes highly expressed in *T. media* and 10,839 unigenes highly expressed in *T. mairei*, were identified. In total, 120 jasmonic acid-related DEGs were annotated, suggesting variation in jasmonic acid's metabolism and signaling pathway between *T. media* and *T. mairei*. Furthermore, a large number of genes related to the precursor supply, taxane skeleton formation and hydroxylation, and C13-side chain assembly were also identified. The differential expressions of the candidate genes involved in taxoid biosynthetic pathways may explain the variation in the taxoid contents between *T. media* and *T. mairei*.

P1263

Comparative proteomic analyses of two *Taxus* species (*Taxus × media* and T*axus mairei*) to reveal the variations in the metabolisms that associated with Taxol and other metabolites

Juan Hao[1], *Hong Guo*[1], *Lei Zhang*[2], ***Chenjia Shen***[1]
1. Hangzhou Normal University
2. Washington State University

Taxus species are well-known for their taxol, which exhibits antitumor activities and is used for the treatments of various cancers. Although most *Taxus* species are widely spread in many areas, few studies have characterized the variations in the metabolisms of different *Taxus* species. Using an integrated approach involving TMT labeling and LC-MS/MS, we investigated the proteomes of *T. media* and *T. mairei*, and 4,078 proteins were quantified. The screening and classification of differential expressed proteins revealed a large number of metabolism associated proteins. In detail, four enzymes involved in flavonoid biosynthesis pathway predominantly expressed in *T. mairei*. Four enzymes associated with supplying precursors for Taxol biosynthesis and three cytochrome P450 taxoid oxygenases were preferentially expressed in *T. media* rather than in *T. mairei*. Furthermore, variations between the taxoid contents of *T. media* and *T. mairei* were determined by HPLC-MS/MS analysis. Variations between the flavonoid contents of *T. media* and *T. mairei* were determined by HPLC analysis. A number of differential expressed enzymes may provide an explanation for the variation in the metabolisms of different *Taxus* species.

CHD1 (CHR5) and CHD3 (PKL) act antagonistically to regulate seed maturation program in *Arabidopsis*

Yuan Shen

Xinxiang Medical Univeristy

Chromatin modification and remodeling are the basis for epigenetic regulation of gene expression. *LEAFY COTYLEDON1 (LEC1)*, *LEAFY COTYLEDON 2 (LEC2)*, *ABSCISIC ACID-INSENSITIVE 3 (ABI3)*, and *FUSCA3 (FUS3)* are key regulators of seed maturation and are expressed during embryo development but epigenetically repressed after seed germination. The CHD3 protein PICKLE (PKL) is involved in the epigenetic silencing of the genes. However, the chromatin mechanism that establishes the active state of the genes during embryogenesis and seed development is not clear.Our work showed that the *Arabidopsis* CHD1-related gene, *CHR5*, displayed a similar expression pattern as *ABI3* and *FUS3* during embryo development. The mutation of the gene led to decreased expression of *LEC1*, *ABI3* and *FUS3* in developing seeds and reduced accumulation of seed storage proteins. In addition, we found that CHR5 was directly associated with the promoters of *ABI3* and *FUS3* and *chr5* mutations led to increased nucleosome occupancy near the transcriptional start site. To study the functional interaction between *CHR5* and *PKL*, we generated *chr5/pkl* double mutants. Analysis of double mutants showed that CHR5and PKL have an opposite function to regulate embryo gene promoter activity and seed storage protein accumulation. CHR5 regulates embryo identity genes expression by modulating nucleosome occupancy, whereas PKL represses the expression of the geneslikely by promoting H3K27me3.The antagonistic function of *CHR5* and *PKL* on embryo gene expression by acting on different aspects of chromatin modifications suggests important but complex roles of chromatinin the regulation of seed maturation gene expression.

Full-length transcriptome sequences and gene co-expression network analysis applied to the two medical components of naringin and neoeriocitrin biosyntheses in *Drynaria roosii*

*Jingyi Li[1,2], Meiyu Sun[1], Dong Li[1], Fengjie Huang[1], Di Wang[1], Hui Li[1], Quan Xing[1], Yongzhen Pang[1], **Lei Shi**[1]*
1. Key Laboratory of Plant Resources and Beijing Botanical Garden, Institute of Botany, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Drynaria roosii (Nakaike), a large epiphytic fern of the family Polypodiaceae, is a source of traditional Chinese medicine commonly known as 'Gu Sui Bu', wherein its rhizome is particularly valued. The corresponding effective flavonoids components include naringin and neoeriocitrin, the biosyntheses of which are the subjects of considerable interest. In our study, we found that the contents of naringin and neoeriocitrin varied in different tissues and years tested by HPLC. However, the molecular mechanism of these two medical components biosyntheses in *D. roosii* with different tissues and years has remained elusive. Moreover, the investigations of the *D. roosii* transcriptome have never been reported before. Here, we applied a combination of short-read next-generation sequencing (NGS) and single-molecule real-time (SMRT) sequencing to various tissues (leaf, vein, young rhizome, old rhizome) and rhizomes from different years (2,3, 5,6, 8,10 years old) to generate a more complete/full-length *D. roosii* transcriptome. From the SMRT data, 4,364,566 raw reads, 272,121 full-length non-chimeric reads were obtained; moreover, 59,294 CDS sequences were predicted. As with the iterative clustering for error correction (ICE) algorithm, 67,147 high-quality full-length transcripts were assembled with the accuracy of more than 99%. 59,100 transcripts (88.02%) were annotated for their function, thereinto, 52,439 transcripts, 41,844 transcripts, 43,863 transcripts, 37,028 transcripts, 24,876 transcripts, 29,012 transcripts were allocated to Nr, Nt, Swiss-Prot, KEGG, COG, and GO databases, respectively. With using of the NGS data, we detected the unigenes related to phenylpropanoid biosynthesis and flavonoid biosynthesis exhibited marked differential expression in various tissues and rhizomes from different years of *D. roosii*. By analyzing dynamic changes of differentially expressed genes, many potentially interesting genes (*PAL*, *CA4H*, *4CL*, *CHS*, *CHI*, *F3'H*, *UGT*) were identified and suggested that they were responsible for biosynthesis pathways of naringin and neoeriocitrin in *D. roosii* indeed. Furthermore, weighted gene co-expression network analysis (WGCNA) has been widely used as a method to cluster gene expression and metabolite data and identify hub genes in several non-model plant species, and genes with correlated expression patterns can be best identified by using coexpression network analysis of transcriptome data. Thus in our study, we analyzed the temporal-spatial coordination of gene expression in various tissues and rhizomes from different years of *D. roosii* and constructed the gene network using WGCNA to get further insight into the biosynthesis pathways of naringin and neoeriocitrin in *D. roosii*. This work was supported by the National Natural Science Foundation of China (no. 81573519) and the Key Projects of the Chinese Academy of Sciences (no. KZCC-EW-103-3).

6. University of Chicago
7. James Cook University

Mangroves colonize the most marginal habitats for woody plants - at the interface between land and sea. Their origin, diversification and adaptation are of scientific significance, particularly with the impending sea level rises. In this study, a combination of single-molecule long reads and the conventional short reads are generated from *Rhizophora apiculata* for *de novo* near-chromosome level assembly. Genomic sequences of six other species from this major mangrove clade have also been generated. Using these data, we find that the ancestor of Rhizophoreae experienced whole genome duplication, which was soon followed by the intertidal colonization and species diversification 50-70 Myrs ago. In the saline environments, mangrove genomes have evolved unusual amino acid (AA) compositions and experienced rapid protein evolution associated with unique AA substitution patterns. Some of these proteins are found to be associated with traits that are specialized for the intertidal habitats (e.g., vivipary and red bark). Despite the extensive adaptations, mangroves are among the least genetically-diverse plants, likely the result of rapid habit turnovers in the recent geological past, caused by repeated sea level changes. Thus, mangrove genomes can inform about their past evolutionary successes but their low diversity may also portend a possibly difficult future.

The evolution of plant microRNAs—Insights from a basal eudicot sacred lotus

Tao Shi
Wuhan Botanical Garden, Chinese Academy of Sciences

MicroRNAs (miRNAs) are important noncoding small RNAs that regulate mRNAs in eukaryotes. However, under which circumstances different miRNAs/miRNA families exhibit different evolutionary trajectories in plants remains unclear. In this study, we sequenced the small RNAs and degradome from a basal eudicot, sacred lotus (*Nelumbo nucifera* or lotus), to identify miRNAs and their targets. Combining with public miRNAs, we predicted 57 pre-eudicot miRNA families from different evolutionary stages. We found that miRNA families featuring older age, higher copy and target number tend to show lower propensity for miRNA family loss (PGL) and stronger signature of purifying selection during divergence of temperate and tropical lotus. Further analyses of lotus genome revealed that there is an association between loss of miRNA families in descendent plants and in duplicated genomes. Gene dosage balance is crucial in maintaining those preferentially retained *MIRNA* duplicates by imposing stronger purifying selection. However, these factors and selection influencing miRNA family evolution are not applicable to the putative *MIRNA-likes*. Additionally, the *MIRNAs* participating in lotus pollen-pistil interaction, a conserved process in angiosperms, also have a strong signature of purifying selection. Functionally, sequence divergence in *MIRNAs* escalates expression divergence of their target genes between temperate and tropical lotus during rhizome and leaf growth. Overall, our study unravels several important factors and selection that determine the miRNA family distribution in plants and duplicated genomes, and provides evidence for functional impact of *MIRNAs* sequence evolution.

Metabolomic analysis of alfalfa (*Medicago sativa* L.*)* root with symbiotic rhizobia under alkali stress

Tingting Song, *Hua Cai*
Northeast Agricultural University

With respect to salinity stress, alkaline salt causes more severe damage to plants than neutral salt, due to the additional effect of pH stress. However, the mechanism by which plants respond to alkali stress is not fully understood. Here, we studied the effects of root nodule symbiosis on alkali stress in alfalfa using comparative metabolomics. *Rhizobium*-nodulized (RI group) and non-nodulized (NI group) alfalfa were treated with 200 mmol/L $NaHCO_3$ and root samples were subjected to malondialdehydyde (MDA), proline, glutathione (GSH), superoxide dismutase (SOD), and peroxidase (POD) content analysis, as well as metabolite profiling with gas chromatography combined with time-of-flight mass spectrometry (GC/TOF-MS). Phenotypically, the RI alfalfa exhibited a greater resistance to alkali stress than NI plants. Physiological analysis and metabolic profiling revealed that RI plants accumulated more antioxidants (SOD, POD, GSH), osmolytes (sugar, glycols, proline), organic acids (succinic acid, fumaric acid, and alpha-ketoglutaric acid), and metabolites that are involved in nitrogen fixation. Our pairwise metabolomics comparisons revealed that RI alfalfa exhibited a distinct metabolic profile in conferring alkali resistance relative to NI alfalfa. Our study provides new information about the relationship between non-nodulized, rhizobium-nodulized alfalfa and alkali resistance, giving valuable insight into the mechanisms mediating alkali resistance in legume crops.

Spiciness in the age of discordance: Genome-scale patterns of incongruence in the phylogeny of peppers and relatives (*Capsicum/Lycianthes*, Solanaceae)

Daniel Spalink[1]*, Kevin Stoffel*[2]*, Allen Van Deynze*[2]*, Lynn Bohs*[1]
1. University of Utah
2. University of California-Davis

Discordance among gene trees can have important consequences for our understanding of the evolution of key traits in organisms of ecological or economic importance. For example, the cultivation of peppers (*Capsicum spp.*, Solanaceae) is a global, multi-billion-dollar industry, yet our understanding of the origin, diversification, and significance of their pungency has been confounded by genes with either poor resolution or discordant evolutionary histories. The genus *Capsicum* includes species with extremely pungent, variable, or non-pungent fruits. The closest relatives of the peppers belong to the genus *Lycianthes*, which has non-pungent fruits. Our previous work, based on a concatenation of two chloroplast and two nuclear gene regions, suggests that *Lycianthes* is paraphyletic in relation to *Capsicum.* This backbone phylogeny, however, is only weakly supported. Thus, with our current dataset we are limited in our ability to investigate when or where pungency originated, how it has changed through time and space, or its ecological significance. In this study, we sequenced transcriptomes of four species of *Capsicum* and *Lycianthes* that span the major clades from our four-gene phylogeny. Our primary objectives were to identify genome-scale patterns of discordance among gene trees, to determine the underlying causes of this discordance, and to estimate a representative species tree. We constructed hundreds of gene trees and compared the resulting topologies. We then mapped the genes onto the twelve chromosomes of a complete *Capsicum annuum* genome to visualize the genomic structure of gene history and determine if the physical proximity of two genes on a chromosome can predict their level of discordance. We found 24 distinct topologies among the eight species and 890 nuclear genes included in our analysis, with each topology supported by at least six genes. Nearly 300 genes supported a topology that placed *Lycianthes biflora* sister to a clade of *Lycianthes* and a monophyletic *Capsicum*. Over 100 nuclear genes placed *Lycianthes biflora* as sister to *Capsicum* but not the remaining *Lycianthes*, while the plastome and 82 nuclear genes supported reciprocally monophyletic genera. All three possible topologies among the three pungent peppers included in this study were supported to varying degrees, the most common of which was recovered by 539 genes. We found no pattern between the physical position of genes on the *Capsicum annuum* genome and their evolutionary history, as the 24 topologies were supported by genes scattered within and among each of the pepper's 12 chromosomes. Within each chromosome, we found no significant relationship between the physical distance between genes and their level of discordance. To further explore these issues, we have used our newly sequenced transcriptomes to design baits to target over 2401 genes, which we are currently using to expand our dataset to include all members of *Capsicum* and *Lycianthes*.

Identification of $1R_S.1B_L^{PavonMA1}$ wheat-rye chromosome translocation in F1, F2 hybrids of bread wheat using cytological and molecular genetic methods

Liudmyla Sudarchuk, *Ivan Motsny, Oleksandr Rybalka*

Plant Breeding and Genetics Institute – National Center of Seed and Cultivars Investigations (PBGI)

One of the common methods of enriching the gene pool of wheat is the introgression of genetic material from related species. The best practical results were obtained using the short arm of chromosome rye 1R *Secale cereale L.* in wheat breeding. Segment of chromosome derived from Petkus variety contains genes that are closely linked to the short arm of chromosome rye $1R_S.1B_L$ and that improve the adaptability of bread wheat (*Pm8*, *Yr9*, *Lr26* and *Sr31*). Importing of 1RS chromosome to wheat genome contributes to wheat yields, although reduces the quality of flour. Wheat line with modified wheat-rye translocation ($1R_S.1B_L$*PavonMA1*) has wheat cluster instead of *Sec*-1 rye cluster, and thus in the short arm of translocation there had been moved positive wheat quality genes, in particular allele *Gld1B2* (*Gli-B1d*). The main goal of this scientific work was the investigation of chromosome behavior in meiosis of F_1 hybrids obtained by crossing of line $1R_S.1B_L$*PavonMA1* which has a modified wheat-rye translocation with bread wheat variety Kuyalnik and identification of wheat-rye modified translocation in F_2 hybrids. A significant decrease in the level of homologous chromosome pairing causing aneuploidy with the frequency 5.3% has been revealed in the wheat line Pavon^{MA1}, which has a modified wheat-rye translocation $1R_S.1B_L$*PavonMA1*. The "hybrid desinapsis" which is premature complete or partial disjunction of bivalents was observed in F_1 hybrids (Kuyalnik×Pavon $^{MA1)}$. The hybrids were not cytologically constant; their meiotic index ranged from 77.8% to 95.5%. Pavon^{MA1} line does not contain any reciprocal intergenomic translocations with respect to Kuyalnik variety. Any case of forming 21^{II}_{Closed} was not observed among 571 pollen mother cells (PMCs) studied, that indicated the presence of pairing between the short arms of the translocation and intact 1B chromosomes. The F_2 hybrids had been investigated for presence of specific PCR-amplification products. Molecular markers were selected for this study: rye microsatellites *Xrems*1303-$1R_S$, secalin-specific STS-marker *ω-secalin* and wheat microsatellites *Xgwm18*-$1B_S$, *Xgwm550*-$1B_S$. In the result of PCR-analysis for F_2 hybrids there was detected amplicon of 290 bp size by *Xrems*1303 locus. The mentioned fragment was observed in line Pavon^{MA1} and Petkus variety. 400 bp fragment of amplification by *ω-secalin* locus was detected only in Petkus variety which contains in its genome locus *Sec*-1. F_2 hybrids with modified wheat-rye translocation $1R_S.1B_L^{PavonMA1}$ originated from Petkus rye were analyzed with the molecular genetic markers *Xrems*1303 and *ω-secalin*. The conducted investigation will be useful for the creation of new wheat varieties which hold in their genome resistance genes to different fungal deseases.

HpQTL: A geometric morphometric platform to compute the genetic architecture of heterophylly

Lidan Sun[1], *Qixiang Zhang*[1], *Tangren Cheng*[1], *Rongling Wu*[2], *Jing Wang*[2], *Mengmeng Sang*[2], *Libo Jiang*[2]

1. Beijing Key Laboratory of Ornamental Plants Germplasm Innovation & Molecular Breeding, National Engineering Research Center for Floriculture, Beijing Forestry University

2. Center for Computational Biology, College of Biological Sciences and Technology, Beijing

Heterophylly, i.e., morphological changes in leaves along the axis of an individual plant, is regarded as a strategy used by plants to cope with environmental change. However, little is known of the extent to which heterophylly is controlled by genes and how each underlying gene exerts its effect on heterophyllous variation. We described a geometric morphometric model that can quantify heterophylly in plants and further constructed an R-based computing platform by integrating this model into a genetic mapping and association setting. The platform, named *Hp*QTL, allows specific quantitative trait loci (QTLs) mediating heterophyllous variation to be mapped throughout the genome. The statistical properties of *Hp*QTL were examined and validated via computer simulation. Its biological relevance was demonstrated by results from a real data analysis of heterophylly in a wood plant, mei (*Prunus mume*). *Hp*QTL provides a powerful tool to analyze heterophylly and its underlying genetic architecture in a quantitative manner. It also contributes a new approach for genome-wide association studies aimed to dissect the programmed regulation of plant development and evolution.

bridge, MA, USA
4. Edward P. Fitts Department of Industrial and Systems Engineering, North Carolina State University, Raleigh, NC, USA

The billions of specimens housed in natural science collections provide a tremendous source of under-utilized data that are useful for scientific research, conservation, commerce, and education. Digitization and mobilization of specimen data and images promises to increase their utilization. While digitization of natural science collection specimens has been occurring for decades, the vast majority of specimens remain un-digitized. If the digitization task is to be completed in the foreseeable future, innovative, high-throughput approaches are needed. To create a data set for the study of global change in New England, we designed and implemented an industrial-scale, conveyor-based digitization workflow for herbarium specimen sheets. The workflow is a variation of an object-to-image-to-data workflow that prioritizes imaging and the capture of collections-level data. The workflow utilizes a novel conveyor system developed specifically for the task of imaging flattened herbarium specimens. Using our workflow, we digitized almost 350,000 specimens over a 131-week period. Our project has demonstrated that it is possible to capture both an image of a specimen and a core database record in 35 seconds per herbarium sheet plus additional overhead for container-level data capture, barcode application, and movement of specimens between the collections space and the conveyor system. This rate was in line with the pre-project expectations for our approach. Our throughput rates are comparable with other similar, high-throughput approaches focused on digitizing herbarium sheets and is as much as three times faster than rates achieved with more conventional non-automated approaches used during the project. We report on challenges encountered during development and use of our system and discuss ways in which our workflow could be improved. The conveyor apparatus software, database schema, configuration files, hardware list, and conveyor schematics are available for download on GitHub.

Characterization of lignin monomers biosynthesis genes in rice (*Oryza sativa* L.) by using CRISPR/Cas9 system

Muhammad Hassan Askri Syed, *Lingqiang Wand*
Biomass and Bioenergy Center, College of Plant Sciences and Technology, Huazhong Agricultural University

Lignin is second most abundance biopolymers among all vascular plant and plays substantial role in stress response, mechanical support and water transport in plants. The expression, evolutionary and functional study of genes related with lignin biosynthesis provides an excellent model to study the coordinative evolution of a biochemical pathway in plants and helps to develop better strategies for bioenergy feedstock improvement. In this regard, CRISPR/Cas9 technology which is a welcoming advancement in genome editing, owing to its efficiency, precision, ease of adoption and versatility. This study proposes that the agricultural fitness of the rice plant can be improved by modifying the H, S and G lignin monomers ratio. In addition, it is aimed to characterize seven of the twenty seven lignin biosynthesis genes identified in rice by our laboratory, evaluating individual as well as collective events of reduced lignin, checking productivity of transformed plants and to know secondary functions of selected genes. Furthermore, this study will significantly play role in improving knowledge on composition of secondary cell wall specifically in rice and developing improved approaches for biofuel production.

Prediction of protein–protein interactions by evidence combining methods

Ji-Wei Chang[1,2], *Yan-Qing Zhou*[1,2], ***Muhammad Tahir Ul Qamar***[1,2], *Ling-Ling Chen*[1,2], *Yu-Duan Ding*[1,2]
1. National Key Laboratory of Crop Genetic Improvement, Huazhong Agricultural University, Wuhan 430070, Hubei
2. College of Informatics, Huazhong Agricultural University, Wuhan 430070, Hubei

Most cellular functions involve proteins' features based on their physical interactions with other partner proteins. Sketching a map of protein–protein interactions (PPIs) is therefore an important inception step towards understanding the basics of cell functions. Several experimental techniques operating *in vivo* or *in vitro* have made significant contributions to screening a large number of protein interaction partners, especially high-throughput experimental methods. However, computational approaches for PPI predication supported by rapid accumulation of data generated from experimental techniques, 3D structure definitions, and genome sequencing have boosted the map sketching of PPIs. In this review, we shed light on *in silico* PPI prediction methods that integrate evidence from multiple sources, including evolutionary relationship, function annotation, sequence/structure features, network topology and text mining. These methods are developed for integration of multi-dimensional evidence, for designing the strategies to predict novel interactions, and for making the results consistent with the increase of prediction coverage and accuracy.

Genome sequencing and preliminary assembly of tung tree (*Vernicia fordii*)

Xiaofeng Tan
Central South University of Forestry and Technology

Tung tree (*Vernicia fordii*) is an economically important non-edible woody oil tree originated in China. It is mainly distributed in subtropical areas of China and used to produce tung oil for centuries. Argentina, Africa, Paraguay and the United States have introduced and cultivated the tree. Tung tree seeds contain 50-60% oil with about 80 mole α-eleostearic acid (9cis, 11trans, 13trans octadecatrienoic acid). Because of the three special conjugated double bonds in eleostearic acid, tung oil is easily oxidized and forms a unique polymer after being exposed to air, to form a tough, glossy, waterproof, insulative and anticorrosive surface on the object it is coating. Tung oil is widely used in paints, varnishes, coatings and finishes due to these excellent properties. Tung oil is also a high-quality raw material for producing biodiesel and composite functional material. Besides, tung tree is an important ornamental with bright-color flowers before leaves. The objective of this study was to sequence the tung tree genome. We obtained the low heterozygosity tung tree plant from inbred lines through SSR marker selection. DNA libraries with different insertion fragments (180 bp, 500 bp, 800 bp, 3 Kb, 10 Kb, 15 Kb, 20 Kb) were constructed from the tung tree genome. These fragments were sequenced at both ends using paired-end sequencing method by Illumina Hiseq 2000. PacBio library was constructed and sequenced by the third generation sequencing. The *Aleurites cordata* Thunb., male and female plant of *Vernicia Montana*, close relatives of *Vernicia fordii*, were used for resequencing of the genomes. We obtained the whole genome sequencing data followed by assembly and bioinformatics analysis. The total amount of genome sequencing was 326.60 Gb with a coverage of 249.46X. Preliminary analysis showed that the tung tree genome was 1.3 Gb, not heterozygous but contained highly duplicated sequences. We obtained the preliminary assembly result with 60.6 Kb of Contig N50 and 803.8 Kb of Scaffolds. Total length of the assembled sequence was 1.12 Gb, approximately 85% of the predicted genome size. Transcriptome data were used to assess the genome data. The results showed that the coverage of unigenes was 94.97% and that the matching rate of reads achieved 88.3-95.6%. These data indicate that the assemble result of the tung tree genome is of high integrity. Based on the HI-C technology, a total of 1107.82Mb length sequences were located on 22 chromosomes, accounted for 98.92% of the whole genome sequences. This study provides fundamental information for evaluating GC distribution and sequencing depth distribution, annotating genes, and analyzing evolution and biological functions in subsequent studies.

Population transcriptomics uncovers expression variation pattern of differentially expressed genes between natural population and transplanted population of *Miscanthus lutarioriparius* (Poaceae)

Chengcheng Tao[1,3], *Qin Xu*[1], *Zhihong Song*[1,3], *Caiyun Zhu*[2,3], *Wei Liu*[2], *Tao Sang*[1,2]

1. Key Laboratory of Plant Resources and Beijing Botanical Garden, Institute of Botany, Chinese Academy of Sciences

2. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences

3. University of Chinese Academy of Sciences

Miscanthus lutarioriparius, a perennial species distributed in the middle and lower reaches of Yangtze River of China is a candidate of promising energy crops due to huge biomass and high cellulose content. Previous studies of this plant suggested the expression variation of differentially expressed genes (DEG) played an important role in acclimation among the individuals under stress environment. However, it is unclear whether there was a random change of expression diversity under different environments for each gene. To answer the question, we identified 1886,2417 and 685 DEG by comparing the population transcriptome of leaves between samples from natural habitats (NP) and from transplanted fields which located in Jiangxia Hubei Province (JH), Qingyang Gansu Province (QG) and Dongying Shandong Province (DS), respectively. E_d was used to measure the level of gene expression variation and the mean E_d of DEG tends to be lower than that of background genes under all environments. In contrast to expression variation, the average genetic diversity of DEG represented by π was not significantly different from that of background genes in DS and was very close to the value of background genes in JH and QG. Results of GO enrichment analysis suggested the functional classifications of DEG were found to be similar in each comparative analysis between natural habitats and transplanted field while the subset of DEG among them were in the minority (103 DEG). These results implied that the DEG between natural population and transplanted population might be conservative on expression level among individuals under the same environment. At the same time, they were sensitive to changes of environment no matter how it change to make contribution for plant acclimation. Further studies on these genes and their expression patterns among populations would provide some advice for introduction and domestication of *M. lutarioriparius* or even other energy crops.

Genetic basis of nodulation in *Elaeagnus umbellata*

Alexander Taylor, *Yin-Long Qiu*

University of Michigan

Nodulation, a mutualistic symbiosis in which plants exchange nutrients with nitrogen-fixing bacteria in specialized nodule organs on the plant root, plays a critical role in global nutrient cycling. Nodulation appears in several lineages of the nitrogen-fixing clade (NFC) of rosid angiosperms (Fabales, Fagales, Cucurbitales, and Rosales), but does not occur in any other land plants. The evolutionary origin of nodulation in these lineages involved the recruitment of pre-existing pathway – common to all land plants – that mediate the arbuscular mycorrhizal symbiosis. However, specific patterns of gene duplication and recruitment vary between nodulating lineages. These independent, lineage-specific evolutionary histories can provide insights into the genetic requirements for the evolution of nodulation, as well as the evolution of morphological and developmental differences between nodulation in these different lineages. Here we report on an RNA-Seq study of nodulation in *Elaeagnus umbellata,* a species in the Elaeagnaceae (Rosales) that forms coralloid nodules with *Frankia* actinobacteria. We examine the evolutionary history of genes involved in nodulation in *E. umbellata* and other nodulating lineages, using both public and our transcriptomic data to assess the patterns of gene evolution, duplication and recruitment during the origin of nodulation genes in different lineages.

Rhizosphere and endophytic bacteria diversity of *Senecio vulgaris* (Asteracea)

Zhongsai Tian[1], *Lin Xu*[1], *Liang Feng*[1,2], *Dandan Cheng*[1,2]

1. School of Environmental Studies, China University of Geoscience (Wuhan), Wuhan, China

2. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, China

Endophytic bacteria are widely distributed in plants and involve in co-evolution with their host plants. Currently studies on invasive mechanism of alien plants have made great progress, but they mainly focus on the relationship between plants and their natural enemies or competitors, and few previous studies reported the interaction between invasive plant and its endophytic microorganism (especially endophytic bacteria). Research work on endophytic and rhizosphere bacteria of invasive plants helps to understand the relationship between endophyte and plant invasion. *Senecio vulgaris* (Asteraceae), originated in Europe and a widely-distributed weed in temperate regions, has been listed as one of the invasive plants in China. We investigated bacteria communities in the rhizosphere, leaf and root endosphere in 4 *S. vulgairs* populations in Shennongjia, Hubei, China. By selecting specific primers, we successfully amplified the sequence of V5-V7 zone of 16S rDNA of bacteria, and avoided the pollution of plant chloroplasts. After homogenization, the effective sequence of each sample was 12,511, averagely. On this basis, we analyzed the α-diversity and β-diversity of bacteria in rhizosphere and endophytic bacteria, and compared the diversity of bacteria in different plant parts and different populations. As for the α-diversity, the rhizosphere bacteria communities were at the highest level, followed by root endophytic bacteria, and leaf endophytic bacteria diversity in the lowest. The dominant phyla of the three kinds of bacterial communities were also different: Proteobacteria (64.00%), Bacteroidetes (14.42%) and Actinobacteria (9.34%) were dominated in rhizosphere; Proteobacteria (84.01%), Bacteroidetes (12.41%) and Actinobacteria (1.91%) were in roots ; Proteobacteria (70.30%), Firmicutes (13.48%) and Actinobacteria (10.20%) in leaves. The bacterial community in the rhizosphere of different *S. vulgaris* populations shared similar composition, but components and abundance of bacteria in leaves and roots differed between populations.This study reveal that plant compartment affect microbiome composition and suggested that plant genotype may have an important influence on shaping the leaf and root microbiomes of an invasive plant.

Quadruplex DNA in long terminal repeats of maize LTR retrotransposons affects an expression of a reporter gene *in vivo*

Viktor Tokan[1], *Matej Lexa*[2], *Boris Vyskot*[1], *Michaela Vorlickova*[3], *Eduard Kejnovsky*[1]

1. Department of Plant Developmental Genetics IBP CAS

2. Faculty of Informatics, Masaryk University Brno

3. Department of CD Spectroscopy of Nucleic Acids IBP CAS

Guanine rich sequences with pattern $G_3N_{1\text{-}8}G_3N_{1\text{-}8}G_3N_{1\text{-}8}G_3$ can form secondary DNA/RNA structures called G-quadruplexes (G4s). Many cellular processes are influenced by G4s: transcription, translation, splicing, replication, recombination and many others. Recently potential quadruplex-forming sequences (PQS) were found close to promoters within long terminal repeats of plant LTR retrotransposons, the major component of plant genomes. In order to test a potential effect of G4s on retrotransposon expression, we cloned long terminal repeats of maize LTR retrotransposon into vector upstream of lacZ reporter gene. Then, we measured lacZ transcription and translation in transformed yeasts. We found that G4s had an inhibitory effect on translation *in vivo*. Reporter gene expression increased in "mutants" where guanines were substituted in G tracks and so G4s formation was disrupted. In parallel, we confirmed the presence of quadruplexes *in vitro* by circular dichroism and by primer extension. Our results indicate that quadruplex DNA can play a regulatory role in LTR retrotransposon life-cycle and thus affect genome dynamics.

Genetic characterization of endemic and rare plant species in Kazakhstan

Yerlan Turuspekov, *Shyryn Almerekova, Alibek Zatybekov, Saule Abugalieva*

Institute of Plant Biology and Biotechnology

Kazakhstan is the ninth-largest country in the world by territory, and it is home to more than 6,000 plant species. In 2015, a new project was launched with the main goal being to study genetic variation of endemic, rare, and economically important plant species in National State Reserves and National Nature Parks of Kazakhstan. The main goal of the project is DNA barcoding of collected endemic, rare and important plant species by using different types of DNA markers, including universal markers of nuclear and chloroplast genomes. The project combines the efforts of botanists and geneticists from National State Reserves and National Nature Parks, National Universities, Botanical Gardens, and two Biotechnology Research Institutes. Currently 664 populations representing 401 species were collected within this project. DNA samples were isolated and purified for each collected plant and two representatives of each species were genotyped using ITS and *mat*K markers. DNA sequences of studied species were used for phylogenetic analysis and assessment of molecular taxonomy. The information related to the place of the collection, images of herbarium, DNA isolation status, DNA sequences of the ITS and *mat*K markers, and results of phylogenetic analyses were documented and organized in single database of the project.

P1281

The evolution and molecular genetics of apomixis in dandelions (*Taraxacum officinale*)

Peter Van Dijk, *Diana Rigola, Charles Underwood, Rik Op Den Camp, Marcel Prins*

Keygene N.V.

Outcrossing, selfing and apomixis are the three major plant breeding systems. Apomixis (clonal reproduction by seeds) is the least common (~0.1 percent of the angiosperm species). Apomixis is relatively unknown, although Mendel already knew about "constant hybrids". Apomixis fixes the full maternal genome, maintaining genome-wide heterozygosity and epistasis. Although apomixis does not occur in in major crops, apomictic crops would have many benefits for breeding, seed production and agriculture. Knowledge of the molecular genetic basis of natural apomixis genes may help to develop apomictic crops. In this presentation I will first discuss some commonalities in the distribution of apomixis across the flowering plants. After that I will report on the molecular genetics of apomixis in the common dandelion. The fact that apomixis is much less common than selfing may be because it depends on two or more gain-of-function mutations, whereas a single loss-of-function mutation is sufficient for the shift from outcrossing to selfing. Nevertheless, apomixis is phylogenetically widespread suggesting that it evolved many times during the evolution of flowering plants. Apomixis is found typically at the twigs of phylogenetic trees. This suggests that apomicts are of relatively recent origin, possibly because they become extinct soon. Apomixis is strongly correlated with polyploidy, but this could be a secondary association. In contrast to strong selfers, apomicts do not show clear modification of traits that promote outcrossing. This may be due to either evolutionary young age or to lack of adaptive potential due to lack of genetic variation, or both. We studied the molecular genetic control of apomixis in common dandelions. In this species sexuals are diploid and apomicts triploid. By crosses (using apomicts as pollen donors) we could show that apomixis is controlled by two unlinked dominant loci, one controlling apomeiosis, and one controlling parthenogenesis. Apomeiosis, the avoidance of meiotic reduction and recombination during female reproduction, is caused by first division restitution (diplospory). Using two successive forward genetic mutation screens we succeeded in identifying the diplospory gene within the diplospory locus. We show that the dominant diplospory allele is perfectly associated with apomixis in a diverse panel of apomictic and sexual plants.

Genetic diversity of tomatillo (*Physalis philadelphica* Lam.) in Central Western Mexico assessed with SSR markers

Ofelia Vargas-Ponce

Universidad de Guadalajara

Genetic diversity and structure of thirteen populations of *Physalis philadelphica* were analysed with seven microsatellite loci. It is a species of cultural and economic importance in Mexico because of its edible fruits. This taxon can grow under wild, weedy or cultivated conditions. Genetic parameters were determined on 298 individuals from thirteen populations representing a management gradient, including three wild, three weedy and seven cultivated populations. Diversity estimators reveal moderate to high genetic diversity in the total gene pool (P = 100%, n = 14.6, Ae = 7,457, Ho = 0.44, HT = 0.84). This pattern is also observed at the gradient of management. Weir and Cooker estimator reveal a moderate genetic structure value (θ = 0.268) to the total pool a low between management categories (θ = 0.079). AMOVA show a similar pattern (Φst = 0.144, Φct = 0.007). The Bayesian analysis showed that the most likely number of genetic groups is K= 12. From the results we can argue that life history traits of the species, particularly life form, the self-incompatible breeding system, wide distribution, pollination by bees, seed dispersion by birds, mammals, and humans favour genetic diversity and gene flow. The moderate values of differentiation for the species, suggest that anthropogenic management has had slight consequences on the genetic structure of *P. philadelphica*. However, actions as different selection criteria and preferences by cultivate particular morphological phenotypes, some of them restricted to certain geographic areas, contributes to the differentiation of some particular local variants as show the analysis of Bayesian assignment analysis. It is necessary to extend the analysis, including the seven races recognized for this species, in order to prove this hypothesis of differentiation between races of *P. philadelphica.*

Cytogenetic characterization of *Amaranthus caudatus* L.

Prajitha V, *Thoppil J E*

University of Calicut

The present study is aimed for the cytogenetic characterization of *Amaranthus caudatus* an economically important species, cultivated mainly for grain production. Karyomorphological studies in *Amaranthus* are scarce, probably due to higher number of small sized chromosomes. Karyomorphological studies were conducted using mitotic squash preparation of young healthy root tips by acetocarmine and DAPI staining. Karyological parameters and karyotypic formula were established using various software programs and tabulated the karyomorphometric and asymmetry indices *viz*., Disparity index, Variation coefficient, Total forma percentage, Karyotype asymmetry index, Syi index, Rec index, Interchromosomal and Intrachromosomal asymmetry index and Degree of asymmetry of karyotypes. The mitotic chromosome number observed for *A. caudatus* was 2n = 32 with a gametic number n = 16. In *A. caudatus* the chromosome length during somatic metaphase ranged from 0.8698 µm to 1.7722 µm with a total length of 39.1412 µm. Various karyomorphometry and asymmetry indices analyzed revealed the extend of intraspecific variation and evolutionary status of the species studied.

Molecular biotechnology of hop variety type, sex and agrobacterial infection detection

Andrii Venger, *Olga Kolesnyk*

Plant Breeding and Genetic Institute

This work is devoted to usage of molecular genetics and bioinformatics methods for developing the molecular biotechnology of hop variety type, sex and agrobacterial infection detection. Nucleotide sequences of hop genes *chs*_H1, *chs*2*, chs*3*, chs*4, *vps* encoding chalcone synthase were researched for polymorphism. There were obtained indels and single nucleotide polymorphisms in different regions of these genes. The molecular-genetic polymorphism of genes *chs*_H1, *chs*2*, chs*3*, chs*4, *vps* in different regions of 20 hop varieties of Ukrainian breeding was analyzed by polymerase chain reaction (PCR). Polymorphism of fragment length in different parts of genes encoding chalcone synthase was described. Polymorphism analysis of genes encoding chalcone synthase of Ukrainian hop varieties was conducted. The dependence between gene polymorphism and the level of bitter substances in hop cones was shown. Reliability and validity was calculated by Spearman coefficient. The possibility of usage of molecular markers that show the polymorphisms of genes encoding chalcone synthase for determination of hop variety type (aroma of bitter) was shown. Polymorphism of 20 hop varieties of Ukrainian breeding was investigated by microsatellite locus HlAGA7; correlation between

HlAGA7 alleles and hop sex was absent. Y-chromosome specific STS-marker for hop sex determination was confirmed. Nucleotide sequences of agrobacterial Ti-plasmids were researched by bioinformatic and molecular-genetic methods. The possibility of applying of molecular markers of *vir*D2 and *ipt* genes was shown for all types of Ti-plasmid determination. The system of detection of *A. tumefaciens*, which causes crown gall, was optimized using molecular markers of *vir*D2 and *ipt* genes. Genetics formulas of Ukrainian hop varieties were supplemented according to polymorphism of genes *chs*_H1, *chs*2, *chs*3, *chs*4, *vps*. On the basis of bioinformatic and molecular genetic analysis results the molecular biotechnology of hop variety type, sex and agrobacterial infection detection was obtained.

Taming microalgae for transformation and transgene expression

Anongpat Suttangkakul, Anchalee Sirikhachornkit, Piyada Juntawong, ***Supachai Vuttipongchaikij***
Department of Genetics, Faculty of Science, Kasetsart University

Microalgal transformation and transgene expression face many difficulties such as low transformation efficiency, transgene cleavage, low transgene stability, and transcription suppression. This limits the improvement and utilization of microalgae especially for the production of bioproducts. Recent development in the model microalga *Chlamydomonas reinhardtii* has shown a number of improvements for transgene expression through the uses of strategic vector systems and mutagenesis of the host cells. However, this is currently limited to *Chlamydomonas*, whereas other microalgae with potential industrial uses still suffer from this limitation. Here, we tested the transformation efficiency on a number of oleaginous microalgae isolated from natural environments to identify a potential host species and then performed strategic improvements for transgene expression. A strain of *Scenedesmus* species was selected as a host. We tested the expression using various constructs including a reporter-coding gene with or without introns from *Chlamydomonas.* Constructs expressed as transcript fusion with zeocin selectable maker and 2A peptides were also tested. These constructs yielded different levels of improvement for the protein expression. We performed UV mutagenesis and identified three mutants for high transgene expression. Furthermore, to reduce the use of antibiotic for a large scale application, we developed a strategy for selecting transformants using *PSY* gene and light selection. White mutants with *PSY* mutations were generated by UV irradiation and identified by target sequencing of the *PSY* gene. The mutants were tested for complementation and transgene expression. Complemented strains (green colonies) can be selected on agar media using light exposure. The expression of the transgene was confirmed at protein levels. This study provides a proof of concepts for applying knowledges based on *Chlamydomonas* to improve wild microalgae.

Detecting loci contributing to local adaptation through flowering time variation in *Lotus japonicus* in Japan

Tomomi Wakabayashi[1]*, Sachiko Tanaka*[2]*, Stig Andersen*[3]*, Shusei Sato*[4]*, Masayoshi Kawaguchi*[2]*, Hiroaki Setoguchi*[1]
1. Graduate school of Human and Environmental Studies, Kyoto University
2. Division of Symbiotic Systems, National Institute for Bacis Biology
3. Department of Molecular Biology and Genetics, Aarhus University
4. Graduate school of Life Sceinces, Tohoku University

The mechanism of local adaptation through flowering time is one of the important factors to understand the local adaptation in plant species. Improving the recent sequencing technology enables to detect causable candidates for various kinds of phenotypes with genome-wide association study (GWAS). *L. japonicus* is a legume model plant and distributed in whole range of Japan. The archipelago lies in the wide range of latitude and harbors various environments including high mountain ranges and coastline. Based on previous studies, this plant exhibits wide variation of flowering time depends on habitat's latitude. In this study, GWA analyses were conducted with flowering time phenotype and environmental factors of each population's collection sites. Considering the overlaps of the detected genes, several candidate loci for local adaptation through flowering time were found.

Transcriptomic analysis of the regulation of seed germination under salt stress in two sister species (*Populus euphratica* and *P. pruinosa*)

Zhang Caihua, ***Dongshi Wan***
State Key Laboratory of Grassland Agro-Ecosystem, School of Life Sciences, Lanzhou University

Soil salinity is thought to be the most significant abiotic stresses limiting plant growth, development, productivity in semiarid and arid areas. *Populus euphratica* and *P. pruinosa* (Salicaceae) are naturally distributed in desert regions and extraordinarily well adapted to the local salt stress. Seed germination is highly related to seedling survival rate and subsequent vegetative growth, and further directly affects poplar quality. To address the molecular regulatory mechanisms of the seeds germination process underlying salt stress tolerance, a time course (0h, 4h, 12h, 24h, 48h and 72 h) transcriptomic data set was produced and analyzed by the protocol of HISAT, StringTie and Ballgown, coupled with related physiological analysis of two species. We identified two sets of differential expression gene, including 12831 DEGs across time courses samples in the two species, and 8071 DEGs between the two species across time courses samples (the species is host variables and the time across is covariates). The transition of major biochemical processes along the germination time axis of the seed in the poplar is produced partly by more and more highly coordinated transcript dynamics. We suggested that the flavonoid and brassinosteroid are the two most important regulatory pathways for the phenotypic and salinity tolerance differences between *P. euphratica* and *P. pruinosa* during seed germination process under salt stress.

Epigenetic alteration under nitrogen-deplete and nitrogen-replete in photosynthetic microorganisms

Jiangxin Wang[1,2], *Peng Xiao*[1], *Lang Hu*[1], *Qin Shao*[1], *Huan Qin*[1]

1. Guangdong Technology Research Center for Marine Algal Bioengineering, Guangdong Key Laboratory of Plant Epigenetic, College of Life Sciences and Oceanography, Shenzhen University

2. Nanshan District Key Lab for Biopolymers and Safety Evaluation, College of Materials Science and Engineering, Shenzhen University

Nutrients are important to microbes in the environment, while deplete and replete of nutrients are also common in nature. Epigenetics, the study of cellular and physiological traits that are heritable by daughter cells and not caused by changes in the DNA sequences, is well known as connected with many important biological processes, such as development and transgenerational heredity. Cyanobacteria and microalgae play very crucial role in the earth, as the primary producers in the ecosystem. There are lots of studies explored physiological and biochemical changes, and altered gene expressions at different levels such as RNAs and proteins against environmental changes. However, no knowledge about epigenetic information in microalgae, especially under any environmental stress, is reported so far. After treated with nitrogen starvation for 72 h and transferred back to normal complete culture media for 2 continuous generations, DNA samples from the model cyanobacteria and green microalgae, *Synochecystis* PCC 6803 and *Chlamydomonas reinhartii* CC849, were bisulfite converted for next generation sequencing. Interestingly, compared with those of control (CT), DNA methylation sites and patterns in nitrogen starvation (NS) and nitrogen repletion (NR) were found much more similar in both cyanobacterium and eukaryotic green alga. In *Synochecystis*, the methylation levels of CG, CHG and CHH were significantly increased in NS and remained high in NR. Among them, very high CmG levels (~80%) were observed in both NS and NR samples, while CmHG and CmHH levels were relatively low at range of 25-45%. In *Chlamydomonas*, a total of 16,6874 individual mC sites were hypermethylated in NS cells, compared to CT, and among with 40,920 mC were remained in NR cells. Different from *Synochecystis*, only methylation levels of CG were dramatically increased by nitrogen depletion and repletion in *Chlamydomoans*. GO and KEGG enrichment analysis of differentially methylated regions (DMR) indicated that those genes were mainly involved in photosynthesis. This study revealed the global DNA methylation pattern of microalgae between normal and nutrient stress conditions. The result of this study might contribute to a better understanding of epigenetic regulation in microalgae adaptation to the ever changing environment.

Induction of *Xa10*-like genes in rice cultivar Nipponbare confers disease resistance to rice bacterial blight

Jun Wang[1,2], *Dongsheng Tian*[1], *Keyu Gu*[1], *Xiaobei Yang*[1], *Lanlan Wang*[1], *Xuan Zeng*[1], *Zhongchao Yin*[1,2]

1. Temasek Life Sciences Laboratory, 1 Research Link, National University of Singapore, Singapore 117604

2. Department of Biological Sciences, 14 Science Drive, National University of Singapore, Singapore 117543

Bacterial blight of rice, caused by *Xanthomonas oryzae* pv. *oryzae*, is one of the most destructive bacterial diseases throughout the major rice growing regions in the world. The rice disease resistance (*R*) genes *Xa10* confers race-specific disease resistance to *X. oryzae* pv. *oryzae* strains that deliver the corresponding transcription activator-like (TAL) effectors AvrXa10. Upon bacterial infection, AvrXa10 binds specifically to the effector binding element (EBE) in the promoter of the *R* gene and activates its expression. *Xa10* encodes an executor R protein that triggers hypersensitive response and activates disease resistance. Rice cultivar Nipponbare carries two *Xa10*-like genes in its genome, of which one is the susceptible allele of the *Xa23* gene, a *Xa10*-like TAL effector-dependent executor *R* gene isolated recently from rice cultivar CBB23. However, the function of the two *Xa10*-like genes in disease resistance to *X. oryzae* pv. *oryzae* strains has not been investigated. Here we designated the two *Xa10*-like genes as *Xa10-Ni* and *Xa23-Ni* and characterized their function for disease resistance to rice bacterial blight. Both *Xa10-Ni* and *Xa23-Ni* provided disease resistance to *X. oryzae* pv. *oryzae* strains that deliver the matching artificially designed TAL effectors (dTALEs). Transgenic rice plants containing *Xa10-Ni* and *Xa23-Ni* under the *Xa10* promoter provided specific disease resistance to *X. oryzae* pv. *oryzae* strains that deliver AvrXa10. *Xa10-Ni* and *Xa23-Ni* knockout mutants abolished dTALE-dependent disease resistance to *X. oryzae* pv. *oryzae*. Heterologous expression of *Xa10-Ni* and *Xa23-Ni* in *Nicotiana benthamiana* triggered cell death. The 19-amino acid residues at the N-terminal regions of XA10 or XA10-Ni are dispensable for their function in inducing cell death in *N. benthamiana* and the C-terminal regions of XA10, XA10-Ni and XA23-Ni are interchangeable among each other without affecting their function. Like XA10, both XA10-Ni and XA23-Ni locate to the endoplasmic reticulum (ER) membrane, show self-interaction and induce ER Ca^{2+} depletion in leaf cells of *N. benthamiana*. The results indicate that *Xa10-Ni* and *Xa23-Ni* in Nipponbare encode functional executor R proteins, which induce cell death in both monocotyledonous and dicotyledonous plants and have potential of being engineered to provide broad-spectrum disease resistance to plant pathogenic *Xanthomonas* species.

Identification of endogenous small peptides involved in rice immunity using transcriptomics and proteomics analyses

Pingyu Wang, *Ken-Ichi Kosami, Shaolun Yao, Renyi Liu, Yoji Kawano*

Chinese Academy of Sciences

Plant small peptides are important signaling components in plant growth and development. Some plant peptides also regulate plant immunity and function as endogenous elicitor peptides. However, the number of known endogenous peptide families involved in plant immunity is limited. Here, in order to identify peptide involved in rice immunity, we combine transcriptome and proteome analyses of rice plants treated with rice blast fungus *M. oryzae* and rice suspension cells treated with fugal cell wall component chitin. Our combination approach identified 2454 upregulated genes in

RNA-seq and 3327 proteins by MS. Next, among those genes and proteins, we screened small secreted proteins (SSPs) based on two criteria: whose protein length is less than 250 amino acid (aa) and which contain an N-terminal secretion signal peptide sequence. As a result, we isolated 236 SSPs, including several known SSPs related to defense response, such as Bowman-Birk inhibitors. A total of 52 unannoted SSPs were found and considered as candidates of new peptide family precursors. Among them, we found one protein, which we named immune response peptide-1 (IRP-1), putatively containing a 66 aa proteins with a 29 aa N-terminal signal peptide sequence and a conserved C-terminal sequence. Its expression was induced by not only chitin but also bacterial peptidoglycan. Furthermore, overexpressing of *IRP-1* activated the expression of defense gene *PAL-1*. The 52 unannotated SSPs will be useful to further elucidate rice immunity.

Codon usage bias and cluster analysis of plant *CPR* genes

Li Cheng, Yikui Li, Xiaodan Li, Binbin Qian, Sheng Xu, Bing Xia, ***Ren Wang***

Institute of Botany, Jiangsu Province and Chinese Academy of Sciences

Cytochrome P450 reductase (CPR) plays an important role in plant growth, development, biosynthesis of natural compounds and protection against external stimulants. Based on thirty-six *CPR* genes in twelve plants from GenBank, codon usage bias was analyzed by CodonW software, and cluster analysis based on gene codon and coding sequence was performed with SPSS and MEGA5.0 respectively. The effective number of codons (ENC) of *CPR* genes in monocotyledon and dicotyledon ranged from 52.92 to 58.17 and 46.85 to 53.58 respectively, indicating that codon usage bias of plant *CPR* genes was weak. The ENC-plot revealed that all *CPR* genes diverged from the ENC expectation curve, indicating that codon usage bias of plant *CPR* genes was mainly affected by natural selection pressure. The synonymous codon bias of *CPR* genes was different between monocotyledon and dicotyledon, and also was of difference even from the same plant. Based on the relative synonymous codon usage (RSCU), the *CPR* genes in monocotyledon and in dicotyledon were clustered together respectively, which was closer to the traditional classification of twelve plants, reflected the evolution relationship of species, and could be used as a supplementary of phylogenetic analysis. While in the phylogenetic tree based on the coding sequence, *CPR* genes from the same species were clustered into two groups, which could be used for gene classification and function prediction. In this study, codon usage bias and cluster analysis of plant *CPR* genes were investigated to facilitate further research in gene classification and evolution, gene function prediction and protein expression, and plant breeding.

P1293

Comparison of DNA methylation in the developing seeds of yellow- and black-seeded *Brassica napus* through MSAP analysis

Xiaqin Wang, *Jinjin Jiang, Youping Wang*

Yangzhou University

DNA methylation is a crucial modification process implicated in the epigenetic regulation of gene expression, which may be responsible for agronomic trait variation. However, the epigenetic regulation of the yellow- and black-seeded characters of *Brassica napus* has not been reported. In this study, methylation-sensitive amplification polymorphism (MSAP) analysis was performed to investigate the target regions of seed coat variation in *B. napus*; in the analysis, the yellow-seeded rapeseed line derived from the somatic hybrids of *B. napus–Sinapis alba* and the black-seeded rapeseed line were used as materials. Extensive methylation changes were observed between yellow- and black-seeded *B. napus*. In particular, 10% of demethylation and 5% of hypermethylation were detected in yellow rapeseeds compared with black seeds. Nonetheless, this variation was barely identified among different development stages. The relative expression value and 20 polymorphic fragments in MSAP profiles were also analyzed. The gene expression of the demethylated fragments in yellow rapeseeds was upregulated. For instance, bHLH, a transcription factor regulating flavonoid biosynthesis, was upregulated three to five weeks after flowering of yellow seeds. Therefore, epigenetic changes among rapeseed lines with different seed colors help elucidate the formation of yellow seed character.

A gold standard to deconvolute complicated structures of plant genomes with recursive polyploidizations

Xiyin Wang

North China University of Science and Technology

Plants often have complex genomes, due to recursive polyploidizations and genome repatterning. This makes it difficult to deconvolute their genome structures, and barrier the understanding their formation and the exploration of gene functional evolution. It would be a great pity if failing to decipher a newly sequenced genome structure when enormous amount of money and time invested. However, such failures occurred quite often in last several years. Here, we propose our approach to perform the genome structural analysis, adopted by quite several plant genome sequencing efforts, which we suggest be taken as a gold-standard to analyze a new genome sequence.

Genome-wide association analysis of nine agronomic traits in alfalfa (*Medicago sativa* L.) using genotyping-by-sequencing

Zan Wang[1]*, Lin Ma*[1]*, Haiming Zhao*[2]*, Congjun Jia*[1]

1. Institute of Animal Sciences, Chinese Academy of Agricultural Sciences

2. Institute of Dry-Land Farming, Hebei Academy of Agriculture and Forestry Sciences

Alfalfa (*Medicago sativa* L.) is the most important and widely planted forage legumes for hay and silage in the world. Understanding the genetic basis of agronomic traits in alfalfa will provide valuable information for improving alfalfa. In the present study, a broad collection consisted of 322 genotypes from 75 tetraploid alfalfa accessions were characterized phenotypically for nine agronomic traits under three environments. Phenotypic data analysis revealed that nine traits were significantly influenced by genotypes with different traits having various heritabilities. Using genotyping-by-sequencing (GBS), we identified 115,654 SNPs in the collection, and of those, 44757 SNPs were uniquely physically mapped on *M. truncatula* genome. Population structure and linkage disequilibrium analysis showed this collection could be divided into two sub-populations consistent with their origins and the average LD decay for the entire genome was estimated as 51.4 kb at $r^2 < 0.1$. The genome-wide association (GWAS) study by LD identified 42 putative significant marker-trait associations related to the agronomic traits except biomass yield (BY). Candidate genes assigned with the SNPs were also identified and characterized in this investigation. This study demonstrates that integrating GBS and GWAS could be used as a powerful approach for dissecting agronomic traits in alfalfa and providing candidate genes related to important agronomic traits in alfalfa breeding.

P1296

Transcriptomic analysis uncovers the molecular mechanisms of the interactions between *B. napus* and *S. sclerotiorum*

Meiling Xu, Li Lin, ***Jian Wu***

Yangzhou University

Sclerotinia stem rot caused by *Sclerotinia sclerotiorum* is one of the most devastating diseases in many important crops including *Brassica napus* worldwide. Quantitative resistance is the only source for genetic improvement of *Sclerotinia*-resistance in *B. napus*, but the molecular basis for such a resistance is largely unknown. Here, we performed an in-depth transcriptomic analysis to understand the differential defense responses to *S. sclerotiorum* in a resistance line (J964, R-line) and a susceptible line (J902, S-line) of *B. napus* at 0,24,48 and 96 hpi. Both the numbers of and fold changes in differentially expressed genes in the R-line were larger than those in the S-line at 48 hpi. To better understand these genes with different expression patterns or fold changes between the R- and S-lines, we introduced the concept of relative differentially expressed genes (RDEGs). In total, 5,910 up-regulated RDEGs and 3,091 down-regulated RDEGs in the R-line were identified. After monitoring the RDEGs, we found that a set of genes involved in immune responses were induced more intensely in the R-line, including pathogen recognition, MAPK signaling cascades, WRKY transcription regulation, jasmonic acid/ethylene signaling pathways, defense-related protein (PR2, PR3, PR4, PR5-like, PDF1.2b, chitinase, lectin, β-1,3-glucanase and PGIP) production and indolic glucosinolate biosynthesis. Our data also reveal that the degree of differential expression tends to become larger between the R- and S-lines along with the defensive signal transduction chains. The change of the chitinase, β-1,3 glucanase, PGIP activity and the glucosinolates content in the R- and S-lines after *S. sclerotiorum* inoculation were measured. We found that the activities of chitinase, β-1,3 glucanase, PGIP were indeed higher in the R-line than that in the S-line after inoculation, and indole glucosinolate content in the R-line were dramatically increased after inoculation. These results were consistent with the ones obtained by transcriptomic analysis. Thus, the differences between R- and S-line were associated with the intensity of defense responses. Interestingly, we found that the difference of defense responses between R- and S-lines at the early time of infection (before 24 hpi) may be associated with their physical barriers. The stem of R-line developed a more compact vascular and higher content of lignin in the pith, which contributes to limiting the invasion and expansion of *S. sclerotiorum* at the early time of infection. Moreover, we found that the endo-polygalacturonase gene (*SS1G_10167*), cellobiohydrolase gene (*SS1G_09020*) and oxaloacetate acetylhydrolase gene (*SS1G_08218*) and eight candidate effectors might play important roles in *S. sclerotiorum* pathogenicity by monitoring the transcriptomic changes in *S. sclerotiorum*. Thus, above results provide novel information for understanding the complex molecular mechanism of the *B. napus*-*S. sclerotiorum* interactions.

Pseudomonas syringae pv. *tomato* (*Pst*) DC3000 type three secretion system (TTSS) effector AvrPto1 targets and interrupts the SOBIR1-involved resistance signalling pathway

Jinbin Wu

Wageningen University

Leucine-rich repeat receptor-like proteins (LRR-RLPs) and LRR-receptor-like kinases (LRR-RLKs) are cell surface receptors that are essential for detecting invading pathogens and subsequent activation of plant defence responses. In contrast to RLKs, RLPs lack a cytoplasmic kinase domain to trigger downstream signalling leading to host resistance. The LRR-RLK SOBIR1 constitutively interacts with Cf-4 and is required for Cf-4-mediated resistance to *Cladosporium fulvum*. Accumulating evidence shows that SOBIR1 is broadly required for RLP-involved resistance to fungal, oomycete and bacterial pathogens. *Pseudomonas syringae* pv. *tomato (Pst)* DC3000 injects approximate 30 effectors into host cells via the type three secretion system (TTSS) and causes bacterial speck disease on host plants. Here we show that *Sl*SOBIR1 and its paralogs are all targeted by AvrPto1. And the kinase activity of *Sl*/*At*SOBIR1 is not required for the interaction with AvrPto1. Moreover, the auto HR triggered by over-expression of *AtSOBIR1* is suppressed by AvrPto1. Furthermore, Cf-4-mediated HR by recognition of Avr4 is suppressed by AvrPto1, but the effect of AvrPto1 on Cf-4/SOBIR1/BAK1 complex formation is remain unknown.

Transgene by pollen-tube pathway of *Dendrobium officinale*

Kanghua Xian*, Chuanming Fu, Jinxiang He, Qingfang Gong, Jiang Su, Ningzhen Huang*

Guangxi Institute of Botany, Guangxi Zhuang Autonomous Region and Chinese Academy of Sciences

In this paper, the transgenic technology of *Dendrobium officinale* was studied by using pollen-tube pathway with plasmid and agrobacterium vectors as target genes delivery. The main results were summarized as follows: 1. The minimum lethal concentration of kanamycin to seed germination and protocorm growth were 90 mg·L^{-1} and 150 mg·L^{-1} respectively. Further study showed that 100 mg·L^{-1} and 150 mg·L^{-1} of kanamycin were well for selecting transgenic seeds and protocorms during selective culture *in vitro* respectively. 2. Plasmid and agrobacterium containing GFP or GUS gene was transferred into *D. officinale* via pollen-tube pathway. The technology and method were summarized as follows: Collected target plasmid (pSuper1300 and pBI121) and agrobacterium which containing GFP or GUS gene; resuspended the plasmid pSuper1300 and pBI121 to concentration of 100 ng·μL^{-1} with thrice distilled water, while resuspended the agrobacteria which carrying plasmid pSuper1300 and pBI121 to OD_{600} = 0.7~0.8 with the solution of 2% sucrose + 1/2MS + 0.1% silwet-77 + 0.1% AS or 5% sucrose + 0.1% silwet-77 + 0.1 mmol·L^{-1} AS, respectively; during 0.5~2.5h after artificial pollination, used stigma dripping method to transfer into plasmids and agrobacteria which containing target gene; collect the mature seeds; selective culture and PCR certificated that the resistant materials of almost all treatments were integrated GFP and GUS gene. Moreover, compared with agrobacterium as target gene delivery, the plasmid gene delivery could harvest more fruits.

Genetic diversity and population structure of Golden wood (*Phoebe zhennan*) inferred from RAD-seq-derived SNP markers: effects of sequence clustering parameters

Jianhua Xiao[1,2], *Xin Ding*[1,2], *Jie Li*[1]
1. Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Restriction-site-associated DNA sequencing (RAD-seq) and related methods are revolutionizing the field of population genomics in non-model organisms as they allow generating an unprecedented number of single nucleotide polymorphisms (SNPs) even when no genomic information is available. Yet, RAD-seq data analyses rely on assumptions on nature and number of nucleotide variants present in a single locus, the choice of which may lead to an under- or overestimated number of SNPs and/or to incorrectly called genotypes. Using the Golden wood (*Phoebe zhennan*), as case study, here we explore the difference of genetic diversity and sensitivity of population structure inferences to three crucial aspects in RAD-seq data analysis: the minimum depth allowed to merge reads into a stacks, the maximum number of mismatches allowed to merge reads into a locus and the relatedness of the individuals used for genotype calling and SNP selection. Our study estimates the genetic diversity and resolves population structure of the *Phoebe zhennan*, but, most importantly, provides insights into the effects of alternative RAD-seq data analysis strategies on population structure inferences that are directly applicable to other non-model species.

Identifying differentially expressed genes connected to seed shattering in *Elymus sibiricus*, an important forage grass in Qinghai-Tibet Plateau

Junchao Zhang, *Wengang Xie, Xuhong Zhao, Zongyu Zhang, Yanrong Wang*
State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University

Elymus sibiricus is an important forage grass in semi-arid regions, but it is difficult to grow for commercial seed production due to high seed shattering. To better understand the underlying mechanism and explore the putative genes related to seed shattering, we conducted a combination of morphological, histological, physiochemical and transcriptome analysis on two *E. sibiricus* genotypes (XH09 and ZhN03) that have contrasting seed shattering. The results show that seed shattering is generally caused by a degradation of the abscission layer. Early degradation of abscission layers was associated with the increased seed shattering in high seed shattering genotype XH09. Two cell wall degrading enzymes, cellulase (CE) and polygalacturonase (PG), had different activity in the abscission zone, indicating their roles in differentiation of abscission layer. cDNA libraries from abscission zone tissue of XH09 and ZhN03 at 7 days, 21 days and 28 days after heading were constructed and sequenced. A total of 86,634 unigenes were annotated and 7,110 differentially expressed transcripts (DETs) were predicted from “XH09-7 vs ZhN03-7”, “XH09-21 vs ZhN03-21” and “XH09-28 vs ZhN03-28”, corresponding to 2,058 up-regulated and 5,052 down-regulated unigenes. The expression profiles of 10 candidate transcripts involved in cell wall-degrading enzymes, lignin biosynthesis and phytohormone activity were validated using quantitative real-time PCR (qRT-PCR), 8 of which were up-regulated in low seed shattering genotype ZhN03, suggesting these genes may be associated with reduction of seed shattering. The expression data generated in this study provides an important resource for future molecular biological research in *E. sibiricus*.

Transcriptome analysis of *Chionochloa macra* reveals biological features

Haoyu Xiong[1], *David Wharton*[2], *Janice Lord*[3], *Craig Marshall*[1]
1. Department of Biochemistry, University of Otago
2. School of Zoology, University of Otago
3. Department of Botany, University of Otago

The genus *Chionochloa* (tussocks), is mainly endemic and dominates the alpine grassland of New Zealand. *Chionochloa macra*, the slim snow tussock, is one of the most common high mountain tussocks, and is mainly found in the South Island. Previous studies of *Chionochloa* have focused on their ecological features and seasonal variations in chemical composition. Recent research has found species specific features including ice activities and water collection mechanisms in *C. macra* but there have been few studies analyzing the molecular genetics of these characters. Moreover, there are only a few studies on the phylogeny of the *Chionochloa* group based on rDNA and/or mitochondrial markers and the lack of genetic information has hampered further research. In this study, the first transcriptome of *C. macra* was achieved by sequencing the total RNA from four *C. macra* plants with an Illumina Hiseq 2000 platform. A total of 351 million high quality reads

(Q20) were generated and assembled into 901,869 contigs by Trinity assembler. This was finally filtered to 297,695 contigs with a N50 value of 1009. The filtered contigs were searched against NCBI non-redundant database and Swiss-Prot database (E-value<e$^{-5)}$. </eGene Ontology annotations were given to 109,850 contigs by Blast2GO and 42,570 contigs were mapped to KEGG pathways. Essential proteins and metabolic pathways related to C. macra's biological features including high polysaccharide content, triterpenoid expression and water conservation were investigated. Genes coding ice-binding proteins were mapped with mass spectrometry data from ice affinity purification. Alternative splicing events, SSRs markers, SNPs, miRNAs were reported and gene expression profiles were provided for further genetic research in C. macra and other species in this genus.

Comparative transcriptome analysis of the female and male inflorescences of monoecious plant pecan (*Carya illinoinensis*)

*Gang Wang, **Jiping Xuan**, Jiyu Zhang, Xiaodong Jia, Zhongren Guo*
Institute of Botany, Jiangsu Province and Chinese Academy of Sciences

Pecan (*Carya illinoinensis*) is a popular long-lived diploid tree in silviculture and horticulture. As pecan is a wind pollinated monoecious tree exhibiting heterodichogamy, the location and timing of functioning female and male organs are different, often leading to fruit-setting problem and thus yield decreases. The limited availability of pecan genomic information has hindered research on the mechanisms underlying its flower development. In this study, we obtained the first de novo assembly of pecan transcriptome and performed a comparative analysis of pecan female and male inflorescences using RNA-seq technology. A final unigene dataset containing 53,894 unigenes in the female pecan inflorescence was obtained, with an N50 length of 1,411 bp. To obtain insight into the functions of pecan unigenes, the unigenes were then annotated with Nr, Nt, Swiss-Prot, TrEMBL, KEGG and KOG databases. Using the bioinformatics approach, we identified 11,813 SSRs in unigenes and developed primers for 7,725 of them. A total of 26,321 differentially expressed genes (DEGs) were identified between pecan female and male inflorescences. A large number of them were linked to plant hormone regulation, especially gibberellin. In addition, out of 20 MADS-box transcription factors, one was more highly expressed in the female inflorescence whereas eight were expressed at a lower level in the male inflorescence, illustrating that the MADS transcription factors are involved in the flower development. In summary, this first unigene assembly of pecan could contribute to enhancing understanding of the gene specialization in flowers of difference sexes, and also be particularly useful for pecan germplasm management and breeding programs.

A ddRAD-based linkage map and comparative genomics of *Dendrocalamus latiflorus* Munro

***Guoqian Yang**, Dezhu Li, Zhenhua Guo*
Kunming Institute of Botany, Chinese Academy of Sciences

Construction of linkage maps is a first step in exploring the genetic basis for adaptive phenotypic divergence in closely related species by quantitative trait locus (QTL) analysis. Linkage maps are also useful for comparative genomics in non-model organisms. Advances in genomics technologies make it more feasible than ever to study the genetics of adaptation in natural populations. Restriction site-associated DNA sequencing (RAD-seq) in next-generation sequencers facilitates the development of genetic markers and genotyping. We aimed to construct a linkage map of the Dendrocalamus latiflorus Munro of the genus Dendrocalamus (Gramineae) for comparative genomics with rice, Brachypodium distachyon and maize (all belong to the grass family) and for the future QTL analysis of the genetic architecture underlying adaptive phenotypic evolution of bamboo. We constructed the first high-density genetic linkage map of D.latiflorus Munro using a 190 selfing (S1) progenies of a wild species in southwest China. Based on 3,627 RAD-tag markers, a linkage map spanning 3,114.98 cM with 36 linkage groups and an average marker interval of 0.87cM was constructed. We also identified regions of segregating distortion involving transmission ratio distortion (TRD). Synteny and collinearity were extensively conserved between bamboo and rice and other grass species. The dense SNP-based linkage map presented here serves as a basis for future QTL analysis. It will be helpful for transferring genomic information from a monocotyledonous model species, rice, to screen candidate genes underlying ecologically and economically important traits of the bamboo.

Difference of the annual roots of *Malus hupehensis* in transcriptome level

*Chunran Zhou, Hui Cao, Weiwei Zhang, **Hongqiang Yang***
College of Horticulture Science and Engineering, Shangdong Agricultural University

The roots of fruit tree contain perennial roots and annual roots grouped by growth years. Annual roots were divided into absorbing roots, extensive roots and conductive root by function. These differences are the adaption of root to the environment in specific genetic background, which is not only influenced by the environment but also controlled by gene expression. The experiment performed the transcriptome analysis of the annual roots of *Malus hupehensis* Rehd. using Illumina HisSeq 2500 RNA-seq. The 52,217,996 clean reads were obtained after filtering, which contained 10.54G Base in total. 54,396 unigenes were generated after assembling original reads. The unigenes were further blatsed using the BLAST and Blast2GO software in Nr, Swiss-Prot, GO, COG, and KEGG database for homology comparison. 31,530 unigenes were found to be homologous with the genes in these databases and accounted for 57.96% of the total unigenes. There are significant differences among the expression level of a large amount of genes of the absorbing roots, extensive roots and conductive roots. It shows that the expression level of genes producing ammonium transporters protein, subtilisin-like protease, aquaporin protein and casparian strip membrane protein is higher in absorbing roots than that in the extensive roots or conducting roots. The expression level of xyloglucan endotransglucosylase/hydrolase gene is higher in extensive roots than that in conducting roots. In addition, the expression levels of many extension genes are higher in extensive roots than those in absorbing roots or conducting roots. The expression level of genes producing heat shock protein, sugar transport protein and pectate lyase is higher in conducting roots than that in the extensive roots or absorbing roots. The difference of these genes expressions coincides with the functions and growth characteristics of these three types of roots.This work was supported financially by the National Natural Science Foundation of China (No. 31372016).

RNase H1 cooperates with DNA gyrases to restrict R-loops and maintain genome integrity in *Arabidopsis* chloroplast

***Zhuo Yang**, Lingling Cheng, Quancan Hou, Wei Xu, Yantao Hong, Shuai Li, Qianwen Sun*
Center for Plant Biology and Tsinghua-Peking Joint Center for Life Sciences, School of Life Sciences, Tsinghua University, Beijing 100084, China

Maintaining the integrity of organellar genomes is essential for eukaryotic cells. The chloroplast genome in plants is threatened by DNA stresses such as oxidative or photochemical damage from the altered surroundings, but the mechanisms whereby chloroplast genome integrity is maintained are not entirely understood. Here we found that plastid R-loop levels are related to chloroplast genome instability, and this is regulated by an R-loop removing enzyme AtRNH1C. AtRNH1C is predominantly localized in chloroplasts and necessary for chloroplast R-loop homeostasis and development. Interactome analysis revealed that AtRNH1C associates with multiple chloroplast-localized DNA- and RNA-metabolism related proteins, including the core DNA gyrases complex. The interaction between AtRNH1C and AtGyrases was critical for R-loop homeostasis in chloroplast and essential to release the transcription-replication conflicts in the highly transcribed and replication originated cp-rDNA regions, and thus to reduce the DNA damage. Together, our results reveal the plastid R-loop accumulation is the primary cause of cpDNA instability, and provide insight into the maintenance of genome integrity in chloroplasts, in which the evolutionarily conserved RNase H1 and DNA gyrases proteins are involved.

The alternative splicing differentiation of the homeologous genes between the A and C subgenomes in *Brassica napus* L.

***Shengli Yao**, Ming Hu, Dong Caihua, Huang Junyan, Tong Chaobo, Liu Shengyi*
Oil Crops Research Institute, Chinese Academy of Agricultural Sciences, Key Laboratory of Biology and Genetic Improvement of Oil Crops, the Ministry of Agriculture

Polyploidization is known to be prominent and significant force inducing diversification and speciation in plants. Many duplicated genes evolved and diverged accompanying following polyploidization, and their evolution is an important foundation of the polyploid formation. *Brassica napus* is ideal model for studying the formation of allopolyploid. Alternative splicing (AS) is an important mechanism for posttranscriptional modulating gene expression and proteins diversity in higher eukaryotes. Second-generation sequencing technologies have been extensively used to analyzetranscriptomes. However, a major limitation of short-read data is that it is difficult to accurately predict full-length splice isoforms. Here we sequenced the *B. napus* transcriptome using Pacific Biosciences single-molecule real-time (SMRT) long-read isoform sequencingtechnology. We start with all duplicated genes originated from *B. napus*, which have been constructed from chromosome syntenic analysis between two subgenomes in *B. napus*. Through Illumina RNA-Seq sequencing technology, we identified total 109,579 alternative splicing events that occurred at least from 2 biological replicates in 6 tissues in *B. napus* (cultivar "ZS11"). Almost 60% of alternative splicing events occurred in homeologous genes only from one of homeologous genes which belong to the gene in A or C subgenome. Total 26,687 expressed multi-exon genes were highly enriched in GO categories related to binding, regulation, location, transporting, metabolism, transcription, cell component and so on. It shows that intron retention is the most abundant AS type in higher eukaryotes as reported, the proportions of four main AS types in different tissues are similar and most AS events are tissue-specific. The AS gene highly enriched in metabolism, regulation and related pathways, which suggested that alternative splicing plays important roles in posttranscriptional regulation. Through SMRT sequencing we identified 217,963 AS events from 5 pooled the same tissues as Illumina sequencing. Only nearly 30% SMRT isoforms wered recovered with the assembled transcripts from Illumina sequencing. The work suggests that SMRT sequencing is highly powerful in AS discovery and provides a rich data resource for later functional studies of variant isoforms.

Plastid genome comparative analysis between *Platycladus orientalis* and *Thuja koraiensis*

***Dong-Keun Yi**[1,2], Hyuk-Jin Kim[2], Keum Seon Jeong[2], Min Jung Joo[2], Eun Mi Sun[2], Kyung Choi[2]*
1. International Biological Material Research Center, Korea Research Institute of Bioscience and Biotechnology
2. Division of Forest Biodiverstity and Herbarium, Korea National Arboretum

Cupressaceae is most recent speciated family among gymnosperm. The family includes 27~30 genera with about 130~140 species in total. Sequenced plastomes of Cupressaceae show various plastome structure and some genus have very different structure when compared with its related genera. *Platycladus orientalis* was often included in genus *Thuja* as to be called "oriental thuja". But there are many morphological differences between two genera, *P. orientalis* was identified to different genus. Here we have sequenced two complete chloroplast genomes of *P. orientalis* and *T. koraiensis* (Cupressaceae). The genomes are 127,113 bp and 130,381 bp in length, respectively. Comparative chloroplast DNA sequence analyses with two species reveal that gene and intron contents are similar to the Cupressaceae plastome except a few minor modifications. The genome of *T. koraiensis* includes 118 genes (78 peptide-encoding genes, 32 tRNA genes, four rRNA genes, 4 open reading frames) and the genome of *P. orientalis* hs one more tRNA gene (trnP-GGG). The major portion (63.1%) of the *T. koraiensis* plastome consists of gene-coding regions (57.7% protein coding and 5.4% RNA regions), and the major portion (64.7%) of the *P. orientalis* plastome consists of gene-coding regions (59.1% protein coding and 5.6% RNA regions). The overall A-T content of *T. koraiensis* and *P. koraiensis* plastomes are 65.7% and 65.3%, respectively. The A-T contents in the non-coding (70.7% and 70.3%) are higher than in the coding (63.1% and 64.7%) regions. Compared between structures of *T. koraiensis* and *P. orientalis*, plastome structure of *P. orientalis* are similar with structure of genera *Callitropsis*, *Cupressus*, *Hesperocyparis* and *Juniperus* which speciated in comparatively recent date, but *T. koraiensis* have distinctive plastome structure. Structure comparison between *T. koraiensis* and *P. orientalis* shows one inversion and one rearrangement modification. Genome structure comparison among Cupressaceae will provide information of relationship between structure modification and evolution, and scenario of structural modification.

5. Department of Animal and Plant Sciences, University of Sheffield

The development of programmable, sequence-specific nucleases such as Zinc-finger nucleases (ZFNs), transcription activator like effector nucleases (TALENs), clustered regulatory interspaced short palindromic repeat (CRISPR)-Cas9 and CRISPR-Cpf1 systems has provided scientists with easy-to-use tools for genome manipulation. The advantage of these tools is that they target a precise location within the genome facilitating the production of transgene-free homozygous heritable gene edited plants. The most widely used tool, the CRISPR-Cas9 system, recognizes and cuts specific sites that have a protospacer adjacent motif (PAM) of NGG, suitable for editing GC rich regions. Whereas the CRISPR-Cpf1 system recognizes and cut sites that have a PAM of TTTV, which is more suitable for editing AT rich regions. In this study, we have used both CRISPR-Cas9 and CRISPR-Cpf1 to knock out a rice (*Oryza sativa*) ortholog of the *Arabidopsis* Epidermal Patterning Factor like-9 (EPFL9) gene, a positive regulator of stomatal development. Germ-line mutants with edited OsEPFL9 gene were generated by CRISPR-Cas9 system and advanced to T_2 generation, when Cas9-free homozygous mutants were obtained. There were no detectable off-target effects in these plants when we sequenced the potential off-target sites. These plants had a more than eightfold reduction in stomatal density on the abaxial leaf surface. Knockout of the same gene using the CRISPR-Lb-Cpf1 (Lachnospiracae bacterium Cpf1) system led to heritable genome edits and similar phenotypic changes in T_1 generation plants. This study demonstrates the application of both CRISPR-Cas9 and CRISPR-Cpf1 to precisely target genomic locations and develop transgene-free homozygous heritable gene edited plants. It also confirms that the loss of function analysis of the candidate genes emerging from different systems biology based approaches can be performed with these tools. These systems add value to gene function studies.

FY of *Arabidopsis* comprehensively regulates alternative polyadneylation

Zhibo Yu[1], *Juncheng Lin*[1], *Qingshun Quinn Li*[1,2]
1. College of the Environment and Ecology, Xiamen University
2. Graduate College of Biomedical Sciences, Western University of Health Sciences, Pomona

Alternative polyadenylation (APA) plays a crucial role in gene expression regulation across eukaryotes. This process requires a complex set of protein factors. In mammals, the 3’-end processing factor WDR33, a subunit of the Cleavage and Polyadenylation Specificity Factors (CPSF), directly binds to AAUAAA, the most conserved polyadenylation signal in eukaryotic. Arabidopsis FY is the homologue of WDR33. Previous studies have demonstrated that FY was involved in poly (A) site choice of flowering related genes. However, it remains to be clarified whether FY comprehensively involves in poly (A) site choices of other genes in Arabidopsis. Here, using Poly (A) Tag Sequencing (PAT-Seq) approach, we investigated transcriptome-wide poly (A) site profile in a mutant (fy-1) lacking a PPLPP domain of FY. The results showed that poly (A) site choice in a large number of Arabidopsis genes were significantly changed between wild type and fy-1 mutant with adjusted $p<0.05$, suggesting that FY functioned in the process of APA in Arabidopsis thaliana. Functional enrichments analysis of differentially expressed poly (A) site clusters indicates that these genes are significantly enriched in several biological processes, including response to osmotic stress, response to reactive oxygen species, defense response, cell death, among others. To further elucidate if FY mutation affects these biological processes, we assessed the sensitivity of fy-1 mutant to osmotic and oxidative stresses. Comparing to wild type, fy-1 mutant had higher rate of seed germination under salt or drought stress. The results suggested that fy-1 mutant had more tolerance to osmotic stress. Furthermore, the root length of fy-1 mutant was shorter than wild type under methyl viologen conditions, indicating that fy-1 mutant was more sensitivity to oxidative stress. Remarkably, we found that intergenic PATs significantly increased in fy-1 mutant compared to the wild type. To explain this, the expression level of CPL3, a phosphotase for the RNA polymerase II C-terminal domain leading to transcription termination, was determined by qRT-PCR. We found that the expression level of CPL3 significantly decreased in fy-1 mutant. Thus, we speculated that low expression level of

CPL3 is unable to dephosphorylate Ser2 leading to increase intergenic PATs in fy-1 mutant. Taken together, these results suggest that FY regulates poly (A) site selection of *Arabidopsis* genes and is involved in transcription termination.

Pineapple (*Ananas comosus* (L.) Merr.) is the most economically valuable crop possessing crassulacean acid metabolism (CAM), a photosynthetic carbon assimilation pathway with high water-use efficiency, and the second most important tropical fruit. We sequenced the genomes of pineapple varieties F153 and MD2 and a wild pineapple relative, Ananas bracteatus accession CB5. The pineapple genome has one fewer ancient whole-genome duplication event than sequenced grass genomes and a conserved karyotype with seven chromosomes from before the ρ duplication event. The pineapple lineage has transitioned from C3 photosynthesis to CAM, with CAM-related genes exhibiting a diel expression pattern in photosynthetic tissues. CAM pathway genes were enriched with cis-regulatory elements associated with the regulation of circadian clock genes, providing the first cis-regulatory link between CAM and circadian clock regulation. Pineapple CAM photosynthesis evolved by the reconfiguration of pathways in C3 plants, through the regulatory neofunctionalization of preexisting genes and not through the acquisition of neofunctionalized genes via whole-genome or tandem gene duplication.

Genetic and expressional variations of the genes in gibberellin metabolic pathway during japonica rice domestication

Chunyan Jing[1,2], *Sha Zhang*[1,2], ***Fumin Zhang***[1,2]

1. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences

2. University of Chinese Academy of Sciences

Molecular evolution of metabolic pathways is very important to understanding the molecular mechanism of phenotypic differentiation between species, which is also a key to the fundamental problem of biological evolution on phenotypic diversification and adaptation. Japonica rice (*Oryza sativa subsp. japonica*) was domesticated from its wild ancestral species *O. rufipogon* 10000 years ago. During the domestication, evolution pattern and underlying mechanisms of gibberellin metabolic pathway under artificial selection remain unclear in spite of importance of the pathway to plant growth and development. To reveal the pattern and underlying mechanisms, we conducted a comparison on population genetic and expressional variations of all the 21 genes of gibberellin metabolic pathway between japonica rice and *O. rufipogon* occurring in China. The sequences of all the 21 genes in gibberellin metabolic pathway were retrieved from next generation sequencing (NGS) data of japonica rice and *O. rufipogon* samples. Using the sequences, we investigated population genetic variation of all the 21 genes within and between japonica rice and *O. rufipogon*. Our results showed that diversities of five genes of japonica rice had significantly decreased as compared to their wild ancestor, indicating that the genes experienced strong artificial selection during domestication process of japonica rice. Moreover, these genes were mainly located in the branch points of downstream in the gibberellin metabolic pathway. Our analysis of population genetic differentiation displayed that genes with high F_{ST} values were mainly in the branch points of downstream in the pathway, too. The neutral test indicated that the genes that significantly deviated from the standard neutral model were also mainly located in the branch points of downstream in the pathway. On the other hand, we conducted qPCR experiments to compare the expressional variation of all the 21 genes at two developmental stages of seedling and elongation between japonica rice and its wild ancestral species *O. rufipogon*. The experimental results showed that differentially expressed genes (DEGs) identified at both stages were mainly located in downstream of the pathway, including those in the branch points. Based on the results, we conclude that the genes in the branch point of downstream in gibberellin metabolic pathway are main targets of artificial selection during japonica rice domestication process. Because the variation of genes in branch point of downstream in pathway affect mainly the distribution of metabolic flux, we infer that a gene with a higher effect on the distribution of metabolic flux usually is the target of selection in metabolic pathway.

Genetic diversity and domestication footprint of Chinese cherry (*Cerasus pseudocerasus* (Lindl.) G.Don) as revealed by nuclear microsatellite markers

Jing Zhang[1,2], *Tao Chen*[1,2], *Yan Wang*[1,2], *Qing Chen*[1], *Bo Sun*[1], *Hao-Ru Tang*[1,2], *Xiao-Rong Wang**[1,2]

1. College of Horticulture, Sichuan Agricultural University

2. Institute of Pomology and Olericulture, Sichuan Agricultural University

Chinese cherry (*Cerasus pseudocerasus* (Lindl.) G. Don) is a commercially and culturally important fruit crop in China, but the domestication history and genetic relationship of the cherry landraces still remains unclear. To address these questions, we employed nineteen nuclear microsatellite markers to genotype 532 Chinese cherry landrace and wild accessions from 57 populations of 12 provinces in China. All of our samples covered the whole natural distributions in Sothwest China (SWC), Longmenshan Fault Zones (LFZ), Qinling Mountains (QLM) and North and East China (NEC). 16 *Cerasus* relative species (118 wild relative accessions) from 17 natural populations were took as out group in our study. We identified the population structure in Chinese cherry with Bayesian clustering method in STRUCTURE. Our results showed three genetic clusters in Chinese cherry. Wild accessions were assigned into one genetic cluster (WC). Landrace accessions were divided into two different genetic clusters (LC1 and LC2). LC1 almost consisted of the landraces from LFZ and SWC, and LC2 mainly included those from QLM and NEC. We calculated seven genetic diversity indices within populations and within genetic clusters, and conducted the Kruskal-Wallis test for allelic richness (AR) and gene diversity (Hs) among all Chinese cherry populations and between pairwise genetic clusters. Significant loss of genetic diversity were detected in most landrace populations and both landrace clusters during domestication. With Garza-Williamson index and two-phased model of mutation (TPM), we detected significant fingerprint of recent genetic bottleneck in LC1 (LFZ and SWC) but not in LC2 (QL and NEC). Based on historical evidences and our genetic results, we estimated the most probable demographic model for Chinese cherry with the approximate Bayesian computation (ABC) under pruned data (without recent admixed and misclassified accessions identified by STRUCTURE) and full data (all Chinese cherry accessions). Our results under two different datasets showed strong evidence for the independent domestication for two landraces clusters. The parameters estimation in ABC model indicated that the LC2 (QL and NEC) was diverged from the wild ancestors about 3900 years ago, which was earlier than LC1 (LFZ and SWC). Combined with microsatellites and phenotypic data, we found that long-term independent domestication process and different artificial selection have led to two significantly different domestication footprints on the two landrace clusters. To analyze the genetic relationship and recent demographic process among landrace populations and between landrace and wild populations, we estimated the admixture coefficients ($m\gamma$), correlated coefficients (rxy) and genetic draft (F) between pairwise populations. Close genetic relationship was detected between landrace accessions and populations from the neighboring populations and areas. Frequent gene flow from wild accessions was detected in the landraces from QLM and SWC. Our study contributes to the knowledge about the domestication history and genetic relationship for Chinese cherry landraces. As a long-lived perennial fruit crop with high inbreeding, the domestication patterns of Chinese cherry were different from those of some out-crossing perennial fruit crops.

Evolution and diversity of E (z) homolog genes in green plant

Zihua Chen, *Liangsheng Zhang*

Center for Genomics and Biotechnology, Fujian Agriculture and Forestry University

Polycomb group proteins (PcG) methylate lysine 27 of histone H3 and play important roles in the maintenance of silent states of genes. These core PcG proteins, such as Enhancer of Zeste (E (z)), are conserved in animals and plants. By a comparative phylogenetic analysis, we present a potential framework of E (z) gene evolution in green plant lineage. We found the E (z) genes are duplicated in the ancestor of seed plants resulting in two clades: SWN and CLF. Then, E (z) genes are highly conserved in angiosperms. However, Brassicaceae contains two clades by whole genome duplication, which forms MEA and SWN. Similarly, Fabaceae also contains two clades, named MEA-like and SWN-like. Interestingly, codon-based branch analysis among taxa suggests that within the MEA-like, but not SWN-like, continues to evolve under positive selection in Fabaceae. We analyze the expression of MEA-like genes and found that most tissues did not express in soybean, but there is little expression in the heart-shaped embryo, suggesting that it might be specifically expressed in embryonic development. From the sequences analysis and expression, we propose that MEA-like lead to neofunctionalization in soybean or Fabaceae .

P1314

Origin and diversity of *WRKY* gene family in green plants

Hu Yue, *Zhang Liangsheng*

Center for Genomics and Biotechnology; Key Laboratory of Genetics, Breeding and Multiple Utilization of Corps, Ministry of Education; Fujian Agriculture and Forestry University

WRKY gene family is a kind of important transcription factor, which plays important roles in regulating plant development and resistance. WRKY gene can be divided into Group I, Group II and Group III. In order to clarify the evolution of the WRKY gene in plants, we used a large number of genome and transcriptome data, including a variety of species from Chlorophyta, Charophyta, and land plants. According to the phylogenetic tree topology, we re-divided the WRKY family into Group I, Group IIa + IIb, Group IIc, Group IId + IIe and Group III. 12 Chlorophyta species contained WRKY genes, which distributed in Group I and Group III. 16 species of Charophyta have WRKY genes and are distributed in all groups except the family Group IId + IIe. We used three moss genome data, namely *Sphagnum fallax*, *Takakia lepidozioides* and *Physcomitrella patens*, as well as the genome of kind of liverwort species, *Marchantia polymorpha*. There were 36 and 34 WRKY genes in the *T. lepidozioides* and *P. patens*, while only 14 and 11 were found in *M. polymorpha* and *S. fallax* respectively, each of them had a similar distribution pattern of WRKYs. From the topological structure of the Group III phylogenetic tree, four species form a monophyletic group, while the seed plants were divided into another one, and the *M. polymorpha* was further distant from the other three. *P. patens* only had Group IId members, while the other three are distributed in both Group IId and Group IIe. In Group IIa + IIb, their WRKY genes were gathered together with angiosperms instead of gymnosperms. Besides, from the figure Group IIc could be divided into two clades and all the moss were concentrated in one branch. The number of Gymnosperms WRKY is the least in Group III, with no more than 3 in all species. In the GroupIIa + IIb, the *Pinus taeda* and the *Picea abies* are monophyletic, indicating that the WRKY gene of GroupIIa + IIb could be specifically expand in the Pinales.

The genetic architecture of shoot-root covariation during seedling emergence of a dessert tree, *Populus euphratica*

Miaomiao Zhang[1], *Wenhao Bo*[1], *Fang Xu*[1], *Huan Li*[1], *Meixia Ye*[1], *Libo Jiang*[1], *Chaozhong Shi*[1], *Yaru Fu*[1], *Guomiao Zhao*[1], *Yuejiao Huang*[1], *Kirk Gosik*[2], *Dan Liang*[1], *Rongling Wu*[1,2]
1. Center for Computational Biology, College of Biological Sciences and Technology, Beijing Forestry University
2. Center for Statistical Genetics, The Pennsylvania State University

The coordination of shoots and roots is critical for plants to adapt to changing environments by fine-tuning energy production in leaves and the availability of water and nutrients from roots. To understand the genetic architecture of how these two organs covary during developmental ontogeny, we conducted a mapping experiment using Euphrates poplar (*Populus euphratica*), a so-called hero tree able to grow in the desert. We geminated intraspecific F_1 seeds of Euphrates poplar individually in a tube to obtain a total of 370 seedlings, whose shoot and taproot lengths were measured repeatedly during the early stage of growth. By fitting a growth equation, we estimated asymptotic growth, relative growth rate, the timing of inflection point and duration of linear growth for both shoot and taproot growth. Treating these heterochronic parameters as phenotypes, a univariate mapping model detected 19 heterochronic quantitative trait loci (*h*QTLs), of which 15 mediate the forms of shoot growth and four mediate taproot growth. A bivariate mapping model identified 11 pleiotropic *h*QTLs that determine the covariation of shoot and taproot growth. Most QTLs detected reside within the region of candidate genes with various functions, thus confirming their roles in the biochemical processes underlying plant growth.

Genome expansion and the origin of major plant innovations

Ticao Zhang[1], *Qin Qiao*[2], *Jinling Huang*[3]
1. Key Laboratory for Plant Diversity and Biogeography of East Asia, Kunming Institute of Botany, Chinese Academy of Sciences
2. School of Agriculture, Yunnan University
3. Department of Biology, East Carolina University

Major organismal lineages are defined by distinctive structural and physiological innovations. How these innovations evolved over time as a result of increase in gene repertoire remains unclear. In this study, we adopt a new phylogenomic framework to understand the origin and evolution of structural and physiological innovations of major plant lineages based on core genome expansions, each of which includes a synapomorphic genome with shared derived genes for the focal lineage. Our analyses identified two major expansion events coincident with the origin of streptophytes and angiosperms respectively. The synapomorphic genome of streptophytes evolved in a much slower tempo, but is enriched in genes related to adaptation to terrestrial environments. We show that the phenylpropanoid metabolism evolved in charophyte green algae, rather than in land plants. The establishment of the complete flowering network was determined by the origin of several key genes in angiosperms, although the majority of flowering genes evolved at earlier stages. These findings are critical for understanding the interplay of innovations at different levels (e.g., gene, genome, physiological, structural) and the origin of major plant lineages.

Precision automation of tissue and cellular phenotyping classification and quantification based on microscopic images

Ying Zhang, *Jianjun Du*, *Xinyu Guo*, *Chunjiang Zhao*
Beijing Key Lab of Digital Plant, Beijing Research Center for Information Technology in Agriculture, Beijing Academy of Agriculture and Forestry Sciences, Beijing, Germany

Plant phenotyping is defined as the application of methodologies and protocols to measure the specific traits, ranging from the cellular level, organ level, to the whole plant or canopy level, related to plant structure and function (Ghanem *et al.,* 2014). Whole plant phenotyping systems are highlighted combination with advances in machinery manufacturing and automation in image acquisition and analysis that enable notable throughput increase. There have been many progresses on the whole plant phenotyping research, which for example acquire a large number of traits including plant growth, physiological traits, biotic or abiotic stress markers. Organ level phenotyping researches are focus on high-dimensional phenotypic data at elevated spatial and temporal resolution. Such as various imaging technologies have been applied to monitor the root phenotyping non-disruptively and throughout a time period. More importantly, many commercial whole plant or organ phenotyping solutions are available for indoors and outdoors use and which have dramatically changed plant breeding programs and functional genomics in the last decade (Rahaman *et al.,* 2015; Hall *et al.,* 2016). Compared with rapid, precise, and accurate phenotypic traits data from organ level to the whole plant level high-throughput phenotyping (HTP) solutions, the potential of automated phenotyping with cellular resolution is largely unexploited. Operating at a lower throughput, phenotyping at cellular level requires more complex produces, such as extensive sample preparation and advanced microscopic acquisitions. Recent advances in microscope automation provided new opportunities for high-throughput cell level phenotyping, i.e. Micro-CT, LSCM, and SEM imaging. However, Quantitative analysis of those anatomical characteristics based on micro-images is a very tedious work, which mostly relies on manually examination. Obviously, manual examination is labor intensive and underlies human subjectivity and inconsistency that may severely limit the throughput and precision of micro-phenotypic traits analysis, hence high-throughput and accurate analysis methods are strongly needed. A particular focus of our work is the investigation of image process pipeline for different microscopic images, from slide scanning images obtained by classical paraffin embedding and microtome techniques to CT scanning images, which (1) automatically segment maize stems into tissue regions or individual cells, (2) assigns each segment to a vascular tissue or cell type, (3) quantifies phenotypic traits, and also (4) extracts a wealth of morphometric data. Short processing times permit large data sets, which will promote the application of micro-phenotyping in plant breeding programs and functional genomics.

Identification and analysis of candidate genes for the varietal characters of *Phyllostachys edulis* 'pachyloen' by whole-genome resequencing and RNA-seq

Yun Zhang[1], *Ying Zhang*[1,2], *Hong Ran*[1,3], *Yun Feng*[1], *Tao Hu*[1], *Qi-Rong Guo*[1]
1. International Center for Bamboo and Rattan
2. Guangdong Academy of Forestry
3. Chongqing Academy of Forestry

Phyllostachys edulis (moso bamboo) originated from China and is one of the best economic bamboo species with the largest distribution area, most accumulation on volumes, highest production, and best research and utilization degree. There are more than 20 varieties had been released, but *Phyllostachys edulis* 'Pachyloen', one of the cultivar of moso bamboo, is the only accession germplasm with the bamboo wall thickened obviously. It owns desirable traits for its wood and shoots, and has the characteristics of stable heredity. Exploring the formation mechanism of its good traits by whole-genome re-sequencing and RNA sequencing based on the reference genome of moso bamboo, especially for its thick wood, will provide important theoretical basis for bamboo breeding. A total of 260.5 million reads produced approximately 24.5 Gb of sequence for *Phyllostachys edulis* 'Pachyloen' with 12X genome coverage, and mapping of 245 million (97.43%) reads to the reference genome by the whole-genome re-sequencing. The variation including SNP, InDel and CNV have great impact on the change of genomes and the biological characters. In addition, we identified 6631 differentiating genes which were performed the analysis of KEGG pathway, and these genes fall into some metabolic pathway such as the metabolism of starch, carbohydrate and hormone, biosynthesis of carbohydrate, protide, and lipid in the ribosome and endoplasmic reticulum. According to the developmental stages of bamboo from bud to young culm a total of eight times, we gathered the eight shoots of *Phyllostachys edulis* 'Pachyloen' and moso bamboo which were selected as the control group, respectively, and they were proceed the RNA sequencing. For *Phyllostachys edulis* 'Pachyloen' and moso, there were 2.4-4.3 Gb and 1.7-5.6 Gb of sequence respectively. The unique genes and differential expression genes which were gained from the experimental and control group and maybe correlated with the specific qualities could be screened. The unique genes of *Phyllostachys edulis* 'pachyloen' were ranged from 666 to 1839, and the differential expression genes ranged from 1719 to 11033 which were screened based on the value of RPKM (Reads Per Kilobases per Million reads) against the gene co-expression. The genes we selected were processed the GO functional and KEGG pathway analysis. Considering the results of whole-genone re-sequencing and RNA sequencing, the candidate genes for the varietal characters of *Phyllostachys edulis* 'pachyloen' can be identified and analyzed, and the conclusion maybe the scientific basis for the further research.

Development and characterization of polymorphic EST-SSR of *Pteroceltis tatarinowii*, an endangered plant endemic to China

Yunyan Zhang
Nanjing University

With wide distribution in the genome, the microsatellite markers relied on expressed sequence tags (EST) can be linked to genetic traits and applied broadly in population genetics, molecular marker assisted breeding and molecular marker screening of target traits. However, the lack of the *Pteroceltis tatarinowii* genomic and transcriptional dataset limits the application of molecular markers in genetic studies of its populations. In this paper, we used Illumina high-throughput sequencing technique to sequence the *P. tatarinowii* leaf transcriptome, based on which polymorphic microsatellite loci are developed. A total of 42,477 unigenes with an average length of 815 bp were obtained. After aligning with NR, Swiss-Prot, GO, COG and KEGG databases, 23,688 unigenes were assigned. These data provided the foundation for gene expression and function analysis of *P. tatarinowii*. Among the unigenes, a total of 6,543 EST-SSRs were identified and 130 EST-SSRs were selected for validation as EST-SSR markers by PCR amplification. Of these, 48 EST-SSRs were amplified successfully and 32 EST-SSRs were polymorphic among 47 *P. tatarinowii* individuals. Additionally, cross-amplifications of EST-SSR were detected in *Ulmus gaussenii* and *U. chenmoui*, and the versatility and polymorphism were 25% and 87.5%, respectively. The development of the *P. tatarinowii* microsatellite markers provided the molecular basis for the study of the *P. tatarinowii* and other plants in family Ulmaceae.

Improved NGS library preparation methods for high efficiency and low cost genome *de novo* assembly and resequencing

Sheng Zhao[1], *Xiaojuan Deng*[2], *Ying Lu*[2], *Ke Liu*[1], ***Yuxiao Chang***[1]
1. Agricultural Genomics Institute at Shenzhen, Chinese Academy of Agricultural Sciences
2. CAAS Biological Breeding Technology Co., Ltd (CBBT)

The DNA sequencing cost has decreased rapidly in the past years, however, the cost for library preparation part did not have big change. With the launch of Illumina Hiseq X and Novaseq with even more cheap sequencing price, there is an urgent need to decrease the cost for library preparation step, especially for large sample population projects. Here we described two improved next generation sequence (NGS) library preparation methods for either genome *de novo* assembly or resequencing with high efficiency and low cost. The methods introduced here are especially suitable for large sample population project with small budget. The first method we developed is the N-Size-Fragment (NSF) MP library preparation technique, which could generate one library contained up to 10 large DNA fragments ranged from ~2 to 12 kb simultaneously. We tested the performance of the method in rice genome de novo assembly and prepared a library contained 10 fragments with very sharp size distribution. A total of 80Gb Paired-end 250 bp sequence data generated from this library achieved the de novo assembly scaffold N50 more than 0.8Mb. The total reagent cost for NSF-MP library preparation and Hiseq 2500 PE250 bp sequence was only ¥30,000 (~ $ 4,300) for a rice genome. The second method we improved is a high-throughput shotgun sequence library preparation workflow, in this workflow, we omitted some unessential steps and mix the barcoded library before size selection and quantification with special calculation, by this modification, the total time/hand-on time were decreased ~50% with no compromise of the sequence data quality and data distribution among the mixed individual library. By using this method, it need only ¥500 (~$70) for one rice genome resequencing with 10-fold coverage.

Genome-wide identification of QTL for seed yield and yield-related traits and construction of a high-density consensus map for QTL comparison in *Brassica napus*

Weiguo Zhao

1. Shaanxi Rapeseed Branch of National Centre for Oil Crops Genetic Improvement

2. Huazhong University of Science and Technology

Seed yield (SY) is the most important trait in rapeseed, is determined by multiple seed yield-related traits (SYRTs) and is also easily subject to environmental influence. Many quantitative trait loci (QTLs) for SY and SYRTs have been reported in *Brassica napus*; however, no studies have focused on seven agronomic traits simultaneously affecting SY. Genome-wide QTL analysis for SY and seven SYRTs in eight environments was conducted in a doubled haploid population containing 348 lines. Totally, 18 and 208 QTLs for SY and SYRTs were observed, respectively, and then these QTLs were integrated into 144 consensus QTLs using a meta-analysis. Three major QTLs for SY were observed, including *cqSY-C6-2* and *cqSY-C6-3* that were expressed stably in winter cultivation area for three years and *cqSY-A2-2* only expressed in spring rapeseed area. Trait-by-trait meta-analysis revealed that the 144 consensus QTLs were integrated into 72 pleiotropic unique QTLs. Among them, all the unique QTLs affected SY, except for *uq.A6-1*, including *uq.A2-3*, *uq.C1-2*, *uq.C1-3*, *uq.C6-1*, *uq.C6-5* and *uq.C6-6* could also affect more than two SYRTs. According to the constructed high-density consensus map and QTL comparison from literatures, 36 QTLs from five populations were co-localized with QTLs identified in this study. In addition, 13 orthologous genes were observed, including five each gene for SY and thousand seed weight, and one gene each for biomass yield, branch height and plant height. The genomic information of these QTLs will be valuable in hybrid cultivar breeding and in analyzing QTL expression in different environments.

Regulation of the RNA-directed DNA methylation pathway

Ming Zhou*, Ana Marie S Palanca, Clara Bourbousse, Julie A. Law*

The Salk Institute for Biological Studies

Cytosine DNA methylation is a heritable chromatin mark that plays crucial roles in gene regulation and transposon silencing in eukaryotic organisms. In plants, DNA methylation is established via the RNA-directed DNA methylation (RdDM) pathway, wherein both 24nt small interfering RNAs (siRNAs) and long non-coding RNAs are required to guide methylation at cognate genomic loci. Production of these RNAs is dependent on two plant specific RNA polymerases, Pol IV and Pol V. Pol IV transcripts are converted into double-stranded RNAs by RNA-DEPENDENT RNA POLYMERASE 2 (RDR2), sliced into 24nt siRNAs by DICER-LIKE 3 (DCL3), and then loaded into ARGONAUTE (AGO) effectors. Pol V transcripts serve as templates for the recruitment of siRNA-loaded AGO complexes as well as other downstream RdDM factors, including the *de novo* methyltransferase DOMAINS REARRANGED METHYLTRANSFERASE 2 (DRM2), to facilitate the establishment of DNA methylation and gene silencing. Here we report the roles of several uncharacterized factors in mediating DNA methylation in a locus-specific manner, revealing an additional layer of complexity to the RdDM pathway.

Identification and characterization of stress responsive lncRNAs in plants

Chao Di*, Jiaopei Yuan, Yumin Zhu, Zhi Lu*

MOE Key Laboratory of Bioinformatics, Center for Plant Biology, School of Life Sciences, Tsinghua University

Recently, in addition to poly (A)+ long non-coding RNAs (lncRNAs), many lncRNAs without poly (A) tails, have been characterized in mammals. However, the non-polyA lncRNAs and their conserved motifs, especially those associated with environmental stresses, have not been fully investigated in plant genomes. We performed poly (A)- RNA-seq for seedlings of Arabidopsis thaliana under four stress conditions, and predicted lncRNA transcripts. We classified the lncRNAs into three confidence levels according to their expression patterns, epigenetic signatures, and RNA secondary structures. Then, we further classified the lncRNAs to poly (A)+ and poly (A)- transcripts. Compared with poly (A)+ lncRNAs and coding genes, we found that poly (A)- lncRNAs tend to have shorter transcripts and lower expression levels, and they show significant expression specificity in response to stresses. In addition, their differential expression is significantly enriched in drought condition and depleted in heat condition. We have also tested lncRNA expression levels in rice and have seen similar patterns. Overall, we identified 245 poly (A)+ and 58 poly (A)- lncRNAs that are differentially expressed under various stress stimuli in Arabidopsis. The differential expression was validated by qRT-PCR, and the signaling pathways involved were supported by specific binding of transcription factors (TFs), phytochrome-interacting factor 4 (PIF4) and PIF5. Moreover, we found many conserved sequences and structural motifs of lncRNAs from different functional groups (e.g. a UUC motif responding to salt and an AU-rich stem-loop responding to cold), indicated that the conserved elements might be responsible for the stress-responsive functions of lncRNAs.

2. Senckenberg Biodiversität und Klima Forschungszentrum (BiK-F), Frankfurt am Main

3. Goethe-Universität, Frankfurt am Main

4. Senckenberg Museum für Na

Chromosomal speciation processes gain increasing attention in plant systematics and evolution, and new approaches revealed a high diversity in chromosome numbers even within recognized taxa. Reliable counts linked to known accessions are thus needed yet often hardly available. We present a new online database of chromosome counts and flow cytometric ploidy estimates of the flora of Germany with a detailed documentation of the examined material, and its sampling location. The chromosome database builds upon a relational database and includes standardized taxon identification, study date, georeferenced locality and additional collection as well publication details from which the karyological information was extracted. In order to reach the best compatibility with other botanical publications of the study region, taxonomic concepts and nomenclature follow the "Rothmaler" (Jäger *et al.,* 2011), the widely accepted field flora of vascular plants in Germany. Our continuously updated database currently comprises over 11 000 datasets and 1678 taxa and is available at http://chromosomes.senckenberg.de.

Transcriptome analysis of the hybrid origin of *bauhinia blakeana*

Wm Tang[1], *Sl Kwok*[1], *Rl Davidson*[2,5], *Hs Kwan*[3], *Sc Edmunds*[2,5], *Skw Tsui*[1,4]

1. School of Biomedical Sciences, The Chinese University of Hong Kong

2. Beijing Genomics Institute, Hong Kong

3. School of Life Sciences, The Chinese University of Hong Kong

4. Hong Kong Bioinformatics Centre, The Chinese University of Hong Kong

5. GigaScience

Bauhinia blakeana Dunn, commonly known as Hong Kong Orchid Tree, was adopted as the city flower of Hong Kong in 1965 and became the flora emblem of HKSAR in 1997, appearing in local coins and banknotes. It was first discovered in Pokfulam in the 1880s and is now planted all over the city. It has long been suspected that *Bauhinia blakeana* was the hybrid from two related species, *B. purpurea* and *B. variegata* as it is a sterile plant without seeds and unable to propagate under natural condition. Also, very limited genetic information of this plant was available before the era of molecular biology. Lau *et al.,* (2005) determine the paternity of B. blakeana by using analysis of variation in inter-simple sequence repeat (ISSR) markers to study the genetic polymorphism and morphology based methods, while Mak *et al.,* (2008) conducted the identification study for Bauhinia species by sequencing the internal transcribed spacer 1 (ITS1), chloroplast rbcL and atpB-rcbL intergenic spacer among them. They provided the evidence to support the hypothesis while sequencing data revealed that genetic distance between B. blakeana and B. variegate was closer than B. blakeana and B. purpurea, while B. purpurea is the maternal lineage of B. blakeana. However, the genomes of the Bauhinia family were still not available. Next-generation sequencing (NGS) technology including RNA sequencing (RNA-seq), provided the gateway for scientists to have better understanding of gene expression, biochemical pathways of metabolites synthesis, diversity characterization and evolution study without relevant prior sequencing data. In this study, whole-transcriptome sequencing of leaves from B. blakeana, *B. purpurea* and *B. variegata* plus flowers from *B. blakeana* was performed using next generation sequencing. Approximately 5.4 Gbp high quality (HQ) reads were obtained from each tissue and unigenes of *B. blakeana* (94,755), *B. purpurea* (111,976) and *B. variegata* (81,757) were obtained after de novo assembly. We also pooled the reads of flowers and leaves from *B. blakeana*, resulting in 123,668 unigenes. We investigated the number of very similar transcripts between *B. blakeana* and each of its parents, *B. blakeana* and *B. purpurea* yield 11,082 clusters, while *B. blakeana* and *B. variegata* yielded 8,390 clusters, suggesting that *B. blakeana* is closer to *B. purpurea*, in contrast with Lau's findings. These initial results support that transcriptomics data mining is an effective way to discover similarities and differences of genetic make-up among species with the same genus. We will further investigate how gene expression affects seed germination, sterility, defense against herbivores and pathogens and even medicinal value.

Genetic analysis fails to distinguish the "new" diploid African Baobab

Alice Muchugi, *Hendre Prasad, Samuel Muthemba, Robert Kariba, Simon Kangethe*

World Agroforestry Centre

Until recently, there were eight species documented in the monophyletic genus *Adansonia*; six species endemic to Madagascar, one in Australia and one in Africa. However, a second diploid species *A. kilima* was recently described and its presence confirmed in mainland Africa. Unlike the other previously recorded Adansonia species which are diploid, the African baobab, *A. digitata* is tetraploid. The existence of diploid *A. kilima* was confirmed on basis of floral morphology, pollen and chromosome numbers. According to the species description *A. kilima* and *A. digitata*co exist in the same ecology. However, *A. kilima* was said to be restricted to moderate elevations (650-1500 m), while *A. digitata* is widespread throughout Africa in elevations below 800 m. Interestingly, genetic analysis using SSR and ITS markers of samples from a 200 m to 1300 m transect failed to resolve the two species distinction. The proposal that the tetraploidy evolved rather relatively recently contrasts *A. digitata* wide distribution across mainland Africa.

Comparative analysis of alternative polyadenylation between *japonica* and *indica* of rice during developmental gene expression regulation.

Qian Zhou[1], *Haihui Fu*[1], *Dewei Yang*[2], *Xinfu Ye*[2], *Xiaohui Wu*[1], ***Qingshun Q. Li***[1]
1. College of the Environment & Ecology, Xiamen University, Xiamen 361102, China
2. Rice Research Institute, Fujian Agriculture Academy, Fuzhou, China
3. Department of Automation, Xiamen University, Xiamen 361005, China
4. Graduate College of Biomedical Sciences, Western University of Health Sciences, Pomona, CA 91766, USA

Rice is one of the most important food staple in the world, which also is the model plant of monocots. Two subspecies of rice, *Oryza sativa* L. ssp *indica* and *japonica*, which are widely planted throughout Asia, exhibiting apparent phenotypic variations in development and environmental responses. Alternative polyadenylation (APA) can regulate gene expression by producing multiple transcripts of different length from a single gene, and it has been found play an important role in rice growth and development. However, APA-mediated transcriptional regulations underlying the physiological and biochemical differences between the two subspecies have never been reported. In this study, we employed a poly (A) tag sequencing approach (PAT-seq) to compare the genome-wide landscapes of APA and poly (A) signals (PAS) in 14 different tissues and developmental stages of the cultivate line 93-11 of O. sativa ssp. indica and Nipponbare of O. sativa ssp. japonica. A total of 40,697 Poly (A) Clusters (PACs) in the two subspecies were resided in 25,068 genes, 88.26% of which had the same PACs numbers both in 93-11 and Nipponbare. About 1151 and 5845 unique PACs were found to be specific in 93-11 and Nipponbare, respectively. Five 93-11-specific PACs in eight genes encoding NBS-LRR disease resistance protein were located in CDS region, which may give rise to non-function transcripts, whereas the Nipponbare-specific PACs in 16 NBS-LRR resistance protein encoding genes were located in 3' UTR. It indicates that the different resistance to bacterial infection between the two subspecies may be regulated by APA. We further examined APA switching events, and found that more switching genes of Nipponbare mainly enriched in the plant growth biosynthetic process such as photosynthesis and carbohydrate metabolic process tend to use distal PACs in booting stage, whereas the switching gens during the mature and germinating stages preferred to use distal poly (A) sites in 93-11. Most of differentially expressed (DE) - PACs between the two subspecies were identified in the booting stage including the leaf 60-days, stem 60-days, root 60-days and anther, which suggested that the significant differences of gene expression occurred. Co-expression analysis of DE-PACs suggested that darked, lightcyan and yellow modules related to reproductive development and metabolic process had strong correlations with mature pollen of rice, which showed specific single nucleotide profile around PAS. Our results offer a new insight into the differentiations in transcriptional dynamics and functional significance of APA during growth and development processes of the two rice subspecies and provide potentially useful information for future breeding work.

P1418

Arabidopsis JMJ24 reinforces transcriptional gene silencing by stabilizing RDR2

Shulin Deng, *Nam-Hai Chua*
Temasek Life Science Laboratory, National University of Singapore

RNA-directed DNA methylation (RdDM) is the major pathway that initiates *de novo* DNA methylation in *Arabidopsis* and sets up a self-reinforcing silencing loop between DNA methylation and H3K9me. However, a key issue is the requirement of a basal level transcript from the target loci to initiate the RNA based silencing. How the heterochromatic silenced loci are transcribed remains largely unknown. Here, we show that JMJ24, a JmjC domain-containing protein counteracts H3K9me to promote basal level transcription of endogenous silenced loci in *Arabidopsis*. JMJ24 functionally resembles the fission yeast JmjC protein Epe1. The transcript promoted by JMJ24 is, at least in part, processed to small RNA to initiate the RdDM. Genome-wide transcriptome profiling indicates that transcript levels of TEs are more likely regulated by JMJ24, compared with protein-coding genes. Our data suggest that JMJ24 plays a conserved role in promoting basal level transcription of endogenous silenced loci to reinforce the silencing. We also provide evidence of JMJ24 stabilizes RNA-dependent RNA polymerase 2 (RDR2).

Potential horizontal gene transfers in *Nymphaea colorata* genome

Chaoxian Zhao[1,2]***, *Ruiliang Zhu*[2], *Liangsheng Zhang*[3], *Yang Liu*[1]
1. Shenzhen Fairy Lake Botanical Garden, Shenzhen, China, East China Normal University, Shanghai, China
2. East China Normal University, Shanghai, China
3. Center for Genomics and Biotechnology, Fujian Agriculture and Forestry University, Fuzhou, China

Horizontal gene transfer (HGT), also known as lateral gene transfer, is one of the paths for sharing genetic information among different organisms. It is well known that HGT is an important driving force for the evolution of prokaryotes, such as bacteria, but HGT is rare in eukaryotes. Aquatic plant lives in fresh water, is easily exposes to bacteria, and hence has more chance to obtain HGT genes. Here, based on the newly sequenced genome (unpublished data) of *Nymphaea colorata*, a floating aquatic plant and one of the earliest angiosperms, we simply test the hypothesis that aquatic plants carry micro-organisms originated horizontal transferring genes. We used a local python script that newly developed in the HGT-inferring pipeline (https://github.com/Chao-Z/Horizontal_gene_transfer_project), to calculate HGT AI, HGT Index as well as HGT Identity value of the top BLASTP hit of each *Nymphaea* protein sequence among different microbe and plant lineages. Preliminary analysis showed that 1,194 *N. colorata* genes do not appear in both algae and protist lineages, and are

candidate HGT genes from microbial donors. The other 572 genes appearing in algae and/or protist are also potential HGT genes, which are all belonging to class C genes with three evaluating values equal to or higher than 30. In addition, the difference of determination of three values suggests that combining HGT AI, HGT Index, as well as HGT Identity can get a more comprehensive set of potential transferring genes.

P1430

The mitochondrial genome of *Nymphaea colorata* is highly repetitive with active repeat-mediated homologous recombinations, and largest organellar introns

Shanshan Dong[1,2]***, *Chaoxian Zhao*[3], *Shouzhou Zhang*[1], *Hong Wu*[2], *Liangsheng Zhang*[4], *Yang Liu*[1]

1. Fairylake Botanical Garden, Shenzhen & Chinese Academy of Sciences, Shenzhen, China

2. College of Life Sciences, South China Agricultural University, Guangzhou, China

3. Department of Biology, School of Life Sciences, East China Normal University, Shanghai, China

4. Center for Genomics and Biotechnology, Fujian Agriculture and Forestry University, Fuzhou, China

Flowering plant (angiosperm) mitochondrial genomes are dynamic in genome structure. Mitogenome of the earliest angiosperm *Amborella* is remarkable for its carrying rampant foreign DNAs; in contrast to *Liriodendron*, the other only known early angiosperm mitogenome, described as fossilized. To better understand the characteristics of early angiosperm mitochondrial genomes, we assembled the complete mtDNA for *Nymphaea colorata* using PacBio long reads. The assembly received an average depth of 585×, and yields a circular chromosome of 617,195 bp. The genome encodes 41 protein coding genes, 20 tRNA and 3 rRNA genes. With 48.89% of the total length represented by repeated sequences, *Nymphaea* has one of the most repeat-rich mitogenome among angiosperms. Repeated sequences contributed substantially to its intron size, making *Nymphaea* possess one of the longest mitochondrial introns among angiosperms. It has been reported that repeats can result in mitogenome intragenomic recombination. Benefit from the long PacBio reads, we evaluated homologous recombinations among repeated sequences with at least 85% similarity within *Nymphaea*; altogether 1,187 repeats ranging from 50 to 3,293bp were examined. Recombined reads were detected from 913 repeats with an average recombination frequency of 5.97%. Our result revealed that smaller repeats tend to induce more recombinations, reflecting the importance of small repeats in evolution of angiosperm mitogenome structures. A total of 755 RNA editing sites were identified in *Nymphaeamt*DNA, and 84.24% of which are shared across *Amborella*, *Liriodendron* and *Nymphaea*; Extensive gene order changes were detected in the three mitogenomes, but 12 ancient collinear gene clusters were identified among them. *Although* many foreign DNA insertions were found from *Amborella* mitogenome, none was observed fromNymphaea.

Plant grafting: How genetic exchange promotes vascular reconnection

Jing Wang[1], *Libo Jiang*[1], *Rongling Wu*[1,2]

1. Beijing Forestry University

2. The Pennsylvania State University

Grafting has been widely used to improve horticultural traits. It has also served increasingly as a tool to investigate the long-distance transport of molecules that is an essential part for key biological processes. Many studies have revealed the molecular mechanisms of graft-induced phenotypic variation in anatomy, morphology and production. Here, we review the phenomena and their underlying mechanisms by which macromolecules, including RNA, protein, and even DNA, are transported between scions and rootstocks via vascular tissues. We further propose a conceptual framework that characterizes and quantifies the driving mechanisms of scion-rootstock interactions toward vascular reconnection and regeneration.

Synthetic microProteins as a tool to regulate flowering in *Oryza sativa*

Tenai Eguen, *Stephan Wenkel*

University of Copenhagen CPSC

Changes in the photoperiod of plants serve as an important environmental que for the transition from vegetative to reproductive state. Flowering in short-day plant, *Oryza sativa* is controlled by Hd1, a homolog of *Arabidopsis* flowering regulator CONSTANS. Under non-inductive long day conditions, Hd1 represses the transcription of *Ehd1* and florigens *Hd3a* and *RFT1*, thereby delaying flowering. In order to control flowering in *O. sativa* in long day conditions, synthetic microProteins were expressed in rice as an approach to regulate flowering time. MicroProteins are small proteins containing protein-protein interaction domains that negatively regulate larger, related proteins by engaging them in novel complexes which often alters their biological function. The synthetic microProtein rice plants show a conversion from short day rice plant to long day plant without compromising grain yield. This research will reveal a comprehensive approach involving the use of microProteins as biotechnological tools to control important traits in crop plants.

Genetic epistasis interaction between *BrFLC1* and *BrFLC2* in regulating flowering time variation of *Brassica rapa*

Jian Wu

Institute of Vegetables and Flowers, Chinese Academy of Agricultural Sciences

Brassica rapa is an mesopolyploidy sepcies. FLOWERING LOCUS C (FLC), a repressor of flowering, encodes a MADS-domain transcription factor in *Arabidopsis*. FLC has four orthologs in *B. rapa* as a consequence of the whole genome triplication. The four copies of the FLC gene increase the potential variation in flowering time in *B. rapa*. While all the four copies have been reported to be functional in flowering time control, little is known on their interaction manners in flowering regulation. To analyze the interactions among the multiple BrFLCs, we developed a set of near-isogenic lines (NILs) of *B. rapa* carrying nine allele combinations of BrFLC1 and BrFLC2 by introgressing the functional allele (late allele) or non-functional allele (early allele) of BrFLC1 and BrFLC2 into the genetic background of recurrent parental line L58 (ssp. parachinensis). The flowering phenotype were mostly determined by the genotype of BrFLC2 and almost independ of genotype of BrFLC1. The NILs flowered significantly earlier as long as loss-of-functional allele of BrFLC2 exists, consistantly the NILs harbouring functional allele of BrFLC2 flowered latest. The phenotypic effects of BrFLC1 were visible only when genotype of BrFLC2 fixed. The results indicated that BrFLC2 has an epistasis effect on BrFLC1 in flowering time regulation of *B. rapa.* Transcriptional analysis showed among the four copies of FLC, BrFLC3 expressed on the highest level. BrFLC1 expressed higher than BrFLC2, and the expression of mutiple FLCs did not show dosage compansation when BrFLC1 or BrFLC2 or both of them loss-of-function.

The non-brittle rachis of domesticated barley independently evolved by loss-of-function mutations in *BTR1* and *BTR2*

Goetz Hensel[1], *Mohammad Pourkheirandish*[2], *Nils Stein*[1], *Takao Komatsuda*[2], *Jochen Kumlehn*[1]
1. Leibniz Institute of Plant Genetics and Crop Plant Research (IPK)
2. National Institute of Agrobiological Sciences (NIAS)

Grain crops were essential for humans to transition from hunter-gathering to agrarian societies. Barley (*Hordeum vulgare* L.) was a founder crop in this process, and the most important step during its domestication was the occurrence and selection of plants that retained mature grains on their inflorescence and thus allowed effective harvesting. Classicial genetic studies have established that the non-brittle rachis of domesticated barleys is associated with a genotype of either btr1BTR2 (btr1-type) or BTR1btr2 (btr2-type), suggesting that loss-of-function mutations in either of these two closely linked genomic loci were sufficient to prevent the formation of constriction grooves at the rachis nodes. These disarticulation zones themselves are a major prerequisite for the free dispersal of mature grains in barley's wild ancestor *Hordeum spontaneum.* In this study, the functional verification of candidate genes of the two BTR loci was achieved through transgenic complementation of btr1-type barley using BTR1-candidate ORF1 driven by its native promoter and, likewise, by complementation of a btr2-type accession by BTR2-candidate ORF3 driven by the maize UBIQUITIN1 promoter. Both approaches independently resulted in the brittle rachis character, which co-segregated with the respective transgene in progeny of the primary transgenic plants. The functionally confirmed *BTR1* and *BTR2* genes share no significant similarity with one another at either the nucleic acid or the amino acid sequence level, which supports the hypothesis that they act complementarily. We further conclude that the non-brittle rachis type independently evolved more than once during barley domestication.

The first illumina-based *de novo* transcriptome sequencing and analysis of sumac (*Toxicodendron vernicifluum* (Stokes) F. A. Barkley)

Guoqing Bai[1,2], *Yun Jia*[2], *Sifeng Li*[1]
1. Institute of botany of Shaanxi Province
2. College of Life Sciences, Northwest University

Toxicodendron vernicifluum (Stokes) F. A. Barkley is widely used as an economic plant due to its abundance of raw lacquer, however the limited transcriptomic and genomic data hinder research on the regulatory mechanisms underlying its raw lacquer formation. In this study, RNA sequencing technology was employed to generate the transcriptomic profiling of *T. vernicifluum*. A total number of 148,093,436 clean reads were obtained and used for *de novo* assembly by Trinity program, which produced 87,856 unigenes with an average length of 701.61 bp and an N50 length of 1206 bp. Through similar comparison with known protein databases, 46,522 (52.95%) unigenes were annotated in Nr, Swiss-Prot, Kyoto Encyclopedia of Genes and Genomes (KEGG), Cluster of Orthologous Groups (COG) and Gene Ontology (GO). Accordingly, potential simple sequence repeats (SSRs) and transcription factors (TFs) were identified in *T. vernicifluum*. Furthermore, we identified five candidate genes associated with the lacquer composition in three varieties. This study is the first report on transcriptome information in the *Toxicodendron* species and provides rich gene transcript resources for further studies on understanding the molecular basis of raw lacquer formation, and serving the genetic improvement and resource utilization in *Toxicodendron* plants.

Field-based Phenomics platform: image-based methods for analyzing morphological traits and agronomic performance under different Nitrogen treatments for sweet potato

Yu Zhang
The University of Tokyo

Spatial variability in a crop field creates a need for precision agriculture. Early detection and management of problems associated with crop yield indicators can help increase yield and subsequent profit. Remote sensing can be used to assess spatial variability in crop yield. While highly predictable spatial variability may be amenable to multiple approaches of site-specific N management, strong temporal variability is much more difficult to manage. Remote sensing techniques that use the crop to indicate its N status show considerable promise for improving N management. Infrared and near-infrared (NIR) imaging systems are advantageous in their ability to visualize plant grown in field, but are currently limited by their small analysis volume and often low resolution and precision, as well as their cost, accessibility, and low-throughput. With further advancements, IR/NIR technologies have the greatest scale-up potential for the eventual non-destructive imaging and phenotyping of field-grown plant root systems. Although these current root growth systems and imaging technologies are still unable to accurately visualize and quantify complex, mature plant root systems grown under field conditions, they have contributed greatly to increase the precision and efficiency of 2D and 3D spatial. Management of fertilizer and watering in agriculture is very difficult. A part of N is lost in the atmosphere or leached into groundwater, lakes, and rivers, which causes severe environmental pollution. Despite that major crops can utilize only 30 – 40% of the applied N. In addition, plant response to each N source show stage specific difference and very sensitive. To solve this case of problem, development of remote sensing technology is useful to evaluate agronomic performance. In this study, we set up three different N application fields to make different yield performance with diverse genotypes of sweet potato as one simulation of different agronomic performance.

3D Modeling and Estimating of Leaf and Stem Shape of Nursery *Paprika* Plants by a Novel Multi-camera Photography System

Yu Zhang
The University of Tokyo

In plant growth and phenotyping, accurate measurements of plant structure parameters are very crucial. Over the past three decades, 2D imaging has been applied to a variety of aspects, ranging from structural analysis, stomata movements and photosynthetic diagnosis, herbicide control, disease detection and yield estimation. However, as 2D imaging is not robust against the occlusion of plant organs, such as overlapping leaves and stems and changing shapes during the measurement, most of these applications are either for large-scale analysis or for simple plantvariables' measurements at the early growth stage. Recently, 3D imaging technologies for the robust measurement of plant growth and phenotype parameters have emerged and been applied for solving this problem owing to the advance of sensing technology. Among the most noticeable applications of 3D imaging technology in agriculture are the 3D model construction for plant and the properties estimation for plant growth. In this research, a novel solutionwas proposed to improve surface representation and construct 3D plant models through automated feature extraction and key point matching across images based on the Structure from Motion (SfM) algorithm. Our method could solve some problems or limitations of other methods, such as high cost, self-occlusion, low accuracy, information missing, noises, and so on. This study aimed at estimating and comparing plant parameters with different cameras and lenses for 3D imaging. We have, therefore, developed a high-efficiency multi-camera photography (MCP) systemcombining Multi View Stereovision (MVS) with Structure from Motion (SfM) algorithm. In this study, we measuredsix variables of nursery paprika plants and investigated the accuracy of 3D models reconstructed from photos taken by four lens types at four different positions. The results demonstrated that error between the estimated and measured values was small and the root mean square error (RMSE) for leaf width/length and stem height/diameter was 1.65mm ($R2=0.98$) and 0.57mm ($R2=0.99$), respectively. The accuracies of 3D model reconstruction of leaf and stem by 28 mm lens at the first and third camera positions were the highest and the percentages of the number of leaf and stem whose 3D model shape surface area reconstructed over 95% to real shape were about 47% and 100%, respectively. The results confirmed the feasibility of the proposed new methodology for the reconstruction of fine-scale plant model and accurate estimation of the plant parameters. It also displayed that our system is an ideal systemfor capturing high-resolution 3D images of nursery plants with high-efficiency.

Ethnobotanical studies and floristic diversity assessment through the Geographical Information System (GIS) in Khonjerab National Park of Pakistan.

Qamar Abbas
Karakoram International University, gilgit, Pakistan

The Gilgit-Baltistan of Pakistan is famous in the world on the basis of its floristic biodiversity, massive glaciers out-side the polar region, glorious rivers, streams, forest, range lands, fabulous valleys, and high mountainous ranges. The area is consider as a home of world highest mountain ranges, i-e Junction of Karakoram, western Himalayas, and Hindukush. The Khonjerab National Park is geographically lies in the Karakoram ranges, extreme northeastern part of the Pakistan, at Pak-China border, north end of the Hunza and Nager district covers an area of 6150 km^2. The diversified climatic and topographic conditions, a large number of medicinal, aromatic and commercially important plant species are existing in this region. The frequent and detail field visits conducted in this area during May to September 2014-15 to explore the natural treasures of the area. The total 78 medicinally and economically important plant species were reported, belonging to 59 genera and 45 families. The adequate information about the biodiversity distribution evaluated through the geographical information system (GIS 10.2), and traditional uses of these plant species collected from the buffer zone communities of the national Park through questionnaires and interviews. This study elaborated the effective assessment of floral status and future threats for the biodiversity of the region. The major threats and challenges for biodiversity conservation and the Park management are overgrazing, road and buildings constructions, anthropogenic activities of the traders, and tourists.

Quinoa (*Chenopodium quinoa* Willd.), A potential new crop for Egypt

Magdi T. Abdelhamid
National Research Centre

Quinoa (*Chenopodium quinoa* Willd.) is one of the main food crops of the Andean mountains, where it has been a staple crop for thousands of years. It is characterized by an outstanding protein quality and a high content of a range of vitamins and minerals, and for that reason it has been selected by FAO as one of the crops destined to offer food security in this century. Quinoa is grown in a wide range of environments in the South American region, however Quinoa requires temperate temperatures especially during flowering and for most genotypes short day-length to flower and produce seeds. Therefore Quinoa fits to the Egyptian winter climate. The genetic variability of quinoa is huge, which makes it possible to select, adapt and breed cultivars for growth under Egyptian conditions. Other very important properties of Quinoa for its successful development in Egypt are its good growth in poor soils, drought resistance, high water use efficiency and salt tolerance. The high nutritional quality and multiple uses in food products make Quinoa ideal for utilization by the food industry as well as for local consumption and even consumption at the farmers own house, thus providing a huge market. Furthermore there exist high price markets in Europe because of shortage of the high quality seeds that can be produced in the dry Egyptian climate. Developing Quinoa in Egypt require further dissemination of information among farmers and consumers, proper marketing and efficient post-harvest technologies, as well as continued development of better Quinoa varieties. Quinoa could be an important new crop for Egyptian agriculture, providing highly nutritive and versatile food products for the population, and a new raw material for the industry. In particular, it could be cultivated in many of the marginal environments afflicted by drought or salinity stress, which currently suffer from very low productivity.

Ornamentals and energy crops for environmental and economic sustainability in Nigeria.

A.A.Warra Aliyu Ahmad Warra
Kebbi State University of Science and Technology, Aliero

Nigeria is faced with environmental erosion such as deforestation, water, soil and air pollution dumping of toxic waste and industrial pollution. Further, Nigeria is also witnessing periodic instances of floods, drying up of rivers and lakes drop in agricultural yield, loss of bio-diversity. All these problems have contributed to rapid negative effects to climate, sanitation and health. In this paper ornamental plants and energy crops of Nigeria, their role in environmental remediation and resource recovery are presented. These plants are used as biofences to protect crop fields from grazing animals and to prevent erosion. Ornamentals plants haves gained recognition in the developing of mega/smart cities of Nigeria. They are used for decorative purposes in landscaping; they beautify the home and places such as streets in general public places and institutions. They contribute in the environmental and socio-economic development. Cultivation of energy crops have found wide application for economic sustainability and rehabilitation of environmentally constrained lands. In some ancient and modern communities, respondents claimed that ornamental plants arrest dust, supplies oxygen and help as wind break. These plants produce value added non-edible products and are traditionally used as cosmetics for e.g. manufacturing of soap. Researchers suggest that the detoxification or complete removal of the toxicity is essential before their use in industry or medicinal applications. Products from *Jatropha curcas, Ricinus communis*, *Thevetia peruviana*, *Terminalia mantaly* and *Polyalthia longifolia* and their environmental and economic applications presented in the paper. This would widen the market scope in agri-biobusiness for value chain and value additions.

Biosynthesis, characterization and evaluation of some medicinal activities of *Cinnamomum iners* bark extract mediated biocompatible silver nanoparticles

***Geo Vigila Antony Varuvel*[1], *Sahayaraj Kitherian*[1], *Jansi M*[2]**
1. St. Xavier's College (Autonomous), Palayamkottai, Tirunelveli, Tamil Nadu
2. ST Hindu College, Kottar, Nagercoil, Kanayakumari district, Tamil Nadu

Cinnamomum (Lauraceace) is an economically important tree which includes 250 species distributed in Asia and Australia. Cinnamon is used as flavouring agent in teas, bakery products and an important ingredient in several Indian cuisines. There has been a great interest in recent years on biosynthesis of nanoparticles using plant extracts for their bioactivity due to less toxicity. In our present investigation, we have synthesized the silver nanoparticles (Ag-NPs) using *Cinnamomum iners* bark extract, *in vitro* antioxidant and antimicrobial activities have been evaluated. To biosynthesize Ag-NPs, the reaction mixture contained aqueous bark extract of *C.iners* and an aqueous solution of $AgNO_3$, which was initially colourless, turned into reddish-brown, indicating the biosynthesis of Ag-NPs. Their characteristic surface plasmon absorption was observed at 429 nm. Biosynthesized Ag-NPs was characterized using UV-visible spectroscopy, Fourier transform infrared spectroscopy, X-ray diffraction (XRD), zeta potential, scanning electron microscopy, and high-resolution transmission electron microscopy (HRTEM). The *in vitro* antioxidant assays such as 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2,2'-azino-bis (3-ethylbenzothiazoline-6-sulphonic acid) (ABTS), Ferric Reducing Antioxidant Power (FRAP) and superoxide scavenging activities were performed using standard procedures. The XRD pattern depicts the prominent peaks at 35.77°, 39.17°, 52.71°, and 54.82° which corresponding to (100), (102), (104) and (006) reflections, respectively. Various shapes spherical, rod, hexagonal of Ag-NPs were identified using HRTEM. Among various solvents, ethanol bark extract exhibited higher total phenolics (545.94±11.54 mg GAE/g extract), flavonoids (723.33±6.40 mg RE/g extract) and tannins (44.11±8.40 mg GAE/g extract). Significant ABTS free radical scavenging activity was observed in ethanol bark extract (1092.81±2.94 μM TEAC/g extract) of *C. iners* whereas, 1015.19±3.57,739.80±5.40 and 472.50±23.88 μM TEAC/g extract) of lower activity were displayed in acetone, Ag-NPs and water extracts, respectively. Higher ferric reducing activity was exhibited in ethanol bark extract (5840.05 mM Fe (II) E/g extract) while 5642.60, 2896.67 and 1731.07 mM Fe (II) E/g extract) were displayed in acetone, water and Ag-NPs, correspondingly. Higher superoxide (54.87%) and DPPH (3.25 IC_{50}) radical scavenging activities were observed in biosynthesized Ag-NPs. In disc diffusion method, biosynthesized Ag-NPs (10mg/ml) exhibited higher antibacterial activity against *Escherichia coli* (1.33±0.03cm), *Staphylococcus aureus* (1.06±0.03cm), *Serratia marcescens* (0.83±0.03cm), *Klebsilla pneumoniae* (1.06±0.03cm), *Pseudomonas aeruginosa* (1.53±0.03cm) and antifungal activity against *Candida albicans* (1.46±0.06cm), and *Aspergillus fumigatus* (1.23±0.03cm), respectively. The ethanol bark extract of *C.iners* displayed only least activity against *E. coli* (0.86±0.03cm), *S. aureus* (1.00±0.00cm), *K. pneumoniae* (0.83±0.03cm). Due to significant bioactivity of Ag-NPs, this may be effectively used as a natural plant-based drug and their mechanism of action should be investigated in further studies.

Taxonomic revision of the *Ficus* section Malvanthera (Moraceae) in New Guinea.

Billy Bau Bieso

New Guinea Binatang Research Center

There are over 800 *Ficus* species occurring as hemi-epiphytes, terrestrial trees, shrubs and creepers in tropical rainforests and in sub-tropical region. The genus is classified based on their morphological characters into six subgenera; *Ficus, Synoecia, Sycidium, Sycomorus, Pharmacosycea* and *Urostigma*. Past studies in New Guinea still showed inconsistencies in the section Malvanthera (*Urostigma*) and this study is important to define the species concepts within this taxa. The main objectives are to revise taxonomic concepts within *Ficus* section Malvanthera in New Guinea, and to re-describe all species with synonyms using original type images and circumscribe potential new species, based on morphological and genetic characters. Fieldwork had included making botanical collections and involved studying its ecological features and gathering of proper botanical specimens with at least ten duplicates which had already been distributed to other overseas herbaria. Laboratory compilation of 605 digital images of 202 herbarium specimens from BRC, LAE, BRI, CANB, SING, K, and BM had their key distinguishing characters measured digitally using the *ImageJ* software. Preliminary results included 22 fertile botanical collections from the PNG LNG Vegetation Monitoring project and Mt. Wilhelm altitudinal *Ficus* plots near Bundi Station, in the Madang Province of Papua New Guinea. In addition, 605 digital images had 195 duplicates with 108 of their duplicate images have already been databased into the Malvanthera Access Database. A quarter of these images have already been measured digitally using the *ImageJ* software and tested using the Statistical software package *Canoco v.5*. It is highly likely from the field collection samples that one set of botanical collection from the Bundi area along the Mt. Wilhelm transect showed significant morphological variations to the others that have already been described.

A review of the phytochemistry and ethnopharmacology of *Tridax procumbens*

Samantha Beck, *Olga Kopp*

Utah Valley University

Originating in Central and South America, *Tridax procumbens*, a member of the Asteraceae family has great ethnobotanical potential. It is a perennial plant with a capitulum inflorescence that results in abundant production of achenes, making it a noxious weed if not controlled. The purpose of this paper is to review the traditional uses of *T. procumbens*, along with the documented biological activity in order to highlight the importance of continuing research on this species. An in-depth review of the literature of this species was done using different sources, including ScienceDirect, Web of Science, Nature, PubMed and other databases. *T. procumbens* produces secondary metabolites that have been reported to have a variety of medicinal uses such as: anti-anemic, anti-inflammatory, anesthetic, pain relief, antimicrobial, antioxidant, anticancer, and immunomodulating properties. Different methods of extraction were compiled to show the wide range of various *T. procumbens* extracts in a variety of biochemical research. This paper shows that more exploration is needed for the potential of *T. procumbens*' secondary metabolites as medicine or preventive treatment, making it a promising ethnobotanical resource.

The application research of ferns on slope restoration

Jingru Cai, *Jianxin Xu, Wenzhu Liu, Yanhui Shen, Tanghuang Qian*

Shenzhen Techand Ecology & Environment Co., Ltd.

The Herb plants are always used as pioneer species on slope restoration, and which always combined with seeds of shrubs and trees in hydroseeding for reforestation quickly. But Herbs would decay when upper levels'crown density increase as time goes by. While ferns can grow well in the lower layer as shade-tolerance plants group, which is good choice to fill up the undergrowth vacancy. Researchers of Shenzhen Techand Ecology&Environment Co., Ltd have been working for vegetation diversity and stability of slope many years. In recent years nine kinds of good slope growing ferns were collected from south-China and west-China areas such as *Nephrolepis auriculata, Nephrolepis biserrata, Cyclosorus parasiticus, Blechnum orientale, Pteris fauriei, Pteris cretica* var. *nervosa, Woodwardia unigemmata, Pteris vittata, Macrothelypteris torresiana*. Incomplete culture technique and artificial seed technology were used for propagation of ferns, as well ferns transplanting and vegetation carpet were researched for practicability and application way on slope restoration. Results were as follow: (1) The general breeding system of ferns was established. Aseptic prothalli of ferns were obtained by spore induction, and of which proliferation rate was 4-5; The optimal combination of artificial seed coating for inhibiting bacteria and promoting germination was screened out by orthogonal experiment, and artificial seeds could germinate and grow normally. (2) Ferns transplants had a high survival rate on slope, and dued to slow growth, transplants had little effect on growth of shrubs and herbs at the beginning of spray-seeding. From the density point of view, it is appropriate to plant *Cyclosorus parasiticus, Pteris Fauriei* and *Macrothelypteris torresiana* with 40cm*40cm density, while *Nephrolepis biserrata* reproduces by runner tips and crown diameter of *Blechnum orientale* seedlings is more than 100 cm, which can be configured by point planting. (3) Ferns' roots could pass through coconutfibre and grow well, so that ferns vegetation carpet was workable. Aseptic prothalli of ferns could grow after sowing 18 days on coconutfibre, and roots of which could grow into it with juvenile sporophyte growed after 48 days; while using 2-months seedlings as planting materials, ferns'roots could pass through coconutfibre after 48 days. The suitable thickness of coconutfibre is 0.5 cm considering uniformity and weight. After being spread on slope, ferns' vegetation carpet should keep enough water within 30 days for ferns'roots growing into soil.

Biological characteristics and propogative technique of *Euonymus Grandiflorus*

Yan Chen[1,2], *Yi Sun*[1,2]

1. Beijing Botanical Garden

2. Beijing Floriculture Engineering Technology Research Centre

Euonymus grandiflorus is small arbor of *Euonymus* L. in Celastraceae, which is distributed mainly in northwest and southwest area of China. *Euonymus grandiflorus* with better resistance, bright-colored and longtime autumn leaves is optimum color-leafed plant while seldom applied in urban landscape. Biological characteristics of *Euonymus grandiflorus* had been observed. The result showed that phenological periods including sprouted stage and leaf expansion stage of *Euonymus grandiflorus* in different years had the difference, while blooming stage and leaf color change were similar, early blooming stage was in the middle of June, late blooming stage was in the middle of July, the whole flower period lasted nearly one month; leaf color change started on 10th October, defoliation stage was close to late November, leaf color period from early October to late November reached more than 50 days, during that period the leaf cholorophyll content decreased while anthocyanin content rised sharply, which caused the bright amaranthine leaf. The ornamental value of *Euonymus grandiflorus* was much better than other color-leafed plants. The different methods of propogation, including sowing seeds from different provenances, cutting, grafting and tissue culture at different time were tested. The optimum way of rapid propogation on *Euonymus grandiflorus* in Beijing area was grafting before branch burgeoning in spring, stock should be 2 or 3 years old seedling of *Euonymus bungei* and scion should be one year old healthy branches of *Euonymus grandiflorus*. Cultivation technique and application of *Euonymus grandiflorus* in Beijing area were studied and discussed. The conclusion indicated that *Euonymus grandiflorus* was suitable to grow in the place with full sunlight, well-drained and loosen soil. It was better to apply *Euonymus grandiflorus* in block or group planting methods, matched with tall color-leafed arbors, evergreen trees and some low color-leafed shrubs in order to increase landscape level, enrich landscape color and extend the ornamental period.

Studies of leaf functional traits and foliar vasculature for montane and subalpine woody plants of Yushan National Park in Taiwan, R. O. C.

Shau-Ting Chiu[1], *Wei Cheng*[2]

1. Botanical Garden and Division of Biology, National Museum of Natural Science, Taichung, Taiwan, R.O.C.

2. Department of Biology, National Chung Hsing University

‘‘Functional traits’’ capture fundamental tradeoffs that determine species’ ecological roles. Establishing morpho-physiophenological traits which impact fitness indirectly via their effects on growth, reproduction and survival, the three components of individual performance can become the foundation of ecological forensics. This study initiated leaf functional traits about Ericaceae in Nanhsi area along altitudinal gradients from Nanhsi Forest Dynamics Plot (Nanhsi FDP) to the subalpine Mount. Yushan. Carrying on the standard protocol of leaf functional traits can input, provide and accumulate long-term ecological forensics data and renewal conservation information for National Park’s management and long-term ecological research. Sampling area from 1,800 m to 3,900 m above sea level in Nanhsi area, 1,210 leaf samples were collected from 242 shoots for 178 individuals of 9 species and 5 genera in Ericaceae. Laminar density of the sampling rhododendrons was usually low toward the high altitude. Leaf dry matter content (LDMA) of most rhododendrons was between 0.3 and 0.5. Only those LDMA values of *Gaultheria itoana* Hayata and *Vaccinium randaiense* Hayata increased along their enlarging leaf areas. Leaf thickness inclined along the LDMA but declined in specific leaf area (SLA), except *Lyonia ovalifolia* (Wall.) Drude. The smallest closed areoles in leaf vasculature occurred in *Rhododendron morii* Hayata and the largest ones occurred in *R. rubropilosum* Hayata. Short terminal veins with obvious bundle sheath of *R. morii* displayed probably the C4 photosynthetic pathway. On the contrary, the bundle sheath of *R. rubropilosum* was not dominant. Results are the first time to show the leaf functional traits applied to the same rhododendron species in different habitats, sun- or shade-leaves of the same individuals and the adaptation to special montane ecosystem. Nanhsi FDP with the largest plot area at the middle elevation of Taiwan had diversed of plant functional groups, including *Castanopsis carlesii* - *Machilus japonica* evergreen and *Alnus formosana* deciduous broad-leaved forests. Among leaf traits of four functional groups of leaf habits and growth forms, the LCC of tree growth form was significantly higher than that of shrub. Evergreen trees had the highest LDMC and LD. However, deciduous shrubs had the lowest. Deciduous trees had higher LNC, SLA and lower C:N than evergreen trees. Temperature, humidity, illuminance, and canopy openness were significantly different between deciduous forest and evergreen broad-leaved forest. LNC, C:N and LDMC significantly correlated with canopy openness. Although the elevation was the most identical environmental factors for species distribution and leaf functional traits by canonical correspondence analysis and redundancy analysis, the elevation actually reflected microclimate trend of the temperature gradient. Microclimate effect was indeed the key environmental factors. Due to leaf lifespan, leaf size, vein density and other leaf traits of different species had different invested proportion between the main and the fine veins. Leaf functional traits reflected varied plant survival strategy for adaptation. Deciduous and evergreen broad-leaved forests with different species composition display that the main effect on leaf functional traits was at the species level. The varied plant community implied the habitats of fitness that had close interaction with leaf functional traits. It would fulfill the important mission of long-term monitoring and also shows the efforts and contribution of Botanical Garden and National Park in conservation.

5. Centre for Social Evolution, Section for Ecology and Evolution, Department of Biology, University of Copenhagen

Podaxis pistillaris (Agaricales, Basidiomycota) is the name often given to the conspicuous, torpedo-shaped fungal fruiting bodies that form during the rainy season on termite mounds across southern Africa. The species was described initially in 1,871 in the genus *Lycoperdon* by Linnaeus based on a specimen from India. In 1881, Linnaeus described a second species, *L. carcinomale*, from a specimen sent to him by Carl Thunberg who collected it during his travels in South Africa. In 1812, William Burchell made a painting of the fungus during his exploration of Southern Africa, of which a black-and-white picture was printed in Doidge's 1954 encyclopaedic lists of all South African fungi. By 1,933,33 *Podaxis* species have been described from Africa, Asia, Australia and the USA, but Morse, an American mycologist, lumped all as synonyms of *P. pistillaris*, and although another 12 species, including two from South Africa, were subsequently described, most authors conveniently referred to all these fungi as *P. pistillaris*. Despite its frequent association with termite mounds, virtually nothing is understood of the biology of this fungus. In a quest to better understand its association with termites and to resolve the taxonomy of the fungus, we studied a collection of Southern African specimens from the National and Schweickerdt herbaria in Pretoria, and we had access to several specimens from the USA, Mexico, India, and Africa, including the type specimens of the two species described by Linnaeus. In addition, we collected fresh specimens from several locations. We visited the sites where Thunberg collected his specimen in the Western Cape Province, and where Burchell made his painting in the Northern Cape Province, but we could not find fresh specimens at these sites that could assist in resolving the taxonomy of these species, as these areas experienced a severe drought during the preceding year. At least we could confirm that the original collections were probably from *Trinervitermes* (*Termitidae*, *Nasutitermitinae*) termites. However, we distributed flyers to local farming communities in both the Western and Northern Cape with photographs of the fungus and requests to contact us should these be observed. Good summer rains fell soon after our visit and we received fresh specimens within six weeks after distributing the flyers. One of these specimens came from a farm close by the camping site where Burchell made his painting. DNA was extracted and the ribosomal LSU and ITS regions successfully sequenced from all the fresh and almost all herbarium specimens, including some that was older than 100 years. Phylogenetic analyses showed that the southern African specimens forms at least five well-supported lineages that probably represent distinct species. Four of these lineages seem to be associated with termite mounds, while the fifth seems to be free-living on open ground. Our study not only provided the first ever phylogeny for the genus, but emphasized the value of herbarium specimens for taxonomic and ecological studies. The one fresh specimen collected by a farmer from the Burchell site will serve as type for a new species resembling Burchell's painting.

Cape citizen science: Public engagement for plant disease research in a biodiversity hotspot

*Jm Hulbert, **Zw De Beer**, Mj Wingfield*
Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, Pretoria

The Cape Floristic Region of South Africa is an important biodiversity hotspot. It is important to conserve plant communities in this region for many reasons including their exceptional endemism. Many species in these communities are also threatened with extinction. Cape Citizen Science is an initiative to involve the public in research to assess the threat of plant-killing *Phytophthora* species. The initiative has pioneered many methods of public engagement in plant disease research. These include a targeted sampling campaign and various environmental education activities that could be implemented in other communities threatened with plant disease. Public contributions have broadened the collection of samples included in the research and reports of dying plants have generated new areas of interest. Cape Citizen Science has demonstrated that citizens can be invaluable for plant disease research and that the act of research can serve as a platform for public engagement and environmental education.

Using big data to unleash the drug discovery potential of ethnobotany

John De La Parra
Northeastern University

A large database, covering thousands of years of human-plant interactions and containing culturally and geographically diverse ethnobotanical information on the selection and use of medicinal plants for neglected protozoan diseases has been created and mined for provable drug discovery leads. Candidate species were prioritized and subsequent phytochemical characterization and bioassays were completed. This study's large-scale accounting for indigenous plant knowledge indicates that medicinal plants are regularly chosen because of specific environmental conditions. Additionally, plants subjected to attack by insect herbivores are often observed to have higher levels of more diverse specialized metabolites, many with unique bioactivities. By querying the database, an initial test candidate species was chosen. *Pentalinon luteum*, a traditional Seminole medicinal plant chosen with careful attention to environmental conditions, regularly undergoes heavy seasonal herbivory by the larvae of the Oleander moth, Syntomeida epilais. These larval predators consume and store unique cardiac glycosides that are produced by their plant host. While these compounds are highly toxic to their predators, as the ethnobotanical database in this study shows, plants with high cardiac glycoside content have had a long history of medicinal value to humans.

In addition, a very closely related raditional medicinal species (*Pentalinon andreuxii*) mined from the database, was shown to be effective against the neglected protozoan disease Leishmaniasis. To control for this variability of indigenous selection and herbivory-induced stress responses, in vitro tissue cultures have been created to investigate the effects of the addition of stress-signaling hormones as correlated to indigenous plant selection. By scanning a large dataset of available ethnobotanical information, a robust study of the relatively unexplored aspects of how humans choose medicinal plants is presented.

Allelopathic effect of the weed *Pennisetum polystachion* (L.) Schult. against the commonly cultivated pulses

Archana E R, *John E. Thoppil*
University of Calicut

Allelopathy is the direct or indirect effect of a plant on other plants of its vicinity through the production of phytochemicals that are released into the environment. *Pennisetum polystachion* (L.) Schult., commonly known as mission grass is a vigorous annual or perennial weed in tropical region, that are capable of spreading along roadsides into both agricultural and natural habitats by producing large numbers of seeds. The present study was designed to reveal the phytoconstituents in the plant extract and to investigate its allelopathic effect. 500 g/500 mL stock was prepared. Various concentrations of 5%, 25%, 50%, 75% and 100% were taken and distilled water was kept as the control. The seeds of three commonly cultivated pulses were used for the study *viz*. *Phaseolus, Cicer* and *Vigna*. The effect of the plant extract on the germination of the pulses were studied by noting various parameters like number of seeds germinated, length of the root, fresh weight and dry weight of the seedlings. The germination and growth rate of the cereal seeds were found to be directly proportional to the concentration of the weed extract. The germination was found to be 83%, 57% and 90% in *Phaseolus, Cicer* and *Vigna* respectively, in the lowest concentration while it was found to be 53%, 23% and 23% in the pure extract. In contrary, 96%, 60% and 93% of germination was seen in the distilled water control. Root length was measured on the day 2 which was found to be in the ranges of 7.3 cm-2.9 cm in *Phaseolus*, 3.54 cm-1.56 cm in *Cicer* and 11.7 cm-7.78 cm in *Vigna*, according to the increasing concentration. Average root length in the control seeds were obtained as 7.78 cm, 4.43 cm and 11.84 cm, respectively. Similar gradation was obtained in the fresh weight and dry weight of the seedlings. The fresh weights showed a range of 2.48 g-1.47 g, 6.75 g-5.8 g and 3.87 g-3.47 g; dry weight showed the range of 0.413 g-0.328 g, 2.99 g-2.64 g and 0.72 g-0.64 g in *Phaseolus, Cicer* and *Vigna*, respectively. The control showed fresh weights of 2.64 g, 6.95 g and 4.43 g while dry weights of the same were found to be 0.453 g, 3.09 g and 0.74 g. The allelopathic effect of the aqueous extract of the weed *Pennisetum polystachion* is clearly evident from the above results. The plant also shows considerable presence of the secondary metabolites like phenols, flavanoids, terpenoids, alkaloids and other phytochemicals. This might be the reason for the allelopathic effect of the plant. Thus, it is important to eliminate or control the vigorous spreading of the weed in to the agricultural lands.

Journal Impact Factor and evaluation of botanical researchers in Latin America

Alina Freire-Fierro
IKIAM Universidad Regional Amazónica/Asociación Latinoamericana de Botánica-ALB

Although originally created to evaluate journals, the Journal Impact Factor (JIF) has nowadays become one of the main factors to evaluate productivity and impact of scientific researchers worldwide. These bibliometrics, though understandable applied to journals published in English, are completely unfair to non-English journals. This situation is worse in Latin America, where the tradition of research/publishing high quality papers, even in Spanish, is relatively new. Additionally, and while for other sciences the impact of journals can be measured in a time span of 2, 3, 20 years, in botanical research many articles/works published more than 200 years ago are still being cited. Adding to these problems, the evaluation of impact factor of journals is made primarily in English language publications, as it has been reported for example, that out of 100 Panamian publications, none had been included in the evaluation of the recently modified science index, the Science Expanded Index (SCI-Expanded). While even in English-speaking countries, many institutions have agreed not to use the Journal Impact Factor as a measurement for a researcher's productivity or impact (e.g., signage of the DORA agreement in the US) or have used other methodologies for this evaluation (e.g., the Research Excellency Framework REF2014 in the UK); in Latin America, many governments/institutions are still using it. As examples, JIF is being used for evaluating researchers by Mexican National System of Researchers (SNI), Colombian Colciencias, and Ecuadorian National Registry of Researchers (RNI). And in Perú for example, JIF and H indices count up to 35% of the total score for a researcher's categorization in the National Directorate of Researchers and Innovators (DINA). This unfair evaluation from Latin American governments and institutions towards researchers' productivity, really hurt scientific development in the region. Since very good and experienced Latin American researchers want to keep their high academic status, they will continue to publish in English, giving therefore a positive feedback for journals published in English in detriment of journals published in Spanish. As recent as of December 2015, Clarivec Analytics, the current owner of former Thompson Reuters' Institute for Scientific Information (ISI), creator of the IJF, has developed a new index that does not consider the Journal Impact Factor, the Emerging Sources Citation Index, in order to solve this situation. Still though, one of the requirements for journals to be evaluated by this new Index is that the articles in these journals have to have English cited references. Taking into consideration the stated above, I consider and encourage to the botanical community and to scientific organizations to sign the DORA agreement, and to follow the methodologies used by REF2014, but modified to reflect Latin America's scientific research reality. Additionally, and as a scientific community, we consider that it is our duty to request the Latin American governments to stop using the JIF as one of the most important elements in their evaluations of researchers in the region.

Practical botanical activities: The use of images for teacher aid

Bruno Takami Fujiwara*, Hector Barros Gomes, Carolina Patricia Costa Soares Dos Santos, Eliana Akie Simabukuro*
Universidade Federal de São Carlos

The use of practical activities as teaching resource is an experience of scientific investigation and discoveries, relevant to approximate the students of it study object and to mean abstract concepts. The teaching of botany presents these abstract conceptualizations, mainly in the area of vegetal physiology due to the absence of the plants in the students' daily life. In order to facilitate the process of development of practical activities and to bring students closer to botany, this work developed practical activities botany protocols with the additional of having comments and images of the experiments to assist the teacher in the development of the class, facilitating the preparation and execution of the activity. The experiments developed morphological, anatomical and physiological analysis of the plants at different stages of development, with different species, to demonstrate the existing biodiversity. All the practices were previously elaborated to obtain the images and to allow suggesting more than one option for the development of the activity, in order to ensure greater success in the development of the teacher's class. The experiments resulted in eight protocols with the following themes: "Fruit evaluation", "Seed germination", "Photomorphogenesis", "Asexual reproduction", "Geotropism", "Effect of luminosity", "Effect of substrate" and " Effect of density ", which respectively try to analyze the variety of fruits as to the shape, color, layers, edible parts, quantity and arrangement of the seeds; Germination of different types of seeds, with varied germination rates; Germination and development of seedlings under conditions of incidence and absence of light; Reproduction of several species by cutting; Development of plants on the influence of gravity; Effect caused in the development of seedlings submitted to different light incidences; Effect caused on the development of seedlings in different types of substrates; And effect caused on the development of seedlings grouped under different density conditions of individuals. The protocols cover botanical contents (morphology, anatomy and physiology) and ecology that pass through all the years of elementary school 2 and high school, and can be worked more than once in different years, with different approaches and deepening, without the need following a pre-established sequence. In this way, these activities allow teachers and students to work on some broader themes using plants as examples, rather than keeping the picture just in animal diversity. Thus, the teacher has several options for differentiated activities to insert in his planning, while continuing to work on content suggested by the National Curricular Parameters of Science and Biology, established by the Ministry of Education (Brazil) and the State of São Paulo Education Department.

Tracking the long-term dynamics of mountain biodiversity with a network of citizens and rangers. Winners, losers, and steady organisms

Maria Garcia*, Iker Pardo, Pablo Tejero, Jose Luis Silva, Daniel Gomez*
Spanish National Research Council (CSIC)

Mountains shelter the highest biodiversity in temperate ecosystems. While many species are common or shared by different mountain ranges, others are endemic, rare, at the limit of distribution, or trapped on top of high summits. But we do not have many evidences on the real and precise effect of climate change and land use change at the species level. Such knowledge constitutes a challenge that can only be undertaken with a large network of people. Four years ago, with the support of a European LIFE project, we launched a program called "adopt a plant" to monitor the density and abundance of populations of many kinds of different plant species in the NE of Spain, an area covering from the semi-desert till alpine summits. The key of the program is the personal training of volunteers and rangers in the field, after agreeing on a simple but scientifically robust design. The network is now made of 150 people from 21-76 years old, and is fast expanding. Since they get the commit of visiting the adopted plant for the next 10 years, they are providing us with the most accurate information on the demographic performance of more than 250 populations of 150 plant species, representing all kinds of life histories (short- to very long-lived herbs and shrubs), habitats (forests, wetlands, grasslands, rocky areas..) and altitudes. This information is key to determine population trends, and forecast extinction risks in the short and mid-term, as well as to test the effect of temporal fluctuations and natural perturbations. Small devices recording the precise temperature at the populations will help us to understand sensibility to climatic fluctuations, as well as information on how the particular habitat has changed over the last 60 years at each monitored population. As far as we know, this is a unique project disentangling the effect of climate and land use change on different kind of species, and demonstrating the value of coordinating researchers, administrative staff, and citizen science.

P1343
The novel nortriterpenoid glycosides from *Salicornia bigelovii* and their effects on STAT3 signaling pathway

Fuqin Guan*, Qizhi Wang, Yu Shan, Yu Chen, Min Yin, Fei Liu, Ming Wang, Youyi Zhao, Xu Feng*
Institute of Botany, Jiangsu Province and Chinese Academy of Sciences

Salicornia L. (Chenopodiaceae) is a genus of annual apparently leafless halophytic herbs that have articulated, succulent stems. *Salicornia bigelovii* was evaluated as an oil seed crop and seasoned vegetable with direct seawater irrigation. Although the economic value of this plant has already been discovered and developed, its medicinal value has been ignored for a long time in China. Investigation of characteristic constituents of *Salicornia bigelovii* led to isolation of thirty-five compounds, including seven 30-nortriterpenoid glycosides and nine oleanane-type triterpenoid glycosides, with four of them new. Then twenty-one triterpenoid glycosides, isolated from *Salicornia bigelovii* and *Salicornia europaea*, were evaluated for their cytotoxicity and their effect on STAT phosphorylation. Eight compounds showed cytotoxicity against breast carcinoma (MCF-7, MDA-MB-231, MDA-MB-468), liver carcinoma (HepG2) and lung carcinoma (A549), with IC_{50} values of 10-70 μM. A new 30-nortriterpenoid glycosides, named Bigelovii A, inhibited interleukin-6 inducible STAT3 and STAT5 activation in dose-dependent and time-dependent fashions. Treatment with the protein tyrosine phosphatase (PTP) inhibitor pervanadate reversed the Bigelovii A-induced down-regulation of STAT3, suggesting the critical role of both SHP-1 and SHP-2 in its possible mechanism of action. Bigelovii A also downregulated the expression of STAT3-regulated gene products that mediate apoptosis, cell proliferation, and invasion. These results suggested that the novel nortriterpenoid glycoside from *Salicornia bigelovii* may impart health benefits when consumed, and should be regarded as potential chemopreventative agents for cancer.

Micropropagation as an alternative to the growth of *Dionaea muscipula*.

José Antonio Guzmán-Nava
Ecovoraz S. de R.L de C.V

In this study we develop a protocol was developed on for the micropropagation of *Dionaea muscipula*. Dionea is a monotypic genus of carnivorous plant in the family Droseraceae, *Dionaea muscipula*. The only species of *Dionaea muscipula*, of whose common name is Dionea flytrap or Venus flytrap, that catches live prey. Due to its popularity, the demand for these plants is increasing, however, growing large quantities of these plants is difficult. They are reputed to be difficult to grow. Thus, the cultivation of plant tissues by means of the micropropagation technique could be seen to be the way in which a larger number of individuals could be obtained in a shorter time and without having seeds. Ecovoraz has given itself to the task of growing these plants by means of of being able to make a medium of culture, for the invitro growth of *Dionaea muscipula*, obtaining very favorable results. Plants from the market of Madre Selva Xochimilco city of Mexico at Mexico City were used. They are given a method of disinfection disinfected under greenhouse conditions with quaternary ANIBAC salts. Subsequently, the Murashige and Sook medium was were used as the base for the concentration of micronutrients and macronutrients. Stock solutions were then used and were used at a concentration of 25%, 50%, 75% and 100%. The culture medium was supplemented with Indol 3 butyric acid 1.24 and 6-bencial aminopuria 1.5 mg. Our results indicate that forAs a result in which the for a salts concentration of 25%, we obtained on average concentration of salts at 25% averaged 18 shoots, the concentration of for 50% was obtained on average 32 shoots, while at nutrient concentration of 75% an average of 46 outbreaks were developed, and in at the 100% concentration an average of 26 shoots were obtained. This implies that, in order to obtain the greater. For which protocol to establish a greater number of outbreaks, we require is the concentration of 75% concentration of MS salts, adding plus 1.5 mg of 6-benzylaminopurine and 1.24 mg of indole-3-butyric acid.

P1345

Leaf microscopic features of some local vegetables found in Nong Khai province, Thailand

Piriya Hassa*, Paweena Traiperm*
Department of Plant Science, Faculty of Science, Mahidol University

Local vegetables are plant grown for the consumption in local areas such as field, orchard or nearby house, which locals can easily harvest and reduce costs of production. Local people, especially the Northeastern Thai people, routinely consume various local vegetables for nutrition and health maintenance. In Nong Khai, a northeastern province of Thailand, people have received a number of food cultures from different races, including Thai, Laos and Vietnamese. Thus, Nong Khai province is suitable to study the local vegetables consumption. In forensic science, plant remains normally appear as evidence in a crime scene. For example, incompletely digested food in a stomach of dead bodies can be promising evidence to approximate time after the food had been eaten before death and to predict the locations where the food was prepared. For some cases, leaf fragments can facilitate the process of case conclusions by comparing the information with a testimony by a witness in that the specific origin of victims can be identified. However, the information about leaf anatomy of Thai local vegetables have been scarcely published because of the locally specific consumption of plants. Therefore, leaf epidermal peeling and leaf transverse sectioning methods were applied to examine leaf microscopic features of 17 species of local vegetable found in Nong Khai in order to find specific characters of each species for identification criteria. Stomatal pattern from leaf epidermal peeling on the adaxial surface consisted of anomocytic, tetracyclic, paracytic, and anisocytic types. While the abaxial surface exhibited anomocytic, actinocytic, diacytic, and cyclocytic patterns. Anticlinal cell walls vary from straight, straight to curve, and wavy. Three types of indumentum: unicellular trichomes, multicellular trichomes, and multicellular gland were found. The leaf transverse sectioning shows cuticle thickness, mesophyll layer, indumentum and vascular bundle characters. The important characters of each species were extracted and used to construct the key to species of 17 plants.

Potato wild relatives (*Solanum* sect. *Petota*, Solanaceae) from Brazil: Filling the gaps of knowledge in herbaria and gene banks

Gustavo Heiden[1]*, Luís Henrique Dal Molin*[2]*, Laísa Barcelos*[2]*, Guilherme Klasen*[2]*, Daiane Vahl*[2]*, Caroline Castro*[1]
1. Embrapa Clima Temperado
2. Universidade Federal de Pelotas

The potato (*Solanum tuberosum*, Solanaceae) is one of the most important crops and one of the most complete foods, providing high quality protein, vitamins and minerals, as well as being a source of energy supplied by carbohydrates. Plant breeding has contributed positively to the Brazilian potato production, with the launching of varieties adapted to the different producing regions of the country. However, the process of selection of more productive genotypes present as a setback the narrowing of the genetic basis of the cultivated species. In this context, it is essential that we dedicate sufficient efforts to the collection and conservation of germplasm of wild potato relatives with potential for use in crop breeding. To fill the gaps of knowledge and collections in herbaria and gene banks of genetic resources of wild potato relatives (*Solanum* sect. *Petota*, Solanaceae) for crop breeding, we are proceeding the taxonomic revision of wild species of potato from Brazil; mapping the geographical distribution of herbaria samples and gene banks; identifying the collection gaps in ex situ collections of germplasm; realizing fieldworks to fill the sampling gaps of germplasm and evaluating the morphological and agronomical characteristics of the accessions maintained in the Embrapa Clima Temperado gene bank of potato and its wild reatives. The main results are the taxonomical revision of herbaria collections and gene bank accessions, the morphological characterization of Embrapa wild potatoes genebank accessions using potato descriptors; the mapping of geographical distribution of wild potatoes herbaria and genebank samples and the identification of priority areas to collect germplasm, providing new material for breeding programs of the cultivated potato. A total of 655 occurrence data were collected for the native potato species in Brazil. The taxonomic revision of wild potato samples demonstrated that there are more than two taxa native to the country, a number higher than currently recognized. Through the morphological characterization of genebank accessions, we verified a great phenotypic variation in vegetative and reproductive traits, including tuber characteristics of agronomic value. Despite the occurrence of phenotypic diversity, it is necessary to increase variability through new collections, besides the application of other characterization methods to improve the use of conserved genetic resources. The mapping analysis revealed that there are areas located in four Brazilian states (RS, SC, PR, and MG) that are not yet sampled through the collection and introduction of new accessions in the gene bank, especially in the states of Santa Catarina and Paraná. Our results highlighted new priority areas for the collection of wild potato germplasm in order to increase the genetic variability in the gene bank of Embrapa Clima Temperado with the introduction of new accessios from Brazilian areas previously not sampled. The Embrapa genebank of potato and its wild relatives currently has 76 accessions of wild relatives from collections in the Southern and Southeastern regions of Brazil. This germplasm can be used as a source of resistance genes to biotic and abiotic stresses which are not found in the potato gene pool (CNPq).

Conservation and public education about *Fissidens macaoensis*

Pou Ieng Hong[1], *Li Zhang*[2], *Kun Fong Leong*[1], *So Mui Cecilia Cheung*[1]

1. Civic and Municipal Affairs Bureau (Instituto para os Assuntos Cívicos e Municipais), Macao SAR, China

2. Fairy Lake Botanical Garden, Shenzhen & Chinese Academy of Science, Shenzhen, China

Macao is located at the south-western tip of the Pearl River Delta of China and has a total area of 30.5 square kilometers. Macao is a prosperous city which supports over 640,000 residents and attracts more than 30 millions of tourists every year. It is one of the cities that have highest population density around the world. Before 2006, we knew almost nothing about the biodiversity of bryophytes in Macao. In order to present the whole picture of Macao's plant diversity and also arouse the general public's concern on these small but valuable natural resources, the Civic and Municipal Affairs Bureau (Instituto para os Assuntos Cívicos e Municipais, IACM) of Macao SAR has collaborated with Fairy Lake Botanical Garden on bryophytes since October 2006. This collaboration has brought various fruitful results, including scientific research and science educations about bryophytes. In 2011, *Fissidens macaoensis* bas been published as a new species for science. As the first species of bryophyte and the second species of plant named with "Macao", *F. macaoensis* is significant to Macao. Since *F. macaoensis* is very miniature and its populations are restricted in small and narrow area, we are now employing multiple measures for saving this species, including public education, setting up strict protection measure and propagation in lab via spore culture.

P1348
Diversity and utilization of indigenous vegetables and edible plants in Bang Krachao, Samut Prakarn Province, Thailand

Tassanai Jaruwattanaphan, *Pongson Wongsong*

Department of Horticulture, Faculty of Agriculture, Kasetsart University

Fifteen villages in the Ehlanzeni District within three local municipalities were visited for the study. Thirty eight participants were identified on the basis of referrals, which included a traditional health practitioner (THP), herbalist, elderly people, middle age and youths. Ethnobotanical data was collected by means of interviews using semi-structured questionnaires. Data analyzed revealed that infants within the communities were treated with traditional medicine for ailments such as colic, nail biting, sunken and bulging fontanelles. *Hypoxis hemerocallidea* Fisch., C.A.Mey. & Ave-Lall, *Lippia javanica* (Burm.f.) Spreng. *Vachellia karroo* (Hayne) Banfi & Gallaso and *Annona senegalensis* Pers. subsp. *senegalensis* were amongst plants species which were frequently reported to be used medicinally. Decoction were mostly prepared from roots (79%) followed by bulbs (8%). In terms of administration of the medicines most of the plants were taken orally. The use of medicinal plant species in maternal healthcare has been perceived to be effective and reliable in preventing illness amongst communities within this district municipality. Validation for scientific efficacy will be needed as the search of new drug development continues.

P1349
Bioactivity and chemical profiling of rhizome methanolic extract of *Amomum masticatorium* Thwaites (Zingiberaceae)

Sinitha K, *Dr John E. Thoppil Thoppil*

University of Calicut

Rhizome of Zingiberaceae plants have been used in traditional medicine since ancient times. They also form ingredients of many Ayurvedic and Unani preparations. *Amomum,* an important genus of Zingiberaceae is used in traditional medicine. *Amomum masticatorium* rhizome is used to chew with betel in Srilanka. The anti-inflammatory and antiproliferative activities of the methanol extract of *Amomum masticatorium* rhizome were observed in various experimental models. *In vivo* anti-inflammatory activity was evaluated in carrageenan and formalin induced paw edema test in mice and compared with that of standard drug diclofenac. In both the models the extract showed significant reduction in edema. The extract at 200mg/kg b. wt showed significant reduction in carrageenan induced paw edema at 3rd hour and chronic edema on 6th day. The *in vitro* anti-inflammatory activity of the extract was investigated by various methods *viz*. albumin denaturation, membrane stabilization assay and proteinase inhibitory activity. Results showed that, the extract exhibited significant anti-inflammatory activity by inhibiting the heat induced albumin denaturation with IC50 value 34.15 ± 0.404 µg/ml, effectively stabilized RBC membrane with IC50 value of 51.47 ± 1.56 µg/mL and significantly inhibited proteinase activity with IC50 value of 52.8± 0.61 µg/mL. The anti proliferative activity was evaluated by MTT assay. The extract showed significant activity with IC 50 value 85.01 µg/mL. The extract was also subjected for GC-MS analysis to reveal their phytoconstituents like 4-Isobutylphenol (28.58%), 2,3-Dihydro-1-benzofuran (11.68%), Octadecyl palmitate (6.81%), γ-Sitosterol (5.73%) *etc.* From the results, it is concluded that, methanol extract of *Amomum masticatorium* rhizome exhibited significant anti-inflammatory and anti-proliferative activity, which may be due to the presence of active phytochemicals in it and can be used as a source for potential drug.

P1350

Utilization of ethnobotanical knowledge of *Aphanamixis polystachya* (Wall) Parker in production of beneficial phytochemicals

Rakhesh K V, *Ashalatha S Nair*
Department of Botany, University of Kerala

Aphanamixis polystachya (Wall) Parker belongs to the family Meliaceae is a medicinally important tree. Traditional healers used various plant parts for treatment for liver and spleen disorders, tumours, rheumatism, ulcer, dyspepsia, intestinal worms, skin diseases, leprosy, diabetes, eye diseases, jaundice, haemorrhoids, burning sensation, arthritis and leucorrhoea. Proper utilization of the ethnic knowledge of this plant will provide the key for finding cure for various diseases in our community. Very few biological works of medicinal interest have so far been carried out on this plant. The petroleum ether extract of the leaves yielded a neutral compound designated aphanamixol. The bark extract yielded a high quantity of aphanamixinin. From the ethanolic extract of powdered stem bark, a new saponin, poriferasterol-3-rhamnoside has been isolated and characterized. The Isolation and characterization of roots ethanolic extract yields limonoid and flavonoids along with aphanamixinin. A lignin polystachyol, two lignan glycosides, lyoniside and nudiposide, and a sterol have been isolated from a MeOH extract of the dried bark of *Aphanamixis polystachya.* Its principle secondary metabolite components, two terpenoids amooranin, aphanamixin and an alkaloid rohithukine isolated from bark were well studied for treatment of cancer, ulcers, *etc.* in modern medicine. Development of these promising drugs demands alternative method for production of these secondary metabolites. TLC analysis on bark and leaves revealed the presence of these secondary metabolite fractions. Alternative *in vitro* methods were also developed to produce these compounds. The invitro methods will help in conservation of wild germplasm and boost modern medicine production for various ailments.

Investigation on sacred plants, in North Maharashtra: Diversity, ethno economics and conservation

Swapnil Khare, *Shubhangi Pawar*
Pratap College Amalner

North Maharashtra is comprised of three districts Viz. Jalgaon, Dhule and Nandurbar. It is situated at the northern border of Maharashtra and lies between 22^{o} 38’ to 22^{o} 3’ Northern latitude and 73^{o} 47’ to 76^{o} 28’ East latitude and located in the upper Tapi basin and Deccan traps covering all most the whole area. The range of western ghat (Sahydri Mountains) extends in the western part of Khandesh where as Satpura mountain extends in the north eastern direction. The forest in general dry deciduous type. Tribal community such as Bhil, Pawara, Tadavi, Kokani, Mavachi, Gavit inhibit the hilly forest. The ancient Indians worshiped nature. They considered the plant, animals, lakes, reveres are sacred. The sacred groves are the pockets of climax vegetation preserved on religious ground. Such several patches are present in remote tribal areas of North Maharashtra which are still unexplored. The presence of sacred groves is due to certain taboos, strong beliefs with mystic folk lore. Due to civilization in remote area, culture of tribal’s is changing to urban pattern. Much beliefs folk lore are being ignored and forgotten in near future. The urban folk have started exploiting these sacred plants, groves and tribal culture. The region of North Maharashtra constitutes a vast diversity in sacred plants and groves which are playing the role of reservoirs of biological diversity. It is richer in number of plant species. It is often contains many endangered plant species. A large population living in and around the forest areas is extremely poor. They almost entirely dependent on the forest product and renewable resources from these forest. The raw material such as leaves, branches, flowers and fruits are utilized for various byproducts. Some fruits of wild trees are sold in market for various purpose. Though the raw material is comparatively less. Some of them play important role in economy of local people. The sacred plants and flora of sacred groove not only used for religious purpose but Bhagat, Vaidus, some Doctors used those plants for health care. The practice of the nature conservation is very ancient tradition in India. The protection provided to many plants such as People, Umber, Wad trees is well known. A patch of forest receiving the protection because of their association some deity. With the weakening of religious beliefs plants wealth is now in danger of losing this traditional protection and under pressure due to deforestation.

The potential of useful plants as flagship species to counteract plant blindness

Peter Pany[1,2], *Christine Heidinger*[2], ***Michael Kiehn***[1]
1. Core Facility Botanical Garden, University of Vienna, Vienna
2. Austrian Educational Competence Centre for Biology (AECCbio), Vienna

One option to counteract plant blindness (the phenomenon that people overlook plants in everyday life) is to use plants for teaching and learning which are interesting for students. A questionnaire was developed to explore students' interest in useful plants, subdivided in five subgroups: medicinal plants, stimulant herbal drugs, spice plants, edible plants and ornamental plants. The analysis of data for 1,299 students aged between 10 and 19 years showed (for all ages and both genders) that medicinal plants and stimulant herbal drugs trigger high interest, whereas spice plants, edible plants and ornamental plants raise less interest. As mean values cannot be used to draw conclusions on an individual level, a frequency analysis of individual interests was performed. Based on the identified interest profiles, recommendations are made which plants to use from different subgroups of useful plants in order to best concur with students' interest.

International Association for Plant Biotechnology: Meeting global challenges

Eoin Lettice[1,2], *Barbara Doyle Prestwich*[1,2]
1. International Association for Plant Biotechnology
2. University College Cork, Ireland

The International Association for Plant Biotechnology (IAPB) was founded in 1963 and has as its objectives to promote plant biotechnology, in all its forms, including cell and tissue culture applications. From the early work of Gottlieb Haberlandt (1854-1945), Gautheret and Nobecourt, through to the work of Norman Borlaug and others, plant biotechnology has become an essential tool for plant scientists to expand the agronomic and commercial usefulness of plants. The IAPB hosts a quadrennial conference, the 14th of which will take place in Dublin, Ireland from 19th-24th August, 2018. This will be the first time since 1994 that the conference has taken place in Europe. Topics and themes that will be covered in the IAPB 2018 programme include food security; new plant breeding techniques; *in vitro* culture and morphogenesis; plant nutriomics; biopharmaceuticals and bioproducts; roots and tubers; crops and the bioeconomy; science communication and outreach. Given that many of the global challenges of our time are connected to or can be alleviated by plants (e.g., food security, climate change, energy production, *etc.*), it has never been more important to advance the science of plant biotechnology and our understanding of the botanical world. Agriculture currently occupies approximately 38% of the Earth's terrestrial surface and yields of commonly grown crops have been steadily increasing in recent decades. Despite this, various studies have predicted that global agriculture will need to increase production significantly to keep pace with growing demand and population increases. This will place added pressure on existing agroecosystems and our natural environments. Plant biotechnology is one element of an integrated responses to these global agricultural challenges and the IAPB are committed to supporting the advancement of plant biotechnology and plant science in general. This is achieved by our regular activities, our quadrennial conferences and our peer-reviewed journal *In Vitro Cellular & Developmental Biology-Plant*.

Research progress of wind resistance and evaluation system for landscape trees

Ke-Ke Li, *Ling-Lu Li*
Tongji University

Trees may suffer different damages in areas that storm happens often, the one that happens in forest may cause a series of economic losses, the one that happens in city then brings risks to the life of humans, causing traffic jams, and also economic losses, which has a bad impact on the whole city's normal operation and the eco-system. There is a good chance that climate change may make the extreme weathers happen more often, under this situation we should find the proper factors to deep analyze and evaluate trees' stability in wind. As we know, trees' stability in wind has always been studied in Forestry, Tree cultivation, disaster management and some other fields, multi-disciplinary knowledge is needed for this, like the morphology, mechanics, the physics and the aerodynamics. The thesis focuses on the characteristics of the single tree, and sum up the methods, strategies, conclusions and evaluation system about tree stability, in order to fully understand the internal and external factors that matter most. Thus some conclusions can be used in the future tree selection and management in cities which suffer frequent storms.

(±)-Ganoapplanin, a pair of polycyclic meroterpenoid enantiomers from *Ganoderma applanatum*

Lei Li[1], *Huan Li*[2], *Xing-Rong Peng*[1], *Bo Hou*[1], *Mu-Yuan Yu*[1], *Jin-Run Dong*[1], *Xiao-Nian Li*[1], *Lin Zhou*[1], *Jian Yang*[2], *Ming-Hua Qiu*[1]
1. Kunming Institute of Botany, Chinese Academy of Sciences
2. Kunming Institute of Zoology, Chinese Academy of Sciences

(±)-Ganoapplanin (1), a pair of novel meroterpenoid enantiomers featuring an unprecedented dioxaspirocyclic skeleton constructed from a 6/6/6/6 tetracyclic system and an unusual tricyclo $[4.3.3.0^{3',7'}]$ dodecane motif, was isolated from *Ganoderma applanatum*. Its structure and absolute configurations were determined by spectroscopic analyses, X-ray crystallography and ECD (electronic circular dichroism calculations). A plausible biogenetic pathway, involving a key Gomberg-Bachmann reaction, was also proposed for (±)-1. Biological studies showed that (±)-1 and its enantiomers exhibited different inhibitory activities on T-type voltage-gated calcium channels.

The suggestions on construction of slow life recreation area

in Maluanshan based on biodiversity conservation

Weiying Gu[1], ***Lu Li***[2]
1. Pingshan New District Urban Planning and Land Affairs Center of Shenzhen
2. Baoan Urban Management Bureau, Shenzhen

Maluanshan is a beautiful hilly area undisturbed by human beings in Shenzhen which is belonged to Pingshan District. This area is one of the best preserved areas in ecological environment. There are plenty of species and good ecological base, where vascular plants belonging 161 families, 561 genus and 1,048 species were founded. This study is based on the perspective of urban ecological balance and biodiversity conservation. A series of suggestions were produced to the construction of slow life recreation area including projects of ecological conservation, environmental education and ecotourism.

Women's contribution to plant species discovery: a different use for historic botanical nomenclature data

Heather L. Lindon[1], *Lauren M. Gardiner*[1], *Abigail Brady*[2], ***Maria S. Vorontsova***[1]
1. Royal Botanic Gardens, Kew
2. 79B Mill Street, Oxford

How has women's contribution to science developed over multiple generations? We present the first quantitative analysis of the role played by women in publishing botanical species names, and the first complete analysis of women's contribution to any field of science with a timeframe of more than 260 years. The inclusion of dates with nomenclatural information allows us to get a view of how naming plant species has changed over time. The International Plant Names Index and The Plant List were used to analyze the contribution of female authors to the publication of land plant species names. Authors of land plant species were automatically assigned as male or female using Wikipedia articles. This was followed by manual research for authors marked as female with over 100 names or publishing before 1900. Female authors make up 12.05% of the total number of authors, and they published 2.59% of names. Female contribution has accounted for more than 1% of new species names per decade since 1900, and stood at 11.99% in the first half of this decade. The difference in productivity between male and female authors has declined over time, and female authors are now 80% as productive as their male counterparts. We determined that Elizabeth Blackwell was the first woman to publish a plant name, Amomum verum Blackw., in the 1750's. The most prolific female plant author was Harriet Margaret Louisa Bolus and one of the top 10 most prolific women, Dr. Charlotte Taylor, is still working today. There are only 28 women authors of plant names before 1900 accounting for about 176 species names. In spite of botany's traditional image as a feminine pursuit, women's contribution was not significantly reflected in species authorship until the twentieth century, around the same time as in other branches of science. This study illustrates how such large and nearly complete datasets of people, dates and plant names can be used to answer questions beyond their original intent and scope. The major limitations of the data as it stands now is the difficulty in assigning gender to some of the authors, in particular those of authors with missing or Chinese first names. This means that our analysis is somewhat restricted geographically. However, despite these difficulties we can see a clear trend of the closing of the gap in productivity between men and women when it comes to describing new species today. Studies such as these illustrate the great strides women have made in science over the past 260 years and hopefully will inspire the current generation of taxonomists to close the gender gap.

Assessment, innovation and breeding of Chinese main warm season turfgrass conducted in NBG-CAS

Jianxiu Liu
Institute of Botany, Jiangsu Province and Chinese Academy of Sciences (Nanjing Botanical Garden)

With the aim to nationalize China's turfgrass industry, a lot of work have been conducted on turfgrass germplasm resource collection, assessment, genetic improvement and extension since 1994 in China. They include the following specific topic areas: (1) turfgrass germplasm collection and assessment; (2) studies on stress tolerance of turfgrass including cold, salinity, drought, low pH and flooding; (3) genetic analysis and molecular marker development of important agronomic traits for turfgrass; (4) isolation and functional characterization of genes related to stress tolerance; (5) turfgrass breeding to improve the stress tolerance and decrease the maintenance cost; (6) key technical development of turfgrass establishment and maintenance. On the basis of these works, 1,300 accessions of warm season turfgrasses, belonging to 20 species of 10 genera, were collected. More than 200 research papers and two books were published mainly on the assessment, genetic improvement and utilization of turfgrass germplasm in China. Five cultivars of bermudagrass and zoysiagrass were registered with the Department of Agriculture, China, one cultivar was registered with OECD, and one bermudagrass cultivar was licensed to Barenbrug USA to be marketed globally. Five patents were granted and a first prize of science and technology award at the provincial-ministry level was presented to us. Several research platform were established including National Herbage Cultivar Evaluation Station (Nanjing), Jiangsu Engineering Research Center for Turfgrass Improvement and Propagation, Sport Turf Research and Development Center of Jiangsu Province, and Chinese Test Base of Royal Barenrbrug Group. New cultivars have been used successfully in sports field, ecological restruction in coastal region and erosion control in China.

The research about restoration plants' niche in damaged slope and arrangment model explortion of Southern China

Wenzhu Liu
hen Techand Ecology & Environment Co., Ltd.

In order to construct reasonable plant community and ensure the stability of the vegetation restoration and reconstruction in South China, ecology investigation and data measure of typical slope restoration projects in Shenzhen were carried out. Data were collected for the important value, niche breadth and niche overlap value analysis. The results showed that most of the plants belong to 53 families. Most of them were Euphorbiaceae, Asteraceae, Papilionaceae, Leguminosae. *Leucaena leucocephala*, *Tephrosia candida*, *Mimosa sepiariia* occupied a large proportion of important value in sample plots. The niche breadth value had almost the same sequence with niche overlap value, *Leucaena leucocephala*, *Heteropanax fragrans*, *Tephrosia candida* ranked higher. *Cyclosorus parasiticus*, *Pteris semipinnata* and other ferns had a relatively higher niche breadth in herb layer. Analysis of niche overlap value indicated that competition among *Leucaena leucocephala*, *Heteropanax fragrans* and *Syzygium cumini* was severe, while competition among *Trema cannabina*, *Rhaphiolepis Schefflera octophylla* and other plants was low. When conduct slope restoration, plants with wider niche breadth value and stronger vigor can be used as pioneer species, such as *Leucaena leucocephala*, and *Acacia mangium*. In addition, plants with lower niche overlap value between dominant species should be selected reasonably, for instance, *Rhaphiolepis indica*, *Trema cannabina* and *vines*. In conclusion, both plants' adaptability of the slope environment and competition and succession of species should be taken into consideration to establish a stable plant community of slope. According to the results of investigation, researches on arrangement model and seed quantity of slope restoration plants were carried out by simulating an artificial slope. Tentative combinations of species and quantity were obtained after half a year of observing and data analysis. This study attempted to estimate quality of a slope restoration project from the viewpoint of ecology and explored a new method to establish plant communities.

New ornamental aroids in China

Chunlin Long[1,2], *Bo Long*[3], *Hang Shu*[1], *Yuanyuan Ji*[1], *Yutong Han*[1], *Runfu Li*[1], *Bo Liu*[1], *Hairu Guo*[2,4], *Yu Ji*[2,4], *Li Wang*[4], *Yujing Liu*[1,5]
1. Minzu University of China
2. Kunming Institute of Botany, Chinese Academy of Sciences
3. Yunnan University
4. College of Horticulture and Landscape, Yunnan Agricultural University
5. College of Agricultural Equipment and Engineering, Jiangsu University

Aroids, or plants in Araceae, have become very popular and important potted indoor ornamentals in China. They are also cultivated for cutting flowers and gardens or landscapes. Many exotic ornamental aroids are introduced in recent decades, such as *Aglaonema*, *Anthurium*, *Caladium*, *Dieffenbachia*, *Monstera*, *Philodendron*, *Spathiphyllum*, *Syngonium*, *Zamioculcas*, and *Zantedeschia*. However, there are rich biodiversity of Araceae in China, of which most groups are potential ornamentals. Among its 26 genera and 181 species native to China, 72 are endemic to the country. The biodiversity at ecosystem, species and genetic levels of China's aroids has been reported in the present paper. In China's tropical and subtropical regions, aroids demonstrate great diversity including epiphytic, epilithic, aquatic, and terrestrial habitats. Their propagation strategies are also various, by producing seeds, stolons, tubercles, bulbils and other vegetative organs. China is the diversity center of *Arisaema*. Almost half species (ca. 80 species) of *Arisaema* grow in China, particularly in China's eastern Himalayan region. Native aroid species used as ornamentals in China are from *Alocasia*, *Leucocasia*, *Rhaphidophora*, *Epipremnum*, and *Colocasia*. The most common ornamentals include *Alocasia odora*, *Alocasia macrorhizos*, *Leucocasia gigantea*, and *Rhaphidophora decursiva*. Many other aroids native to China are very potential for future horticulture and gardens. In addition to ornamental values, about 50% of Araceae species in China are medicinal plants. Some species of *Amorphophallus* and *Colocasia* are used for food or industrial purposes. Wild populations of some aroids have been threatened by over harvesting. Conservation strategies had been proposed in this paper. In particular, most species in *Arisaema* should be protected.

Clonal integration mediates the heavy metal tolerance of ferns

Jing-Qi Sun[1,2], *Hua-Zheng Lu*[1], *Hang-Yu Li*[1,3], *Liang Song*[1], *He-De Gong*[2], *Jiao-Lin Zhang*[1]
1. Key Laboratory of Tropical Forest Ecology, Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Menglun, Mengla
2. Faculty of Ecotourism, Southwest Forestry University, Kunming
3. Puer University, Puer, Yunnan

As an environmental friendly and cost-effective technique, phytoremediation (i.e. an ecological restoration technique using plant hyperaccumulator to remove pollutants from environments, e.g., soil, water and atmosphere), becomes more and more popular. Although there are many researches focused on the phytoremediation of toxic heavy metals, the researches about clonal plants, especially clonal ferns were so limited. We carried out two experiments on heavy metal tolerance of two common clonal ferns, *Bolbitis heteroclita* which is a terrestrial fern in tropical seasonal rainforests and *Nephrolepis auriculata* which is an epiphytic fern on the border trees along avenues. One experiment was to survey the tolerance of Pb and Zn of single ramets, while the other was to test the effects of clonal integration on the Pb and Zn tolerance of pairs of ramets. The first one showed that the toxic damages were increased with the concentration of heavy metal and increased from one heavy metal to two metals on both ferns. The second one showed that physiological integration minimized the damages of heavy metals and mediated the tolerance of Pb and Zn of ramets. Our findings clarified that the stresses of single heavy metal on ferns can hardly represent those of multiple heavy metals in the simulated greenhouse studies. Furthermore, we first verified that clonal integration had played an important role in the heavy metal tolerance of ferns. This may imply that the ecological adaptation and strategy of ferns relates to the clonal growth in the long history.

Gungzhou 366 Popular Green Plants Manual

Ling Lu, *Zhiwu Chen*, *Daping Liang*, *Jianzhong Huang*, *Jianji Li*
Humanity Ecology Professional Committe of Guangdong Provin-

cial Ecology Society

With nickname as “Flower City”, Guangzhou is located in the warm and livable Tropic of Cancer belt that is scattered with diverse living things. Growing ornamental plants have become the tradition for people since ancient times. All kinds of plants with various shapes and colors are seen around the houses, displaying a harmonious scene of human living with plant, and also greatly improving the living quality of people. Ornamental plants not only beautify people’s living environment, but also cultivate people’s love to the nature. In recent years, with advances in technology and economy, as well as further popularization of ecological health culture, people not only care about the plant outlook and cultural connotation, but also care about the plant impact on people’s living environment and health. The selection of ornamental plants and growing ways are quietly changing. In order to effectively use the plants around to purify the environment around us, cultivate an ecological civilization featuring human harmoniously living with plants, and build a healthier and beautiful home and community, the project team is working hard to create a way that human and plants can harmoniously live together. After widely analyzing thousands of indoor plants in Guangzhou City, we select the plants according to certain proportion and diverse models, e.g. ornamental vegetables and fruits, ornamental Chinese medicines, and we also introduced new models to finally create the Manual of Popular Green Plan in Guangzhou, providing brief overview of 366 plants that are suitable for indoor and garden growing. Including: Herbs, Shrubs, Vines and Herbaceous Plants and Arbor Plant *etc.* The plants we selected are characterized by ornamental value, health to human, eliminating pollution, medicinal and edible value. Our purpose is to guide the people to grow these plants through organic growing way and fully utilize the plan resources, and we also give warning in the manual of the bad plants that will negatively affect people’s health. Manual includes the following main parts: Plant and Human Health, Concept of Green Plant, Indicators of Green Plant, Chinese Plant Culture. (This project was supported by the Guangzhou science and Technology Innovation Committee in 2015-2016)

Regional “Plant eco-calendar” theoretical framework

Ling Lu

Guangdong Provincial Ecological Society

This thesis intends to elaborate the essential of modern ecology according to the basic principles of modern ecology, the origin and universal development law of the calendar, as well as the examples of the lunar calendar and Gregorian calendar. It points out: calendar is a basic law that human handles grasp their own basic laws of nature and the ecological relationships: a kind of “ecological balance rule” effective and simple theoretical tools. It can not only act as the basic coordinate for human to understand the characteristics of the area and the natural ecological activities at different times, but also can act as guideline for human to figure out correct ecological measures according to the unity of the Earth’s ecosystem and the cycle response/law of changes. Plant Eco-calendar is a calendar system and its applications that are established based on the unity of celestial body periodic motion and the periodic change law of the Earth’s Plant ecosystems, and combine the Earth and the characteristics of regional ecosystems in order to realize the harmonious and healthy development between human and natural environment system. It includes elements such as basic theory, basic calendar law, system and application, *etc.* The establishment of Plant eco-calendar is based on the astronomy, geography and plant ecology, and supported by Chinese lunar calendar, Gregorian calendar, world calendar and farmer calendar, *etc.* The application of plant eco-calendar should not only respect the traditional almanac form, but also innovate calendar form. In the basis of calendar system, set the science popularization content of ecological culture, such as astronomy, geography, phenology, custom, health, planting and breeding, this is an effective way to promote social harmony and cultural science, people’s health and industrial development. This thesis also discusses the theoretical framework including technical route, natural foundation, style and format of the regional “Plant eco-calendar” design, showing broad prospects for future Plant eco-calendar applications.

Origin of plant life unity of meteorite strike energy model and bioenergetic Modem

Ling Lu

cological society of guangdong province

“Meteorite strike is a common and extensive geological process in the solar system”, the Earth is no exception. Based on the causes of meteorite impact on the earth’s crust, the cognition to celestial spiral motion and particle structure in the galaxy, as well as the comparison between meteorite strike energy model and various biomorph on the earth, matching between meteorite strike structure on ground rock stratum and plant and biota, it is inferred that the morphological characteristics of the life on the Earth, including fungi, plants and animals is highly consistent with the development of meteorite strike energy model. This study suggests that the said fact provides the key clue proving the mechanism of the origin of life, including plants, on the Earth. In the course of celestial bodies hitting the earth’s surface, the superior potential energy converted into high-energy physics process such as kinetic energy, thermal energy and nuclear energy, causing the fission and fusion of the particles, the basic material objects of falling celestial bodies, when the structure of these particles is swelling, and the energy information exchanges, the space-time order of energy movement during the meteorite strike process can be “memorized”. As the germ of life on the Earth and under certain conditions, the information they have memorized can express in sequence, such as “gene models.” Plant energy model corresponds to the phase before the main clue of meteorite strike energy model ruptured, while the animal energy model extended to a later phase. The life embryo created during the meteorite strike process continued to develop and evolve under the specific ecological environment on the Earth.

False colour photography of flowers in bee view

Klaus Lunau, *Christian Verhoeven*

Heinrich-Heine-University Duesseldorf

Bees see colours different as compared to humans. Like Humans bees have three types of photoreceptors, but the sensitivity maxima of the bee' photoreceptors are in the ultraviolet blue and green range of wavelengths. Thus, bees are sensitive to ultraviolet, but insensitive to red light. To illustrate the bees' view of flowers, traditionally a colour photo and a UV-photo from the same position are presented next to each other. Some observers are able to imagine how the UV-patters overlays the colour pattern, but most observers fail to imagine a subtraction of the red pattern at the same time. One problem is that the flowers must not display red colour, since also white, yellow and purple colours reflect in the red range of wavelengths. False colour photos solve this problem: from three separate photos taken in the ultraviolet, blue and green range of wavelength, matching the sensitivity range of the bees' photoreceptors, a false colour photo can be digitally reassembled. In doing so ultraviolet is displayed as blue, blue is displayed as green, green is displayed as red, and red is discarded. Thus the colour contrast is displayed in a bee-subjective correct manner. False colour photos of flowers in bee view are able to demonstrate the colour of tiny and protuberant structures of which spectral reflectance measurements cannot be taken due to the minimal size of the measuring spot required. We will explain a cheap and simple technique to produce false colour photos of flowers in bee view.

A review of *Vhavenḓa* ethnobotany

Khathutshelo Magwede
University of Venda

Vhavenḓa are indigenes of the *Vhembe* District within Limpopo province in South Africa. They have a rich social culture that is intrinsically embedded to the natural environment where their livelihood depend on sustainable utilization of plant derived resources. *Vhavenḓa* ethnobotany had been documented in several studies that had reported on different use categories ranging from medicinal, vegetables, fruits, beverages, firewood, building material, craftwork and several minor use categories. Some plant species had been recorded to be utilized in more than one use category. To access information on *Vhavenḓa* ethnobotany, several studies were consulted followed by an ethnobotanical rapid rural appraisal survey within Vhembe District Municipality. Data collected was analysed to determine use category trends of plant species. A total of 512 plant species from 325 genera made out of 110 families were recorded. The list include 34 climbers, 20 grasses, 4 sedges, 149 herbs, 130 shrubs, 1 parasite, 1 epiphyte and 173 trees. Out of a total of 110 plant families, those contributing the largest number of useful plant species were singled out as most ten contributing families in descending order: *Fabaceae* (61 spp.), *Malvaceae* (30 spp.), *Asteraceae* (27 spp.), *Poaceae* (20 spp.), *Euphorbiaceae* (19 spp.), *Curcubitaceae* (17 spp.), *Rubiaceae* (17), *Solanaceae* (17 spp), *Apocynaceae* (16 spp.), and *Anacardiaceae* (14 spp.).The overwhelming majority of plants were reported to be used as medicine for humans and animals healthcare, followed by vegetables, then building material, edible fruits, firewood, craftwork, magic and beverage. Ethnobotanical rapid rural appraisal survey revealed an informative data on plant trend uses from earlier times to present. Data collected from interviews show less plant uses from earlier time to present. Ethnobotanical Knowledge was highest in senior citizens above 60 years of age, followed by adults between the age of 35 and 59 years and lastly the youth below 35 years of age. This empirical finding warrants for immediate recording of *Vhavenḓa* plant uses before it disappears forever. Some enigmatic *Vhavenḓa* plants such as *Muṱavhatsindi (Brackenridgea zanguebarica Oliv.) and Muangaila (Millettia stuhlmannii Taub.*) are facing local extinction in the Limpopo Province because the traditional system of myths and taboos is no longer effective as conservation measure to ensure sustainable utilization.

Medicinal plants used in treatment of maternal healthcare related problems by the Mapulana of Ehlanzeni District, Mpumalanga Province, South Africa

Shalom Mashile*, Peter Tshisikhawe, Ndivhaleni Masevhe*
University of Venda

Fifteen villages in the Ehlanzeni District within three local municipalities were visited for the study. Thirty eight participants were identified on the basis of referrals, which included a traditional health practitioner (THP), herbalist, elderly people, middle age and youths. Ethnobotanical data was collected by means of interviews using semi-structured questionnaires. Data analyzed revealed that infants within the communities were treated with traditional medicine for ailments such as colic, nail biting, sunken and bulging fontanelles. *Hypoxis hemerocallidea* Fisch., C.A.Mey. & Ave-Lall, *Lippia javanica* (Burm.f.) Spreng. *Vachellia karroo* (Hayne) Banfi & Gallaso and *Annona senegalensis* Pers. subsp. *senegalensis* were amongst plants species which were frequently reported to be used medicinally. Decoction were mostly prepared from roots (79%) followed by bulbs (8%). In terms of administration of the medicines most of the plants were taken orally. The use of medicinal plant species in maternal healthcare has been perceived to be effective and reliable in preventing illness amongst communities within this district municipality. Validation for scientific efficacy will be needed as the search of new drug development continues.

Sustainable national network

Gloria Matiella
HuertosMX

In an era where sharing information through the Internet is a must and a sustainable life is becoming a global goal, is it possible to integrate technology, design and horticulture? This is the main question that pushed a thesis work from an idea into an emerging national social program. *Huertos MX* was born to create a national state of mind on the importance of a sustainable and cooperative community where people could be able to communicate and share experiences, tips or even to make a business out of their garden. Urban horticulture has emerged as a new mindset in Mexico. As we live in one of the most polluted cities in the world, it is imperative to search for the best quality products that we can afford. It is known that there are plenty of institutions that promote a sustainable way of life. They offer a variety of courses and workshops where people can get involved with the agriculture community or reestablish their previous knowledge about the subject. Maybe you knew about these courses because you saw their announcement on a flyer, your neighbor told you about them, or you may have seen it on the web. But what if there was a way for you to be able to know most of the members of the urban agriculture community in your city? From the smallest to the biggest corporative enterprise that makes gigantic installations on the rooftop of the skyscraper? *Huertos MX* is a project that searches all current urban, personal, scholar and institutional gardens in Mexico. To make this possible, technology was the way to go. We made a mobile application that helps our users locate people and institutions that share a common goal: sustainability. By doing this, we are creating a national movement to build a network where people can communicate and share anything they want. Imagine a map where the gardening community could locate their peers or costumers, a map of schools that could help parents who are aware of the importance of garden-based learning in their children's lives make an informed decision. These are just some of the benefits that a national map of urban gardens may provide to society.

Perception gaps that may explain the status of taro as an "orphan crop", despite global distribution and value as a starchy root crop and green vegetable

Peter Matthews
National Museum of Ethnology

The present distribution of taro (*Colocasia esculenta*), as a cultivated food plant, extends from southern to northern Africa, western Asia to eastern Asia, throughout Southeast Asia and the Pacific Islands, and through the Americas, from the USA to Brazil. Despite its vast geographical range, high nutritional value, and considerable trade as fresh and processed crop, there has been relatively little interest in the crop and its wild relatives among research funding agenices, and little effective or large-scale assessment of production, trade and usage. There are many historical, cultural, and practical reasons why taro continues to be under-supported as a subject of academic and practical research. Given the proven ability of this crop to grow under diverse climatic regimes, from the equatorial tropics to northern and southern temperate zones, it may be useful to consider perception gaps that contribute to disregard of the crop. Here, a range of perception gaps are suggested, including an apparent gross under-estimation of global production. The FAO is the main organisation responsible for publishing global statistics on food crops, but depends on national-level reports of taro that are generally unreliable, incomplete, or entirely lacking. Production for geographic areas not represented in FAO data can be extrapolated from published estimates for ecologically and culturally comparable areas. This method of first approximation can be used to encourage more accurate data collection, and greater awareness of the present and potential contributions of taro to local, regional, and world food security.

An ethnobotanical survey of wild edible vegetables with additional uses: a study of the Vhembe region in the Limpopo Province, South Africa.

Mokgaetji Georginah Mokganya*, Milingoni Peter Tshisikhawe*
University of Venda

Studies conducted globally evident that rural communities are faced with food insecurity and are chronically malnourished. The use of the wild edible vegetables can be of pivotal use to mitigate the stress of food insecurity. On the other hand, wild edible vegetables can serve multiple purposes such as 1) medicinally 2) and as condiments in special traditional cuisines. A total of 160 participants were interviewed in 16 different villages of the four local municipalities found in the Vhembe district municipality. The interviews aimed at gathering data on ethnobotanical aspects such as local names of wild edibles vegetables, parts used, life forms, mode of consumption, taste and mode of storage. The taxonomic diversity of wild edible vegetables with additional uses is 24 species belonging to 20 genera and 15 families. Thirty six percent (36%) of the wild edible vegetables listed during the survey were herbs. Some of these vegetables were reported to play paramount roles in the traditional therapeutic practices. As for the taste of the vegetables, it was explained by many participants that the ones with bitter taste are capable of lowering the blood pressure. All in all the study indicated that wild edible vegetables can not only serve as vegetables that supplement the maize-based diets, but can also serve as food-medicine, spices to be used in preparations of special Venda traditional cuisines like the one called *bovhola*. The dried fruits of some vegetables can be used as kitchen utensils.

Synergistic effect of Amphotericin B and essential oils against fungal strains known to cause mucormycosis

*Karaleen Anderson, Mariel Hatch, **Olga Kopp***
Utah Valley University

Mucormycosis is a serious but rare fungal infection that occurs in immuno-compromised individuals, infecting the sinuses, brain, lungs and other areas. It is caused by fungi of the order Mucorales, including Mucor, Absidia, Rhizopus and Cunninghamella, among others. The common treatment of mucormycosis includes the use of Amphotericin B, but this treatment can cause adverse side effects, including, chills, fever, headaches, loss of appetite, muscle pain, nausea, and weight loss, as well as fatal syndromes such as hepato and nephrotoxicity. For this reason, it is essential to study new compounds with antifungal activity. In this research, we used a combination of Amphotericin B and essential oils. This will provide an alternative treatment that could allow clinicians to lower the dose of Amphotericin B, thus reducing the side effects while still maintaining and utilizing the effective antifungal properties of both the oil and the drug. Essential oils and their antifungal properties have been thoroughly studied, however, little research has been done on the synergetic effect of essential oils and Amphotericin B on the three most common species isolated in mucormycosis infections, namely *Rhizopus oryzae, Abisidia* *corymbifera* and *Rhizomucor Pusillus*. In this study, we used fungi biofilms to evaluate the synergistic effects between selected essential oils and the antifungal compound Amphotericin B against mucormycosis-causing fungi, in an effort to find alternatives for the high dose of amphotericin B that is currently used to treat this disease.

A comparison between ethnobotanical information and preliminary biological activity test result from Indonesian medicinal plants

Jin Hyub Paik[1], *Jung Gwang Park*[1], *Sei-Ryang Oh*[1], *Paryanto Imam*[2], *Juniarti Fifit*[2]

1. Korea Research Institute of Bioscience and Biotechnology (KRIBB)

2. The Agency for the Assessment and Application (BPPT)

The joint research project for Indonesian Medicinal Plants between KRIBB and BPPT has been conducted since 2008 until 2016. We selected plant species which have ethnobotanical information and compared with the preliminary biological activity test result to use for the basic information of development of natural drug or nutraceuticals. The joint project produced not only high quality of herbarium & plant extracts (more than 2,500 samples), publications, and database but also provided highly potential samples to be successful in development for the benefit of both countries.

The account of *Begonia* flora in Thailand and rediscovery after hundred years of four endemic limestone taxa in Thailand and Myanmar

Thamarat Phutthai[1], *Mark Hughes*[2]

1. Faculty of Environment and Resource studies, Mahidol University (Salaya campus), Nakhon Pathom, Thailand

2. Royal Botanic Garden Edinburgh, Scotland

Thailand is one of high biodiversity in Southeast Asia. One of the most beautiful plant family in Thailand is *Begoniaceae* and can be found all types of vegetation from the mean sea levels to the highest summit of Thailand. Karst vegetation is found many endemic and rare species of flora and fauna in SE Asia. Karst limestone in Thailand has an archipelago-like distribution and a rich and highly endemic flora. Many areas of this habitat are under-explored botanically, and are providing a constant source of new species. During the studied family *Begoniaceae* for the Flora of Thailand project since 2007. Approximately 60 species of *Begonia* spp. are found in Thailand. Most of them are tuberous species and highly level of endemism in one or two localities. Endemic species of *Begonia* spp. are mostly restricted to karst vegetation in Thailand. *Begonia* section *Diplocinium* (Lindl.) A.DC. and *Parvibegonia* A.DC. are commonly found with many members in the mention sections. A new section record for Thailand; *Begonia* section *Apterobegonia* Warb. has been reported for the first time with a new species that could be found in the Northern Thailand. Moreover, the extensive studied of literatures, specimens in various herbaria and extensive field surveys so *Begonia procrifolia* Wall., *B. tricuspidata* C.B. Clarke, *B. surculigera* Kurz and *B. adenopoda* Lem. are new recorded species in Thailand. The original type localities of four new record species are found only in Myanmar with more than 100 years ago of the original publications so the recent study of *Begoniaceae* for the account of the flora of Thailand has been reported the novelties distribution and rediscovery of narrow endemism species after century of four new species record in Tenasserim Range, Thailand. At present, the flora account of *Begoniaceae* are going up over 70% since 2007 and six new species have been described in 2016 from Thailand and Myanmar within three publications.

The *Channapatana* toys and the Indian ivory wood tree

Meenu R. M., *Ashalatha S. Nair*

Department of Botany, University of Kerala, Kariavattom

*Channapatna*toys are traditional craft protected as a geographical indication under the World Trade Organization, administered by the Government of Karnataka. Traditionally, the craft involved lacquering the wood of the *Wrightia tinctoria*-the Indian ivory wood tree. Artisans use ivory wood because of its softness and clean white colour, and the fact that the bright colours of lacquer show easily on its surface. The socio-cultural success of *Channapatna*toys is intriguing. However this unprecedented success has taken its toll on the species. The population of ivory tree is declining since it is put to a number of economic use. The tree is harvested from the wild as a medicine and source of a dye and wood. Leaves are extracted as stock for phyto-remadies. The leaves, flowers, fruits and roots are sources of indigo. Hence the tree is identified and probed as a prospective silviculture species and its micropropagation potential is highly sought after. Earlier attempts at *in vitro* culture of the species identified basal callus mass formation, lack of morphogenetic competence in callus and high cost of production. This study proposes a rapid micropropagation strategy for commercial production of this deciduous tree. Under the regime used in the study, the most critical factor for rooting was activated charcoal (0.05%) along with 6 μM Naphthalene acetic acid. Simultaneous shooting and rooting reduced the time and cost of the protocol. The plantlets hardened with longer photoperiods had better survival percentages when compared with those acclimatised over shorter photoperiods. Hardened plantlets obtained within 45 days, and established in soil with 86.8% survival. This *in vitro* method can be used for rapid mass clonal propagation *W. tinctoria* for conservation strategies, commercial production irrespective of season and for the production of phytomedicines. This method can also be used in gene transformation studies of this obligate autogamous tree species.

Begonia diversity in China and relationships with neighboring countries

Sirilak Radbouchoom[1,2], *Wen-Hong Chen*[1,3], *Yu-Min Shui*[1,3]

1. Key Laboratory for Plant Diversity and Biogeography of East Asia, Kunming Institute of Botany, the Chinese Academy of Sci-

ences, Kunming, P.R. China
2. Karst Conservation Initiative of Yunnan, Kunming, Yunnan, China
3. University of Chinese Academy

Mega-diverse genus *Begonia* L. covers over 1,800 species in the world and seems to be discovered constantly. Asian *Begonia* includes over 650 species, among which, about 200 *Begonia* species or more than 10% of the genus member happen to China, which are endemic of 60% Chinese *Begonia*. Chinese *Begonia* is mostly distributed to South China. The provinces of species richness about *Begonia* diversity in China are Yunnan (102 species) and Guangxi (71 species). In China, *Begonia* sect. *Platycentrum* and *B.* sect. *Coelocentrum* is the two dominant sections in two provinces (Yunnan and Guangxi). Furthermore, South China borders with a few countries, such as India, Myanmar, Laos, and so on. So many species should be shared among these countries. As the two biodiversity hotspots, Himalaya and Indo-China possess high richness about plant species diversity as *Begonia*. The recent data indicated that the amount of *Begonia* species distributing in both area as China and another country as following 23 species with Vietnam, 14 species with India, 12 species with Myanmar, 7 species with both Thailand and Nepal, 6 species with Bhutan, 4 species with Laos, 2 species with Japan, and 1 species with Bangladesh, Indonesia, Malaysia and Philippine respectively. Especially Chinese *Begonia* species share with Vietnam are maximum species, where 22 species in Yunnan, Guangxi and Vietnam, only one species in Hainan and Vietnam. However, as a part of the Indo-China biodiversity hotspot, Laos only shares 4 species with China, which are dispersed species, viz. *B. acetosella, B. handelii, B. longifolia, B. palmata*. It is predicted that more new discovery would occur in Laos with the further herbaria and field work. And as a part of Himalaya biodiversity hotspot, Tibet (Xizang) of China, India and Nepal maybe need more research and surveys to discover more undescribed species. The geographical and taxonomic study on *Begonia* would be useful for supporting conservation of this genus and the evaluation of biodiversity priority.

Orchids and their cultural and historical significance

***Andrea Ravelo**, J. Chris Pires*
University of Missouri - Columbia

Orchids have a widespread distribution, so it is not surprising that they have had a myriad of opportunities to impact human culture and sometimes even affect historical events. Their influence ranges from medicinal and culinary uses to broad horticultural appeal to literary inspiration. Some of the earliest mentions of orchids originate in East Asia where references to a plant called *che lan* by Confucius (551- 479 BCE) seem to refer to *Cymbidium* orchids. The name of the family (Orchidaceae) derives from the genus *Orchis,* which was first used by the Greek philosopher. Theophrastus (370-285 BCE), who described the effect the orchid tubers had on determining the gender of offspring when consumed by a man or a woman. This explanation was apparently inspired by the shape of the tubers, which bear resemblance to human testicles. This visual similarity also influenced the medicinal applications of orchids in other parts of the world. Although orchids are not known for their agricultural importance, one genus, *Vanilla*, stands out for its culinary significance. The vanilla bean, which is used as a flavoring in a wide variety of dishes and cuisines, was first known to be used by the Aztecs and Mayans as part of the drink Chocolatl. The desire to cultivate and produce vanilla outside of the Americas was a driving force in the discovery and application of hand pollination methods, which later impacted the horticultural industry by allowing the creation of thousands of new hybrids. These hybrids helped augment the orchid collections that were starting to form all around the world as travelers and enthusiasts brought back specimens, some which were quite rare and of conservation concern. The resulting (often-illicit) trade activities have been the subject of books (e.g., Orchid Fever) and even Hollywood movies (e.g., Adaptation) as they delve into the sometimes-fanatical dedication of orchid collectors and enthusiasts. Even as current day scientific research starts to clarify some of the questions regarding the processes and interactions that impact orchid biology, the fascination with the family still holds strong and will most likely continue to enrich human culture for many more years.

Plant based quorum sensing inhibitor molecules for the development of antipatogenic drug for resistant pathogens

Sushil Kumar Shahi
Bioresourse Tech Laboratory, Botany Department, Guru Ghasidas Vishwavidyalaya

Antimicrobial and antiquorum sensing (AQS) activities of ethanol, methanol and benzene extracts of different parts of twelve plants were screened against *Pseudomonas aeruginosa* POA1 and *Chromobacterium violaceum* 12472. Depending on the plant part extract used and the test microorganism, variable activities were recorded by well diffusion method. During antimicrobial screening of plants extracts against *Chromobacterium violaceum* 12472 the maximum inhibition showed 21.5±1.5 mm by methanol extract of *Psoralea corylifolia* seed, and against *Pseudomonas aeruginosa* PAO1 the maximum inhibition was showed 5±1.5 mm by methanol extract of *Punica grantum* pericarp. The Antiquorum sensing activity of methanol extracts of *Terminalia bellerica* fruit against *Chromobacterium violaceum* 12472 was recorded 7.75±0.5 mm. The three plant extracts were tested to explore their effect on quorum sensing-related swarming motility of *Pseudomonas aeruginosa* POA1. Maximum reduction on swarming motility of plant extract was recorded the benzene extract of *Mangifera indica* leaf showed 15± 1.5 mm zone. However, the value of minimum inhibitory concentrations (MIC's) in case of *Pseudomonas aeruginosa* PAO1 ethanol and methanol extract of *Terminalia bellerica* fruit, benzene and methanol extract of *Mangifera indica* leaf and ethanol and benzene extract of *Punica grantum* pericarp was found 12.5×10^{-3}. The MIC of ethanol extract of *Mangifera indica* leaf was found 3.75×10^{-5} and in case of *Chromobacterium violaceum* 12472 the MIC value of both ethanol extract and methanol extract of *Terminalia bellerica* fruit, and both ethanol and benzene extract of *Mangifera indica* was found, $6.25\times10^{-}4$. Methanol extract of *Mangifera indica* leaf was 3.75×10^{-5}, and the MIC of ethanol extract of *Punica grantum* pericarp was found 6.25×10^{-4} and benzene extract of *Punica grantum* pericarp was found 1.25×10^{-6} and methanol extract of *Punica grantum* pericarp was found 3.75×10^{-5}. In conclusion, results indicate the potential of these plant extracts in treating microbial infections through cell growth inhibition or quorum sensing antagonism, validating their medicinal use. Thus the drug having quorum sensing molecules may be effective for resistant pathogens.

Varietal development and Horto-taxonomy of Bougainvilleas in India

Sc Sharma[1], *Tao Chen*[2]
1. National Botanical Research Institute, Lucknow
2. Fairy Lake Botanical Garden, Shenzhen

Floriculture is a very lucrative business amounting to 50 billion US$ per year with 10% annual increase. In the floriculture trade, there is always demand for the newer, floriferous and dwarf varieties of ornamental crops. All the cultivated plants have arisen from their wild relatives. *Bougainvillea* is one of the important ornamental climbing shrubs. It was first collected from Rio de Janeiro, Brazil. Bougainvilleas achieved importance in 1920 with the introduction of the cultivar 'Mrs. Butt' in Agri-Horticultural Society, Kolkata, (India) from the Royal Botanic Gardens, Kew. Out of ten *Bougainvillea* species, only *B. glabra*, *B. spectabilis*, *B. peruviana* and a natural hybrid *B.* x *buttiana*, are of horticultural importance. Today, a large number of *Bougainvillea* cultivars (*ca* 500 cvs.) are available from three to multibracted bracts in various color and variegated foliage as a result of the natural hybridization, selection, bud sports, plant and mutation breeding. The Botanic Garden of CSIR-National Botanical Research Institute (NBRI), Lucknow, India is maintaining rich germplasm collection of *Bougainvillea* (*ca* 220*species*/cvs), which serves as the Reference Centre for the R&D work on Bougainvilleas. In the last 50 years, NBRI has developed 25 novel *Bougainvillea* cultivars. 'Shubhra', 'Shweta', 'Hawaiian Beauty', 'Parthasarthy', 'Palekar', 'Zinna Barat', were evolved by spontaneous mutation, 'Arjuna', 'Aruna', 'Los Banos Variegate' were developed by gamma irradiation while 'Chitra' and 'Tetra Mrs. Mc.Clean' were evolved by chemical mutagens. Other institutes which have contributed in the varietal development of Bougainvilleas are Indian Agricultural Research Institute, New Delhi, Indian Institute of Horticulture Research, Bengaluru, Bhabha Atomic Research Centre, Mumbai and KSG & Sons, Bengaluru. 30% of the *Bougainvillea* cultivars have been evolved in India and the country has been recognized as the International Registration Authority for Bougainvilleas. There is lot of confusion in the identification of Bougainvilleas. For boosting the sale of Bougainvilleas, nurserymen give fancy names. In order to check the corruption in the floriculture industry, Horto-taxonomical parameters are employed for the authentic identification and classification of the *Bougainvillea* cultivars.

Empirical analysis on economic sustainable of rice rain-fed area in rural Cambodia

Darith Siek[1,2], *Shiwei Xu*[1], *Wen Yu*[1], *Abdul-Gafar Ahmed*[1]
1. Agricultural Information Institute, Chinese Academy of Agricultural Sciences, Beijing, China
2. Regional Polytechnic Institute Techo Sen Battambang, Ministry of Labor and Vocational Training, Battambang, Cambodia

This paper investigates the economic sustainability of Cambodian rural rice farmers. Rice in Cambodia is a stable crop just as in many other South Asian countries. The rice plants not only provide food to people but also a source of feed for livestock. Based on 2015 survey about of 6 districts of the rural household in Battambang of Cambodia, a total 204 rice farmers were interviewed and a multiple regression models was applied using the method of Ordinary Least Squares (OLS) to determine the factors affecting the Crop-livestock farmers' disposable income. The study aggregated the livestock of 3 species including cattle, pig and chicken in cattle unit standard known as Livestock Unit (LU). The result of the empirical analysis shows that many household demography factors as well as the socioeconomic factors influences the disposable income. The findings in the study provide an insight to the government and extension offices on effective development of economic sustainability of rice farming and livestock production system in the regions.

Phoenix dactylifera ecosystem in Morocco: ecology, socio economic role and constraints to its development

Mohammed Sghir Taleb
Institut Scientifique, Mohammed 5 University in Rabat

The date palm (*Phoenix dactylifera* L.) represents the essential element of the oasis ecosystem for Saharan and pre-Saharan regions of Morocco. It plays an important role, not only due to its economic importance, but also its ecological adaptation to, firstly, to ensure necessary protection for crops against underlying warm and dry sales, and secondly to contribute to the fight against desertification. This is one of the oldest cultivated plant species best adapted to difficult climatic conditions of the Saharan and pre-Saharan regions, because of its ecological requirements and economically most suitable for investing in oasis agriculture. Furthermore, the date palm produces fruits rich in nutrients, provides a multitude of secondary products and generates needed revenue for the survival of oasis populations. In Morocco, the development and modernization of the date palm sector face, both upstream and downstream of the industry, several major constraints. In addition to climate constraints (prolonged drought), in its environment (lack of water resources), to the incessant invasion of disease Bayoud, Moroccan palm ecosystem suffers from a low level of technical and traditional practices prevail and traditional, from the choice of variety and site preparation up to harvesting and recycling of products. In this presentation the author will focus on the role of the date palm ecosystem in the local and national development and on any problems that hinder the development of the date palm cultivation in Morocco.

HSCCC separation of the two iridoid glycosides and three phenolic compounds from *Veronica ciliata* and their *in vitro*

antioxidant and anti-hepatocarcinoma activities

*Qiuxia Lu[1,2], Yiran Sun[1,2], Yueyue Shu[1,2], Shancai Tan[1,2], Li Yin[1,2], Yiran Guo[1,2], **Lin Tang**[1,2]*

1. Key Laboratory of Bio-Resources and Eco-Environment of Ministry of Education, College of Life Sciences, Sichuan University, Chengdu, Sichuan, China

2. National and Local Joint Engineering Laboratory for Energy Plant Bio-Oil Production and Application

Five main compounds, including two iridoid glycosides (catalposide, verproside) and three phenolic compounds (luteolin, 4-hydroxy benzoic acid, 3,4-dihydroxy benzoic acid), were separated and prepared from the crude extract of *Veronica ciliata* by high-speed countercurrent chromatography.n-Hexane/n-butanol/water (1.5:5:5, v/v/v) was used for the separation of catalposide and verproside.n-Hexane/n-butanol/water (3:2:5, v/v/v) was used for the separation of luteolin, 4-hydroxy benzoic acid and 3,4-dihydroxy benzoic acid. The head-to-tail elution mode was used with a flow rate of 5.0 mL/min and a rotary speed of 800 rpm. Finally, a total of 1.28 mg luteolin, 6 mg 4-hydroxy benzoic acid, 2 mg 3,4-dihydroxy benzoic acid, 2 mg verproside and 10 mg catalposide with purities of 98%, 99.1%, 99.5%, 99.8% and 99%, respectively, were obtained from 200 mg of crude extract. In addition, their structure was identified using MS, 1H-NMR and 13C-NMR. To the best of our knowledge, this is the first report of the separation and purification of iridoid glycosides and phenolic compounds from *V. ciliata* by high-speed countercurrent chromatography (HSCCC). Among these compounds, luteolin, 4-hydroxy benzoic acid and 3,4-dihydroxy benzoic acid were separated from *V. ciliata* Fisch. for the first time. The results of the antioxidant activity show that protocatechuic acid and luteolin have strong antioxidant activity compared to 2,6-di-tert-butyl-4-methylphenol (BHT) and vitamin C (Vc). Five compounds also exhibited strong anti-hepatocarcinoma activities.

P1382

Iridoid glycosides fraction isolated from *Veronica ciliata* Fisch. protects against acetaminophen-induced liver injury in mice

*Shancai Tan[1,2], Qiuxia Lu[1,2], Yueyue Shu[1,2], Yiran Sun[1,2], Fang Chen[1,2], **Lin Tang**[1,2]*

1. Key Laboratory of Bio-Resources and Eco-Environment of Ministry of Education, College of Life Sciences, Sichuan University, Chengdu, Sichuan

2. National and Local Joint Engineering Laboratory for Energy Plant Bio-Oil Production and Application, Chengdu

Veronica ciliata Fisch. has traditionally been used in Tibetan medicine for the treatment of hepatitis, cholecystitis, rheumatism, and urticaria. We analyzed the chemical composition of the iridoid glycosides fraction (IGF) isolated from V. ciliata and evaluated the antioxidant and hepatoprotective properties. Te IGF was separated by high-speed countercurrent chromatography (HSCCC) and the main compounds were identifed by ultra-performance liquid chromatography coupled to a photodiode array. We determined the in vitro antioxidant ability of the IGF through radical scavenging assays and assessed the in vivo hepatoprotective potential in an acetaminophen- (APAP-) induced acute liver injury murine model. Te IGF was separated by HSCCC and three major iridoid glycosides (verproside, catalposide, and amphicoside) were identifed as potent antioxidants and hepatoprotective compounds. Treatment with the IGF signifcantly suppressed the APAP-induced elevation in serum alanine aminotransferase, aspartate aminotransferase, and tumor necrosis factor-alpha (TNF-; improved serum total antioxidant capacity; decreased malondialdehyde formation; elevated superoxide dismutase and glutathione activity; and decreased expression of proinflammatory factors (TNF- nuclear factor kappa B) in the liver. Finally, we examined the histopathology of resected livers for evidence of hepatoprotection. The protection conferred by the IGF may be related to the reinforcement of antioxidant defense systems.

P1383

Bioactivity-guided isolation of antioxidant and anti-hepatocarcinoma constituents from *Veronica ciliata*

*Li Yin[1,2], Qiuxia Lu[1,2], Shancai Tan[1,2], Lisheng Ding[3], Yiran Guo[1,2], Fang Chen[1,2], **Lin Tang**[1,2]*

1. College of Life Sciences, Sichuan University, Key Laboratory of Bio-resources and Eco-environment, Ministry of Education, No.24 South Sect. 1, Yihuan Road, Chengdu,

2. National and Local Joint Engineering Laboratory for Energy Plant Bio-oil Production and Application, Chengdu, Sichuan

3. Key Laboratory of Mountain Ecological Restoration and Bioresource Utilization, Chengdu Institute of Biology, Chinese Academy of Sciences, Chengdu

Veronica ciliata Fisch., widely distributed in western China, has been traditionally used in Tibetan Medicine as a treatment for hepatitis, cholecystitis, rheumatism, and urticaria. However, *V. ciliata* Fisch. has not been subjected to detailed chemical constitution analysis and the bioactive studies were restricted to its crude extracts. It is necessary to investigate the active chemical components of these extracts and identify their biological effects. Four iridoid glycosides, (veronicoside, cataposide, amphicoside, and verminoside) were isolated from the ethyl acetate fraction. Among these compounds, veronicoside and verminoside were isolated for the first time from this plant. These compounds exhibited strong antioxidant activity and inhibitory activity on HepG2 cell proliferation. The antioxidant activity of verminoside was equal to Vc. Cataposide, amphicoside and verminoside had stronger antihepatocarcinoma activity than 5-fluorouracil. Four iridoid glycosides, (veronicoside, cataposide, amphicoside and verminoside) were isolated from the extract of *V. ciliata* Fisch. using bioassay-guided screening. Among these compounds, veronicoside and verminoside were isolated for the first time from this plant. The above results indicated that these compounds were the active chemical components responsible for the antioxidant and anti-hepatocarcinoma properties of *V. ciliata* Fisch. The underlying mechanism of their bioactivity is worthy of further investigation.

T6

P1384

Antioxidant and hepatoprotective activity of *Veronica ciliata* Fisch. extracts against carbon tetrachloride-induced liver

injury in mice

Li Yin[1,2]*, Lei Wei*[1,2]*, Rao Fu*[1,2]*, Lisheng Ding*[3]*, Yiran Guo*[1,2]*,* ***Lin Tang***[1,2]*, Fang Chen*[1,2]

1. College of Life Sciences, Sichuan University, Chengdu

2. Sichuan Key Laboratory of Resource Biology and Biopharmaceutical Engineering, Key Laboratory of Bio-resources and Eco-environment, Ministry of Education, Chengdu

3. Key Laboratory of Mountai

Veronica ciliata Fisch. has been traditionally used in Traditional Chinese Medicine prescriptions due to its curative effects for hepatitis, cholecystitis, rheumatism, and urticaria. The present study was focused on investigating the role of ethyl acetate and aqueous extracts of *Veronica ciliata* Fisch. Furthermore, in vitro antioxidant activity (scavenging of DPPH, ABTS, superoxide, and nitrite radicals; reducing power; β-carotene bleaching) and the hepatoprotective effect of the ethyl acetate extract by means of CCl4-induced oxidative stress in mice were investigated. The ethyl acetate extract of *Veronica ciliata* Fisch. displayed more noteworthy in vitro antioxidant activities than the aqueous extract. Moreover, it significantly prevented the increase in serum T-AOC, ALT, AST and ALP level in acute liver damage induced by CCl4, decreased the extent of MDA formation in liver and elevated the activities of SOD and GSH in liver. This activity was found to be comparable to that of bifendate. Histopathological observation of the liver was also performed to further support the evidence from the biochemical analysis. The results indicated that strong antioxidant activities and a significant protective effect against acute hepatotoxicity induced by CCl4 of *Veronica ciliata* Fisch. were concentrated in the ethyl acetate extract. The results suggested that this activity may be due to free radical-scavenging and antioxidant properties.

P1385

Development of chrysanthemum without pollen contamination

Xinhua Zhong, Lichun Hua, Jiangsong Fei, Lulu Huang, Weimin Fang, Fadi Chen, ***Nianjun Teng***

College of Horticulture, Nanjing Agricultural University, Nanjing, China

Pollen contamination of many flowers not only significantly reduce their ornamental value and quickly shorten their vase life, but also cause severe allergic reactions to people, in particular those with pollen allergies. Thus, it is urgent to develop flowers without pollen contamination. Chrysanthemum is among the ten most popular traditional flowers in China and one of the four most popular cut flowers in the world, but the excessive quantity of pollen dispersal during its flowering stage can lead to serious pollen contamination. In the past several years, we have focused on the development of chrysanthemum without pollen contamination. It was found that two types of chrysanthemum cultivars do not cause pollen contamination during flowering stage, the first one is there is no pollen in anthers due to pollen abortion, and the second one is there is a failure in anther dehiscence. Pollen abortion mainly occurs at tetrad phase stage when tapetal cells have been in degradation in advance, and several key protein and genes related to programmed cell death (PCD) were found to possibly result in degradation of tapetal cell. In addition, abnormal hypertrophy of endothecium cell serves as the cellular basis of anther indehiscence; and anther dehydration, the enhancement of anther cell toughness due to a high level of ions may be the determining physiological factors of anther indehiscence. Furthermore, more than 10 new chrysanthemum cultivars without pollen contamination have been developed through crossbreeding programs.

Utilization of *Wolffia arrhiza* extracts for improvement of dry weight and number of nodules in lentil crop

Amit Tiwari

D.B.S. College Kanpur

The dynamic features of aquatic habitats in South-East Asia in general and India in particular have supported luxuriant growth of aquatic weeds. Studies have been made for their utilization in multiple ways in developing countries. *Wolffia arrhiza* is known as noxious weed and rated as one of the ten major weeds growing in South-East Asia, commonly infesting natural impounded waters in India. Studies on effect of *Wolffia arrhiza* extract on dry weight and number of nodule in per plant of lentil crop (*Lens culinaris* D.P.L.-15). Pre-soaking seed treatment for 12 and 24 hrs. were given with 1, 2 and 5 percent ether and water extracts of *Wolffia arrhiza*. Influence of dry weight per plant and consequently number of nodules were increased in treatments of 12 and 24 hrs. with 5 percent ether and water extracts. Results are statistically significance at 5 percent error probability. Present finding are of both academic and economical significance of agriculture of lentil by growers of commercial crop.

Analysis on light response curve characteristics of ten common vertical greening plants

Jia Wang

Shenzhen Techand Ecology and Environment Co., Ltd.

In order to research photosynthetic capacity of common vertical

greening plants, taking ten vertical greening plants as materials, different photosynthetic parameters were determined by using Li-6400 portable photosynthesis system, and the light response curves were drawed. The results showed that *Schefflera heptaphylla* was the strongest adaptability to bright light and the highest light saturation point, which was 281.55 mol·m^{-2}·s^{-1}. The maximum photosynthesis rate of *Schefflera heptaphylla* was the highest, 13.31 mol·m^{-2}·s^{-1}, which showed that *Schefflera heptaphylla* was the strongest photosynthetic capacity and the strongest adaptability to the light, followed by *Nephrolepis cordifolia*, *Peperomia obtusifolia*, *Chlorophytum comosum, Spathiphyllum kochii, Nephrolepis cordifolia* and *Anthurium andraeanum*had lower light compensation points, 7.47 mol·m^{-2}·s^{-1},7.76 mol·m^{-2}·s^{-1},8.2 mol·m^{-2}·s^{-1},9.90 mol·m^{-2}·s^{-1} respectively, which indicated they were stronger adaptability to low light. The lowest transpiration rate of *Anthurium andraeanum* indicated the best water saving and drought resistance capacity, followed by *Nephrolepis cordifolia* and *Dieffenbachia seguine*. The apparent quantum yield of *Nephrolepis cordifolia* was the highest, 0.1059, followed by *Neoregelia carolinae*.

Chemical constituents from *Evodia rutaecarpa* and their activities and chemotaxonomic significance

Qizhi Wang*, Fei Liu, Yu Chen, Yu Shan, Shu Xu, Bi Wang, Xu Feng*

Institute of Botany, Jiangsu Province and Chinese Academy of Sciences/Nanjing Botanical Garden Mem. Sun Yat-Sen., Nanjing, PR China.

Evodia rutaecarpa is an original plant of several crude drugs. The *Evodia* fruits (Wu Zhu Yu) have been used in traditional Chinese prescriptions for the treatment of headache, abdominal pain, migraine, chill limbs, postpartum hemorrhage, diarrhea, hyperbaropathy, dysmenorrhea, nausea, nociception, inflammatory and cancer. In order to discover novel bioactive molecules, we investigated the chemical constituents of *Evodia rutaecarpa*, which led to isolation of five novel indole alkaloids (1-5), together with fifteen known indole quinoline alkaloids (6-20), seven quinolone alkaloids (21-27), ten limonins (28-37), nine flavonoids (38-46), seven triterpenoids (47-53), and thirteen other compounds (54-66). The structures of novel compounds were identified on the basis of MS and NMR spectroscopic analysis, and compound 2 and 5 were confirmed by X-ray crystallographic analysis. The known compound structures were established based on chemical and spectral methods. Nine compounds were isolated for the first time from *Evodia rutaecarpa*. Compounds 2, 4 and 6 showed good cytotoxic activity. The compound 4 showed obvious effect on easing pain, reducing blood viscosity and improving immunity in vivo. Compound 1 and 10 have significant antifungal activity of inhibition enzyme activity on the Lanosterol 14α Demethylase (CYP51). Based on the previous studies, this chemical composition of Subfam. Rutoideae is in accordance with the chemical profile of other species of Rutaceae, and complies with the rule that indole quinoline alkaloids are the characteristic constituents of *Zanthoxylum* and *Evodia* genus plants, which provide reliable evidence for their chemotaxonomy.

Using nature journal to achieve EE outcomes

Ximin Wang

Xishuangbanna Tropical Botanical Garden

Nature journal is a popular activity to inspire kids to appreciate nature. During the journaling, the participants can observe any object, which could be an insect, flower or leaf, very carefully and reflect on their thoughts and feelings. Many natural education organizations in China are using nature journal in their programs. However, how nature journal affects the participants? No serious evaluation has been done yet. In 2016, Xishuangbanna Tropical Botanical Garden organized a nature journal activity in the whole Xishuangbanna. More than 500 students from 14 local schools involved it. After analyzing the objects in the paintings, it shows that the most participants could observe local environment, especially plants to draw. During a questionnaire for 96 students, including participants and non-participants, it found that the participants' attitude and willingness have been improved. But in knowledge, knowledge and skills, no significant differences were found between two groups. Interestingly, after interviewing 48 participants, they said that they did improve their knowledge from nature journal, awareness and attitude, as well. The results showed that nature journal was helpful increasing participants' interests about nature. How to implement it is important.

Functions of service system of natural history museum on plant research and protection

Xin Wang*, Shumei Zhang*

Dalian Natural History Museum

The service function of natural history museum relies on its carrying capacity in the natural science field. As an important research field of natural science, botany conforms to an important component of natural history museum service function system. The paper takes Dalian Natural History Museum as an example to explore the basic role on plant research and protection in the museum series of service function system, such as collection, research and education. From the museum's collection function, the paper use nearly 40,000 pieces of plant collections from plant fossils to existing plant specimens to establish the digital museum system, which provide the basic data and information. A large number of plant collections can provide scientific basis for the classification and identification of plants. Especially precious conservation such as key protection and collections of endangered plant species can provide valuable reference for plant protection. From the perspective of the research function of the museum, the botanical researchers at Dalian Natural History Museum will carry out botanical classification research as a long-term and continuous work, and introduce the new concept of biodiversity into the traditional fields of plant basic science research. The study of plant diversity in this region can be used to understand the distribution of ecological resources of plant resources by means of plant resource investigation, to grasp the current status of plant resources, and to provide effective science for sustainable utilization of plant resources, plant diversity protection and ecological environment protection. From the perspective of the educational function of the museum, the design and implementation of the botanical-based educational curriculum and activity system, the diversified exhibitions based on plants, will not only expand and popularize botanical knowledge content effectively, but also the botany and natural science related disciplines and even the field of art integration, promote research in new areas of botany exploration.

Non-random transmission of parental alleles into artificially grouped crop-wild and crop-weed hybrid lineages in rice (*Oryza*)

Zhe Wang, *Lei Wang, Zhi Wang, Xingxing Cai, Bao-Rong Lu*
Ministry of Education Key Laboratory for Biodiversity Science and Ecological Engineering, School of Life Sciences, Fudan University

The worldwide cultivation of genetically engineered (GE) crops has stimulated great concerns over the undesired environmental impacts caused by transgene flow to crop wild relatives. Therefore, it is important to assess the environmental impacts before the commercial release of GE crops. To analyze the fitness effect of a transgene is a part of the risk assessment for transgene flow. Normally, the F_2 (selfing) or BC_1 (backcrossing with wild/weed) hybrid lineages with or without the transgene (s) derived from artificial crosses between a GE crop and its wild/weedy relatives are used to assess the fitness effect in a common-garden experiment. This is based on the assumption that the artificially formed transgene-present and -absent lineages should have the same genetic background. Therefore, the detected differences between the GE and non-GE lineages are merely resulted by the transgene. However, whether a selective-advantageous transgene influences the random transmission of alleles into transgene-present and -absent lineages, resulting the same genetic background of the lineages, has never been properly demonstrated. To address this question, we produced F_2 and F_3 crop-wild/weedy hybrid lineages in rice with or without the herbicide-resistance transgene (*epsps*, 5-enolpyruvoylshikimate-3-phosphate synthase) to examine the frequencies of alleles transmitted from both parents (GE rice and wild/weedy rice) at multiple microsatellite (SSR) loci in these hybrid lineages. Our results showed significantly increased frequencies of crop alleles in transgene-present hybrid lineages, suggesting that grouping of hybrid lineages using a transgene as a marker can result in the non-random transmission of parental alleles into their hybrid descendants. To confirm such a sampling effect on the non-random transmission of parental alleles, we further examined the effect of artificial grouping on allelic transmission into hybrid lineages, using three neutral SSR loci as markers. We obtained similar results in which selecting neutral markers to form hybrid groups (with or without the markers) also caused the preferential transmission of the parental alleles into different hybrid lineages. Together, these results indicated that using a marker, regardless of a transgene or neutral marker, to form hybrid lineages can cause non-random transmission of parent alleles, which leads to the differential genetic background of hybrid lineages/groups. The non-random transmission of parent alleles into the transgene-present or -absent hybrid lineages may mislead the prediction of the fitness effect of a transgene for the risk assessment of transgene flow from a GE crop to its wild relatives.

The brief history of Camellia hybridization and its new era on creating outstanding cultivars

Zhonglang Wang, *Yunguang Shen*
Kunming Institute of Botany, Chinese Academy of Sciences, Kunming Yunnan

The Camellia genus includes over 260 species with great important values, juvenile leaves and buds of *Camellia sinensis* are used as tea, seed oil *C. oleifera* and other species in this genus is used as edible oil or hair and skin care, and many Camellias are amongst the world's best flowering plants. So far, camellias species have originated over 25,000 cultivars. In recent decades in China, many outstanding camellia cultivars were produced, like many summer blooming cultivars derived from *Camellia azalea,* which make camellias could have flowers year round. Flowers range from simple singles, semi-double, anemone and peony form to fully formal double bloom. Many are large and showy enough to be competition-worthy. And some are very fragrant. Colors are also very abundant than ever. Many new cultivars are more resistant to cold temperatures than those cultivars used to be. In the field of Tea, many new cultivars were derived, like 'Zijuan' which produces higher contain of anthocyandin, and many new cultivation were used from the species in Sect. Thea were used like *C. taliensis* and *C. crassicolum*. In seed oil field, many good cultivars were created and selected with very good characteristics, like high oil content, high quality. These progress will greatly promote the development of camellias' industory.

Investigation of the origin of rice agriculture in lower Yangze river area based on the phytolith record

Yan Wu
Institute of Vertebrate Paleontology and Paleoanthropology

Using rice cultivation as a method to adapt to environment is one of the most important processes in the human civilization history. There is a continuous debate about whether rice remains from archaeological sites in early Neolithic is collected wild rice or early cultivated rice. One of the key research topics is to find out solid scientific evidence of human intervention in the rice growth and plantation. It is obvious that the change of human behavior will cause the change of associated flora to some extent. Here, we will focus on the ancient rice in the lower Yangze river area, and use phytolith distribution pattern as a new research method, which is then combined with the results from AMS^{14}C identification. Then we can investigate whether change of phytolith distribution has occurred due to the manual intervention, which can provide a novel method to research on the origin of rice agriculture.

The compilation of *Plants of China* — an illustrated toolbook for 20 thousand species

Min Li, *Jing Xuan*
Institute of Botany, CAS

The Plant Photo Bank of China (PPBC) is a full-time agency for plant picture management in Herbarium (PE) of Institute of Botany, CAS. Since founded in 2008, PPBC has collected about 3 million photographs of over 25,000 species from 4,146 genera in 538 families. Based on the photograph data, we've started to compile a set of books named *Plants of China*, which is divided into 65 volumes. The set of books is expected to cover all genera and families of native, invasive or naturalized and introduced plant species in China and the species involved are based on the latest classification system. Besides species photographs, their information including the common name, scientific name, distribution map, morphological characters is described in the book. The compilation work is conducted through online editing system which can realize online image selection, text editing and digital typesetting, *etc*. All books are expected to be completed by 2018.

"iFlowers" — an image-based immediate plant identification system

Min Li[1], *Jing Xuan*[1], *Zhi Liang*[2]
1. Institute of Botany, CAS
2. Robusoft (Beijing) Co., Ltd.

"iFlowers" is an APP for image-based plant identification developed by Institute of Botany, CAS and Robu soft Company. It is built by taking advantage of deep learning techniques and based on about 3 million classified plant photographs of over 25 thousand plant species from the database "Plant Photo Bank of China" (PPBC). Through comprehensive use of deep convolution network, image semantic analysis, fine-grained identification and other fields of technology to achieve the image recognition training and detection, the program has realized the immediate identification of plant species. The program's image recognition training has been completed for China's common wild or cultivated plant species, and the real-time shooting recognition has been achieved for more than 11,000 species that covering most of the common species. Not like other APPs, the images used for identification in "iFlowers" are not limited to specific parts of a plant, and the program have realized the identification of all types of vascular plants, such as ferns, gymnosperms and angiosperms. This program can provide service through APP on android and iOS, WeChat public platform (cn-flora) and the website (http://stu.iplant.cn).

Effects of drought stress and calcium levels on some traits of seed corn (Ksc704)

Ali Zaree
Damghan branch Islamic Azad University, Damghan, IRAN

Drought stress reduces the relative water content of plant tissues, limits plant growth, and causes some physiological and metabolic changes in plants. This research compared the effects of calcium on seed yield and on seed oil, protein, and calcium contents of seed corn grown under conditions of underirrigation. A split-plot experiment was conducted using the randomized complete block design with three replications. The experimental treatments in the main plots included four irrigation levels (conventional irrigation, irrigation cessation at the 7-9 leaf stage for 12 days, irrigation cessation at the 7-9 leaf stage for 20 days, irrigation cessation at the 7-9 leaf stage until corn leaves curl). Three levels of calcium spray (the control sprayed with pure water, 4% calcium spray, and 8% calcium spray) were the treatments in the minor plots. Results showed that the maximum seed oil and protein contents were achieved under the mutual effects of irrigation and calcium spray. The highest and lowest seed oil contents were observed in the treatments of conventional irrigation and 8% calcium spray (7.1%) and irrigation cessation at the 7-9 leaf stage until the leaves curled and also in the control treatment (4.81%). However, the treatment of irrigation cessation at the 7-9 leaf stage until the leaves curled and 8% calcium spray resulted in the highest seed protein content (9.43%), and the treatment of conventional irrigation and the control treatment had the lowest seed protein content (8.83%). Results indicated seed oil and protein contents had an inverse relationship: increases in one led to decreases in the other. Considering these results, we can conclude that calcium application under conditions of underirrigation leads to stability of cell walls and increases plant tolerance to drought stress.

Protection and utilization of endangered species, *Acer pentaphyllum*

Shang Gao[1,2], *Dan Li*[1], *Yaqiong Cao*[1], *Jun Zeng*[1], *Shaokui Liu*[1], *Fei Li*[1], *Jiaojun Xu*[1], *Yanbo Hu*[1]
1. Sichuan Engineering Laboratory of Breeding & Cultivating for Colorful Plants
2. Sichuan Colorful Forestry Co., Ltd

Acer pentaphyllum, as a deciduous tree of maple species is endemic in southwest China. It is regarded as one of the world most ornamental valued tree of maple species for its unique leaflets and colorful leaves. In western horticultural field, it is as famousas the Chinese noted dove tree (*Davidia involucrata*). *Acer pentaphyllumis* an endangered species which needs retrievable protection now, and it is also very important to research the origin and successions of maple species. Meanwhile, it's a rare ornamental tree which can make the urban environment more colorful and comfortable. With the protection and utilization, the protection awareness of *Acer pentaphyllum* will be improved further. The propagation of *Acer pentaphyllumis* mainly by seeds, but the population is tiny, which produces certain influence to the breeding efficiency. In this study, a rapid tissue culture system of *Acer pentaphyllumhas* been established. In direct organogenesis way, axillary buds were firstly induced from the stem segments with 0.1 mg/L 6-BA and 0.05 mg/L TDZ, then the axillary buds were proliferated using 0.1 mg/L 6-BA and 0.5 mg/L CPPU, and the regenerated plants were obtained from buds by 0.5 mg/L NAA finally. The study provides a way for saving the endangered species, furthermore, the research finds an approach for landscape application of *Acer pentaphyllum*.

A quick method to access high quality plant images in the wild and indoor

Xin Zhong
Shanghai Chenshan Botanical Garden

We have established a set of shooting methods that can be used to quickly obtain high-resolution images of plants in the field and indoor. In the study of plants, we need to use pictures to show the morphological characteristics of plants. In the past, too shallow depth of field has been a problem: the image outside the focal plane in any case will have a certain degree of fuzzy. Shrinking the aperture and using the flashlight can alleviate the problem to a certain extent, but it can not be solved fundamentally. So, in the digital age, all this has a whole new solution: depth of field stacking, blending all the sharp areas together and produce a completely sharp image. But in the past, this technology can only be used for indoor plant shooting with tripod. We try a number of software and established a set of method that a technician can work in the field, and then get the panoramic picture of plants. All the steps based on modern computers and digital cameras, which take focus stacking to a whole new level, automatically stacking tens or hundreds of frames to make astounding images from microscopy that once could never capture in a single shutter click. These images thus obtained can be used for large format output and printing, fully reflecting the microstructure of the plant, and even replace the dissecting microscope with camera.

Selection of medium for cultivation of *Idesia polycarpa* Maxim. var. *vestita* Diels

Jingbo Zhou[1], *Zirui Zhao*[2], *Hong Chen*[1], *Yuan Jiang*[3]
1. Anhui Vocational & Technical College of Forestry
2. Shanghai Bohao Biotechnology Corporation
3. Anhui Agricultural University

Idesia polycarpa Maxim. var. *vestita* Diels is a kind of important energy and ornamental plant that has the very high utilization value. In order to improve the seed germination rate and cultivate the high quality seedlings, there is need to find an optimal cultivation medium for seedling growth of *Idesia polycarpa* in a plastic cave tray (plug seedling). In this study, four types of media including M1 (soil), M2 (peat : perlite = 2:1), M3 (peat), and M4 (peat : perlite : vermiculite = 2:1:1) were tested in industrialized plug seedling. The seedling growth of *Idesia polycarpa* including plant height, crown diameter, leaf counts, ground diameter, the relative chlorophyll contents of leaves, *etc*. was measured. The results indicated that medium M2 was the best one for the increases in seedling height, crown diameter, leaf counts, ground diameter and the relative chlorophyll contents of leaves. Therefore, medium M2 is recommended in the industrialized nursery process for the seedling growth of *Idesia polycarpa.*

Archived lichen and fungi (1852 – 2010) as biomonitors of atmospheric lead contamination in Australia

Liqin Wu
1. Department of Environmental Sciences, Macquarie University, Sydney
2. Department of Environmental Science and Engineering, Guangzhou University, Guangzhou

Archived lichens (*Cladonia* and *Usnea*) and fungi (*Trametes*) obtained from various herbaria were used as reliable biomonitors of atmospheric lead contamination throughout the Greater Sydney area (New South Wales, Australia) and central and southern Victoria. Lead (Pb) concentrations and their isotopic compositions were determined for the lichens and fungi that had been collected and archived over a 150-year period. The findings in this study show that early metal mining activities have been responsible for elevated Pb levels observed in lichen and fungi archives dating back to the 1880s, particularly in central and southern Victoria. Elevated median Pb values were also measured in archival samples from the leaded petrol era (1932–2001) for both the Greater Sydney and central and southern Victoria regions. Lower median Pb levels were found in samples collected post 2002, following the cessation of leaded petrol consumption in 2002. Lead isotope data of lichens and fungi indicated that the most likely sources of atmospheric lead contamination were natural background lead, leaded gasoline combustion and industrial lead emissions, inter alia other secondary sources. Despite the removal of Pb from petrol, the contemporary lichen and fungi samples investigated in this study demonstrate that emissions from lead sources are persistent in the environment.

Studies on chemical constituents in the roots of *Suaeda glauca*

Yu Shan, *Qizhi Wang, Ming Wang, Fuqin Guan, Fei Liu, Yu Chen, Min Yin, Shu Xu, Xu Feng*
Institute of Botany, Jiangsu Province and Chinese Academy of Sciences, Nanjing Botanical Garden Mem. Sun Yat-Sen

Suaeda glauca (Bge.) Bge. belongs to the family Chenopodiaceae, which is one of the wild resources in saline soil. It is also a dominant species of halophyte in developing the seawater-irrigation agriculture. As a high-quality vegetable and plant resource with the value of health care, there is a broad prospect for its development, which is lack of system research. The chemical constituents and its activities in the roots of *S. glauca* were systematically studied in this paper. In our study, 21 compounds were isolated from the ethanol extract of *S. glauca* by a variety of modern chromatography and spectroscopic methods. Their structures were elucidated by spectroscopic methods, including 1D-, 2D-nuclear magnetic resonance (NMR) and high-resolution time of flight electrospray ionization mass spectrometry (HR-TOF-ESI-MS), including Fourteen flavones: 6,7, 2′-trimethoxy- 5-hydroxyisoflavanone (SG-2), Rutin (SG-8), 5,8-dimethoxy-7,2′-dihydroxy isoflavanone (SG-9), 5,7, 8,2′-tetrahydroxyisoflavanone (SG-10), 5,8, 2′-trimethoxy-7-hydroxyisoflavanone (SG-11), 5,6-dimethoxy-5,2′-dihydroxyisoflavanone (SG-12), 5,6-dimethoxy-7,2′-dihydroxyisoflavanone (SG-13), Quercetin 3-O-β-D-glucoside (SG-14), 7,8, 2′-trimethoxy-5-dihydroxyisoflavanone (SG-15), 2′-hydroxy-6,7-methylenedioxy-S-methoxyisoflavone (SG-16), Kaempferol (SG-17), 5,6, 7,2′-tetrahydroxyisoflavanone (SG-18), 8,2′-dimethoxy-5,7-dihydroxyisoflavanone (SG-19), Quercetin (SG-23); Five sterols: Ergosterol (SG-1), β-daucosterol (SG-3), β-sitosterol (SG-7-a), Stigmasterol (SG-7-b), Spinasterol (SG-7-c); One triterpenses: β-Amyrin (SG-4); One lignan: (-)-syringaresinol (SG-21). Among which, SG-11 and SG-13 are two new compounds, SG-2, SG-10, SG-15, SG-18 are four new natrual products, SG-9, SG-12, SG-16, SG-19 are isolated from the genus *Suaeda* for the first time. The pharmacological activities (cytotoxic effects, antioxidant effects) of isoflavones were evaluated in vitro. SG-2 and SG-12 show antiproliferation activity on human breast cancer cell lines (MDA-MB-231), with an IC50 value of 27.28 μM and 38.31 μM, respectively. The study provides essential chemical information for further development of *S. glauca*.

Evaluation and optimization strategies of green spaces in suburban forest parks of Shanghai, China

Ting Zhang
Shanghai Botanical Garden

Nowadays, Chinese society is facing the challenge of urbanization. With such a fast-paced urbanization in China, the suburban forest park, as the live public infrastructure, is increasingly seen as the new direction in the development of forest park in China. During last few decades, lots of suburban forest parks have been built to meet increasing population recreation requirements in Shanghai, China. In this study we investigate landscape characteristics of 52 sample spots distributed in 7 typical suburban forest parks of Shanghai. We evaluate the quality of the spots varying in 5 types of vegetation structure using the methods of Delphi and AHP. The evaluation system involves twelve indicators (species number, local identify, community structure, health status, ornamental characteristics, individual forms, spatial pattern, seasonal change, the pro-green border, environmental quality, activity quantity and recreation facility), which are belonged to three factors (ecological naturalness, scene beauty and recreational support). The results show the following conclusions. First, tree-shrub-herb structure accounts for 68% of all samples, while tree-herb and shrub-herb layer accounts for 32%. Branch height of horizontal canopy vegetation and highly enclosed vegetation is about 3.2 m, which are higher than those of open grass, semi-open grass with moderate vegetation and vertically enclosed space (2.3 m). Second, semi-open grass with moderate vegetation receives a higher score (7.45) than that of the other four types, followed by open grass (6.89), vertically enclosed vegetation (6.78), horizontal canopy vegetation (6.44) and highly enclosed vegetation (5.66). Third, the horizontal canopy vegetation and highly enclosed vegetation, accounting for nearly 2/3 of all the samples, receive high score in ecological naturalness factor but low in recreational support. Accessible boundary and clean environment in the interior forest landscape should be created to improve their recreation suitability. Meanwhile, open grass and vertically enclosed vegetation are estimated as scenic beauty but get lower score in ecological naturalness. More variation in species and more naturally and densely vegetated area should be able to increase the ecological stability and wide attractiveness.

The ecological mechanism of bryophytes diversity restoration on Volcanic Lava landforms

Xueliang Bai, Yu Wang, Le Zhang

College of Life Science, Inner Mongolia University, Hohhot

The classification and determination of 3247 bryophytes specimens, which were collected from Wudalianchi Volcanos, present 47 families, 128 genera, 286 species and varieties. It is notable in dominant family phenomenon, and the xeric moss Pottiaceae is the largest family. Liverworts is not one of 10 dominant families. Four species are new to China. The variety of species is the highest in the new-period volcanos. Along with the increasing age of the volcanos, the number of bryophytes species, genera and families shows a decreasing trend. Bryophytes are the preponderant vegetative cover in the new-period volcanos, and the microhabitat plays an important role in distribution pattern of bryophyte. The plant modular theory and method are used to determinate the number of archegonium, capsula, reproductive branch and vegetative branch in 15 dominant species. Most species of the ramet ratio in young moss is bigger than the ratio in old moss, which has a growth age structure. The amount of vegetative branches is more than reproductive branches, most species are mainly vegetative reproduction. We found that *Rhytidium rugosum* and *Racomitrium canescen*s have a high speed in spreading, but slow in thickening, which leads to great area species. *Ptychomitrium sinense* and *Grimmia pilifera* grow in an opposite way, which leads to small hill. The study on age structure of population will contribute to the prediction of population development, succession trend, restore potential of species, and restoration of plant diversity in volcanic landforms. The study is significant for the invasion, expansion and maintaining mechanism of bryophytes on the volcanic bare land. It also can provide scientific information for the protection of diversity of botanical species and scientific management in volcano natural reserve. In addition, the study could assist long-term monitoring of volcanic activities.

Prelinnean specimens kept in Herbarium of St. Petersburg State University (LECB), St. Petersburg, Russian Federation

Valentina Bubyreva[1], Vyacheslav Byalt[2]

1. Saint Petersburg State University

2. Komarov Botanical Institute RAS

Herbarium of the Botany Department of the Saint Petersburg State University (LECB) is one of the largest university herbarium of Russia. Its funds contain at least 800,000 herbarium sheets of higher plants. Now Herbarium collection is unique in the structure of the University, both in historical and in scientific terms by geographical coverage and systematic collection of funds, the existing type specimens (more than 3,500 types in the present, as we found). The type collection includes quite a significant amount of rare and original authentic specimens collected by various botanists such as E. Boissier (1810–1885), V. Borbas (1844–1905), H. Cuming (1791–1865), A.P. Decandolle (1778–1841), J. Forster (1754–1794), W. Hooker (1785–1865), G. Schimper (1804–1878), V. Tineo (1791–1856), W. Besser (1784–1842), A. Bunge (1803–1890), R. Hohenacker (1798–1872), G. Karelin (1801–1872), I. Kirilov (1822–1842), St. Krasheninnikov (1711–1755), C. Ledebour (1785–1851), R. Maack (1825–1886), K. Meinshausen (1819–1899), C. Meyer (1795–1855), A. Nordmann (1803–1866), P. Pallas (1741–1811), Ch. Steven (1781–1863), N. Turzaninov (1793–1863), A. Shrenk (1816–1876) *etc*. This Herbarium is probably one of the oldest as Russia storage facilities. The oldest herbarium specimens kept in LECB, belong to the middle of XVII century, or even the end of XVI century. Prelinnean specimens found by us in G. Bongard (1786–1839) and E. Lindemann (1825–1901) collections. Thus, according to Lindemann, in his collection during his lifetime were kept for more than 60 specimens collected by prelinnean J. Breyn (1637–1697) (36), C. Bauhin (1) (1560–1624), A. Clegero (1) (he collected *Juniperus japonica* from Japan in 1688), J. Gmelin (1709–1755) (20). Many specimens found in Bongard's herbarium, but how many relics it contains is difficult to say, since Bongard did not kept accounting herbarium revenues. Currently LECB, revealed more than 60 prelinnean specimens. The most of them were found in herbaria Bongard – specimens belonged to J. Commelin (1629–1692), C. Commelin (1668–1731), Breyn, P. Hermann (1646–1695), G. Steller (1709–1746), Gmelin *etc*., as well as in the herbarium Lindemann to Bauhin, Clegero, Breyn, Gmelin, *etc*. Currently, the oldest specimen found in LECB, is a specimen of C. Bauhin (1560–1624) – *Jucca gloriosa* L., without an exact date on the label, but, undoubtedly, belonged to Bauhin. Some of the old specimens have only historical interest, other are syntypes for species of C. Linnaeus (1707–1778), P. Pallas (1741–1811), J. Lamarck (1744–1829) and others, which is why value these specimens is particularly large. Examples of these types: *Melanthium sibiricum* L., *Anthericum calyculatum* L., *Convolvolus ammannii* Desr., *Convolvulus lineatus* L., *Yucca gloriosa* L., *Andromeda stelleriana* Pall., *Claytonia arctica* Adam, *Claytonia sibirica* L., *Alyssum hyperboreum* L., *Phlox sibirica* L. Thus, LECB is the third in Russia after Moscow State University Herbarium (MW) and Komarov Botanical Institute RAS (LE), which revealed prelinnean specimens, and some of which refers to syntypes of Linnean taxa.

Geographical distribution and conservation of the rare and endangered plant *Madhuca pasquieri* (Dubard) Lam.

Linying Cai, Xinyuan Zhang, Ding Ma, Lu Zhang

South China Agricultural University, Guangzhou, China

As an important component of biodiversity, rare and endangered plants are one of the core contents of conservation biology. *Madhuca pasquieri* (Dubard) Lam. as a rare species currently, its endangered level is Vulnerable (VU) in IUCN Red List. In China listed as national key protected wild plants (II) and wild plants of extremely small populations, it is a kind of rare oil tree species and precious timber species with high medicinal value. With global climate change and habitat fragmentation, it is rather important to study the current situation of *Madhuca pasquieri* (Dubard) Lam. and formulate relevant conservation strategies. In the paper, based on the data of conservations and managements of natural distribution and specimen records of herbariums, the database of the natural geographical distribution was established. At the same time, the population and community characteristics of the main distribution sites were compared, and the current research and protection at domestic and overseas were systematically analyzed. The results showed that: 1) The natural distribution of wild populations of *Madhuca pasquieri* was mainly concentrated in the northern Vietnam, the southern Guangxi, the southwestern Guangdong and the southeastern Yunnan. The vertical distribution range of *Madhuca pasquieri* is wide. In Yunnan, the wild populations grow well above 1,000 m above sea level. In Guangxi and Guangdong, *Madhuca pasquieri* are mainly distributed in the low altitude of 100-600 m mountains or hills; 2) Wild individuals of *Madhuca pasquieri* are scarce, mainly scattered in the nature reserve with less human disturbance. The climate is warm and humid, and the zonal soil are krasnozem and laterite soil. The species composition of the community of *Madhuca pasquieri* forest is richness. *Madhuca pasquieri* is the dominant species in the main forest layer or important companion species in acid rain forest in Guangxi, but the saplings and seedlings of *Madhuca pasquieri* are rare; 3) The artificial cultivation, growth characteristics and chemical composition of *Madhuca pasquieri* has been research. However, these research are still in primary stage. We need to combine the field investigation and long-term experiment, and then use the habitat distribution model to predict the suitable field for the reintroduce of *Madhuca pasquieri* based on *in situ* conservation and *ex situ* conservation. Combining with molecular biological techniques, breeding and cultivation techniques of *Madhuca pasquieri*, expanding its artificial population, we can actively develop its medicinal value, the oil value and timber value, popularize its application in landscaping. In addition, understanding of the origin and evolution of *Madhuca pasquieri* at the molecular level and exploring the endangered mechanism can provide theoretical basis for the effective protection of *Madhuca pasquieri*.

Physiological response of marine diatom *Phaeodactylum tricornutum* to iron concentration in laboratory condition

Zhuoping Cai

Ecological Society of Guangdong Province

Iron supply may influence the biomass, growth rate, composition and primary productivity of phytoplankton in the ocean. The phenomenon of high nutrient low chlorophyll (HNLC) has implied the restriction effect of iron. Most studies have been concentrated in the effect of iron form on the growth, proliferation and structure composition of phytoplankton; yet additional studies on the response of phytoplankton to the iron concentration are urgently required. In the present study, optical density of algal culture, specific growth rate, cell density, cell biomass, chlorophyll a and protein of *Phaeodactylum tricornutum* were characterized in a laboratory simulative experiment by employing a range of varying iron concentrations including 3.15,6.30,9.45,18.90 and 34.65 mg·L^{-1}, so as to investigate the growth characteristics and some important biochemical compositions of marine microalgae in response to iron concentrations. Our results indicated that algal growth differed greatly under the different iron concentrations. The highest optical density at 450 nm (OD450) was 0.877 under the iron concentration of 6.30 mg·L^{-1} in the end of trial; it was decreased with continually higher iron concentrations. Specific growth rate and cell density increased obviously with the increasing iron concentrations within the range of iron concentration from 3.15 to 9.45 mg·L^{-1}, whereas much higher iron concentrations resulted in a decrease of specific growth rate and cell density. In addition, the cell biomass also appeared to be concentration-dependent, which was increased gradually over the entire range of iron concentrations. Iron concentration also caused significant changes in the chlorophyll a content and protein content of marine microalga *Phaeodactylum tricornutum*. For the chlorophyll a content, it rose under iron concentration ranging from 3.15 to 18.90 mg·L^{-1}, but declined under continually higher iron concentrations. For the protein content, it was increased by 9.45 mg·L^{-1} iron concentration but decreased by much higher iron concentrations, with the lowest protein content of 0.104 mg·L^{-1} under the iron concentration of 34.65 mg·L^{-1}. The results suggest that iron concentration is playing a role in the phytoplankton proliferation and metabolism; while there is an optimal concentration range for the growth and physiology of marine microalga *Phaeodactylum tricornutum*. These findings can provide a theoretical base for the control of red tides along the coastal waters and protection of marine biological resources.

Uncaria rhynchophylla (Rubiaceae): A medicinal dietary plant used by Gannan Hakkas in Southern Jiangxi (China)

Limin Cao, *Hua Xu, Xuexiong Wang*

Gannan Normal University

Wild medicinal dietary plants provide food as well as economic income for the indigenous people and are of great importance in treating human diseases. Gannan Hakkas area, Jiangxi Province, southeastern China, is known for its cultural diversity and biodiversity. The Gannan Hakkas (*kejiaren,* belonging to the Han branch, has a thousand-year history), have accumulated traditional knowledge of the utilization of wild plants, especially the medicinal dietary plants, such as *Uncaria rhynchophylla* (Miq.) Miq. ex Havil., *etc*. As a woody lianas of the family Rubiaceae, *Uncaria rhynchophylla* is mainly found in Jiangxi, Hunan and other regions of southernChina. *U. rhynchophylla* is a medicinal dietary plant used by the indigenous people to treat a wide range of body disorders. The hook-like stems of *U. rhynchophylla* are called the world's oldest medicine, mainly used as oral medicine, while its other medical uses remain unknown. In addition to medical applications, its dried stems, roots and root barks are traditionally used by the Gannan Hakkas as food and substitutes of tea. So far, its chemical composition has been documented, but the nutritional elements are unclear. In this paper, we collected the ethnobotanical data of *Uncaria rhynchophylla* from May 2013 to October 2015. The nutritional components (trace elements: Cu, Zn, Fe, Mn, Se and amino acidsthe Gannan Hakkas have provided ethnobotanical information for the modern world. The nutritional component information may indicate that the plant has enormous potential for development as a medicinal dietary plant from Gannan area. Both safety and economic development of the plant should be conducted to allow them to be used to improve health and prevent diseases in the further studies. *Uncaria rhynchophylla* is endangered with economic development, such as deforestation for agricultural purposes, flood, over-harvesting and firewood collection, *etc.* At the same time, the related traditional knowledge is in danger of being lost. Thus, conservation and sustainable utilization of this plant in this area are of the utmost importance.

Genetic diversity and relationship analysis of *Phalaenopsis* germplasm resources

He-Ming Chen[1,2], *Fu-Bing Lv*[1,2], *Zuo Li*[1,2], *Wen-Fang Xiao*[1,2]

1. Environmental Horticulture Research Institute of Guangdong Academy of Agricultural Sciences

2. Guangdong Provincial Key Laboratory of Ornamental Plant Germplasm Innovation and Utilization

Phalaenopsis is the plant of orchids (Orchidaceae) which was the earliest discovered in 1750, and it has been found more than 70 native species which most distribute in the hot and humid regions of Asia, but *Phalaenopsis* of artificial breeding is widely planted in different parts of the world which is one of the world popular tropical orchids and is deeply loved by the masses, known as the orchid queen.At present, the study of *Phalaenopsis* mainly focused on cross breeding, tissue culture and rapid propagation, cultivation and management, disease and insect control, *etc.* But the reports were very few about the genetic diversity and relationship of germplasm resources. Therefore, the genetic distance and R cluster and Q cluster were analyzed through cluster method for 213 germplasm resources of*Phalaenopsis* in order to provide the reference for breeding, classification, application, and genetic relationship. From the frequency analysis, the genetic distance was mainly focused on 0.0 - 0.6 and 0.6 - 2.4 which accounted for 54.93% and 32.86% of germplasm resources respectively, that is, 87.79% focused on 0.0 - 2.4 which showed that the genetic distance was relatively narrow and genetic diversity was relatively low.So hybridization or hybrid of native species with germplasm will make germplasm resources rich. R type cluster analysis showed that 4 traits of leaf (leaf shape, leaf shape, leaf attitude, leaf anthocyanin coloration, leaf texture) and 11 traits of flower (peduncle color, inflorescence type, flower length in front view or flower diameter, flower petals thickness, number of flowers, flower fragrance, flower color, lateral sepal shape, petals shape, lip pubescence and type) played an important role in classification. Q type cluster analysis obtained that 213 resources could be divided into two types in binding line L1= 4.667, namely hybrid and native species, the two types were subdivided into 20 small classes according to the various varieties of similar traits which basicly found out relationship of *Phalaenopsis* germplasm resources.

Synchronous characterization secondary metabolites and carbohydrates in *Bai-Hu-Tang*

Wei-Fang Zhong, Wing-Sum Tong, Shan-Shan Zhou, ***Jun Xu,*** *Hu-Biao Chen*

Hong Kong Baptist University

Bai-Hu-Tang (BHT) consists of four traditional Chinese medicines (TCM), i.e. Gypsum Fibrosum (GF, Shigao), Anemarrhenae Rhizoma (AR, Zhimu), Glycyrrhizae Radix et Rhizoma Praeparata cum Melle (GR, Zhigancao) and non-glutinous rice (NR, Jingmi). In order to characterize the elusive chemical composition of BHT, a combination of analytical approaches including ultra-performance liquid chromatography coupled with quadrupole time-of-flight mass spectrometry (UPLC-QTOF-MS/MS) and ultra-performance liquid chromatography couple with photodiode array detector (UPLC-PDA) was developed and validated to simultaneously qualitative and quantitative determine secondary metabolites and carbohydrates in BHT. The selected ion monitoring mode of QTOF-MS was used to quantify 10 major secondary metabolites, totally, 42 compounds in BHT were tentatively or definitely identified based on the quasi-molecular ions, molecular ions and fragment ions characteristic to each analyte. Meanwhile, pretreatment-UPLC-PDA was selected to characterize sugar composition and content analysis of carbohydrates in BHT. The results demonstrated that the developed methods were instrumental in quality control of BHT. Therefore, the study strengthens the research on the chemical characterization of secondary metabolites and carbohydrates of BHT, which provided a comprehensive analytical strategy for the further chemical and biological evaluation of TCM formulas.

Characteristics of *Platycladus orientalis* natural forests in Yin Mountains

Long Chen[1], *Liqing Zhao*[2]

1. Natural Energy Research Institute

2. Inner Mongolia University, Hohhot, China

Platycladus orientalis natural forests in Yin Mountains are the northwest boundary of Chinese *P. orientalis* natural forests and also one of the most important forest communities, with well solid slope, soil conservation, water conservation and the important role of improve habitats. We selected *P. orientalis* natural forests as the research object, through quadrat investigation, the *P. orientalis* natural forests divided into 8 associations. Studied the characteristic of the flora of *P. orientalis* natural forests, structure characteristic of each association, and the diameter structure of *P. orientalis*. And analysised the ecological series between associations space. The results showed that: (1) There are 96 vascular plants belonging to 30 families, 70 genera in Yin Mountains' *P. orientalis* natural forests; depending geographic component of species, they are contain 8 types and 17 subtypes, the most is the East Pan-North Pole distribution, followed by the distribution of East Asia; (2) The diameter structure of *P. orientalis* follows a typical left partial normal distribution which is a typical growth population, average plant height increased with diameter overall linear growth model; (3) From the analysis of community structure, well-developed side of the *P. orientalis* natural forests showed significant tree layer, shrub layer and herb layer, partly because of human disturb, shrub coverage is generally low, especially disappeared; (4) Disturbed by human extremely, these *P. orientalis* natural forests are in the early stages of development, the average diameter of *P. orientalis* is smaller, and they are also more bifurcation. So we suggest that regarding these *P. orientalis* natural forests as ecological forest and ornamental plantation.

The flowering biological characteristics of caltrop (*Tribulus terrestris* L.)

Panfeng Dai, *Bo Yang*

College of Agricultural/ College of Tree Peony, Henan University of Science and Technology

In order to research the biological characteristics and pollination of caltrop (*Tribulus terrestris* L.), the details of its dynamic flowering, pollen viability and stigma receptivity, pollen count and the number of ovule ratio (P/O value), insects visit flowers behavior and frequency were tested, and *T. terrestris* have been processed in different ways of mating. The results showed that: (1) Population blossom lasts for about 4 months, single flower open lasts one day. (2) Pollen activity continuous downward from high level in the beginning and only be held for about two hours. (3) pollen - ovule ratio of 173, and the outcrossing index (OCI) 2 combining with the results of different mating process showed that the presence of caltrop facultative autogamy self-pollination phenomenon. (4) The most effective pollinators of *T. terrestris* were bees of Apidae and butterfly of Pieridae. Research shows that the breeding system of *T. terrestris* belongs to facultative autogamy. Pollinating animals have an important role to significantly improve their seed rate.

Flowering characteristics and pollination biology of *Dicranostigma leptopodum*

Panfeng Dai, *Zhen Meng, Qiqi Luo*

College of Agricultural/ College of Tree Peony, Henan University of Science and Technology

Wild *Dicranostigma leptopodum* in Luoyang was introduced and blossom characteristics was observed through early spring period. Pollen viability, stigma receptivity, pollen and ovule ratio (P/O) and outcrossing index (OCI) were examined, and artificial pollination test was developed. The main results are as follows: the anthesis of *D. leptopodum* was about 5 days, the population flowering continued for about 56 days. Pollen viability achieved the maximum about 91% at 1-2 h after four petals opening. And no pollen viability was detected after 3 days. Stigma achieved the maximum at 48 h and sustained acceptance about 8 days after opening. The pollen ovule rate (P/O) was 5193.8, and the outcrossing index (OCI) was 5. According to the artificial pollination test, the fruit set rate and seed set rate of *D. leptopodum* were 18.54% and 6.43%, respectively. The results mean that the breeding system was obligate outcrossing and need pollinators as pollinating agents. Insects about 8 species were observed to visit the flower of *D. leptopodum*. The most effective pollinators among these floral vistors were bees (*Apis dorsata*) and (*Sphaerophoria* sp.).

Ethnoveterinary investigation of medicinal plants in Tibet autonomous region

Songjia Dai[1]*, Dexin Xu*[1]*, Long Chunlin*[1,2]

1. Minzu University of China, Beijing, China

2. Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, China

Tibetan ethnoveterinary knowledge, as an important part of Tibetan traditional culture, is declining under the influence of the western medicine. Through the combination of field work and literature research, the common diseases of Tibetan livestock, the Tibetan people's cognition of these diseases and the treatment with ethnoveterinary medicinal plants are gathered and analyzed through the approaches of anthropology, ethnobotany, and linguistics. On this basis, 38 plant species which have been used in the treatment of common livestock diseases in Tibet are analyzed by means of phytochemical and pharmacological information reported previously. The results showed that 30 species of them can be scientifically explained based on the existing literatures, while the remained 8 species need to be further studied in the laboratory. Although the cognition and practice of Tibetan ethnoveterinary medicinal plants have distinct regional features, they are demonstrated scientific implies to some extent.

Collections of the Main Botanical Garden of Russian Academy of Sciences as a base of plant biodiversity conservation

Alexander Demidov, *Mikhail Shustov, Svetlana Potapova*

Main Botanical Garden named after N.V. Tsitsin, RAS

Collections of the Main Botanical Garden is a national and world heritage. Currently the living collections comprise 18,259 taxa: 10,729 species, varieties, forms and 7,530 sorts of plants. They are placed in exposition and collection sites, “The Natural Flora” (1,759 taxa), “Arboretum” (1,564 taxa), “Ornamental Plants” (5,690 taxa), “Cultivated Plants” (2,478 taxa), “Japanese Garden” (100 taxa), “Stock Greenhouse” (6,768 taxa). Cheboksary Branch collections include 2,810 names of plants. The main scientific direction is the development of theoretical bases and the general issue of introduction and acclimatization of plants: analysis of flora and attraction of plant resources in Russia and from abroad; initial assessment of new plants; variation of plants in the nature and under the influence of the transfer from nature to the culture; development of methods of cultivation. The next area - the scientific basis of conservation of plant genetic resource of natural flora *ex situ*: identification in nature and study of rare and endangered plant species; formation of collections of species to be protected; development of methods of cultivation and reintroduction of endangered plant species back to natural plant communities; storage of seeds and plant meristems. One of the key areas – development of scientific bases of ornamental gardening and landscaping: the introduction and study of ornamental plants of natural flora; attracting and testing of diversity of ornamental plants; variety assessment, selection and implementation of valuable varieties in landscaping. Development of theoretical bases and methods of protection of introduced plants from pests and diseases – scientific problem, which is of great practical importance. It is especially relevant for institutions working with introduction of large number of various plants that differ in their biological characteristics and resistance to pests and diseases. An important area of research is to develop the theoretical bases of remote hybridization to create new species, forms and varieties of plants: the scientific basis of hybridization with wild crop; search for new ways of management the processes of speciation and intermutation at remote hybridization. Establishing a National Center for Genetic Resources of wild and cultivated plants will help to fulfill some actual tasks: - organization of the Central Bank of seed and meristems of wild plant flora of Russia; - development of effective methods for clonal micropropagation and conservation of the gene pool of rare and economically valuable plant species in vitro; - creation of online databases "Biodiversity of plants of Russia", "Rare species of Red Book of the Russian Federation, stored in the botanical gardens of Russia? - conducting experimental work on the introduction of less-known and less common fruit, berry, ornamental, new medicinal and aromatic plants; - organization on the basis of inter-institutional ecosystem monitoring center under the stress of anthropogenic pressures; - development of environmental protection methods from diseases and pests. So, collections of The Main Botanical Garden to named after N.V. Tsitsin are able to make a major contribution to strengthening global environmental and food security.

Checklist of local spermatophyte above the slope and artificial slope in urban areas of Lanzhou

Pin Ding, *Jian-Rong Wu, Jin-Xia Li*
Gansu Provincial Academy of Sciences Institute of Biology

Objective: Through investigating, sampling, identifying the slopes and artificial slopes in urban areas of Lanzhou, to provide reference for the selection of the appropriate local plants in artificial slope, and for the data support to study the changes of the plants at slopes and artificial slopes in Lanzhou; Mothed: Begin with June 2013, October 2015 to end, to research, collect and identify the plants at slopes and artificial slopes which gradient are more than 20 degree, and record the plants species; Results: Recorded vascular plants 26 families, 65 genus, 86 species; Conclusion: The numbers of plants species at slopes and artificial slopes were less than in the whole Lanzhou. There were the largest number of species in Gramineae at the slopes and artificial slopes in urban of Lanzhou, Chenopodiaceae and Compositae were the next. For slope and artificial slope greening, it can consider Gramineae or the mode of Gramineae combination of Compositae and Chenopodiaceae.

Novel *Cynomorium songaricum* polysaccharides with enhancement of T cell immune response

Haiyan Fan, *Guilin Chen*
Inner Mongolia University

Cynomorium songaricum, known as "suo yang" in China, is a wild perennial plant mainly parasitizing on the roots of genera *Nitraria* which widely distributes across the deserts of Northwestern China. Fresh *C. songaricum* has been used as edible food resources because of its medicinal and nutritious value. Dried fleshy stems of *C. songaricum* is generally used for reinforcing immune system, treating lumbar weakness and enhancing sexual ability in traditional Chinese medicine. Modern research revealed that polysaccharides from *C. songaricum* displayed a range of biological effects, including anti-fatigue, anti-ulcer, anti-oxidation-related disease, and hypoglycemic activity. So far, there is few reports upon *C. songaricum* polysaccharides (CSP) boosting immunological function because of difficulty to get them. In the current study, we have developed novel CSP that could enhance T cell immune response. The main factor affecting the yield of polysaccharides is the extraction and separation process used. Enzyme-assisted extraction (EAE) attracted much attention due to its high-efficiency, environmental compatibility and simplified manipulation overcoming the shortcomings of the conventional hot water extraction (HWE). Protease commonly has specific cleavage sites to cleave peptide bonds between hydrophobic and amino acids, and has no effect on fats and carbohydrates. EAE was applied for CSP to optimize extraction yield. The study comprised of three distinct stages, a single factor experiment design, a screening procedure using Plackett-Burman design, and an optimization response surface methodology using Box-Behnken design. The optimal extraction conditions were as follows: pH 1.5, liquid-solid ratio 108:1, and temperature 40°C. The optimal extraction conditions resulted in the highest CSP yield, i.e., 23.63±0.21%, which represented an increase of 233% compared to the yield obtained using HWE method. Preliminary characterization indicated that the total sugar, protein, reducing sugar?and uronic acid of the product were 90.63±0.77%, 1.07±0.19%, 1.46±0.029%, and 14.42±0.87% (w/w), respectively. Compared to CSP-HWE, CSP-EAE provided higher contents of polysaccharide as well as lower contents of protein. The CSPs were characterized by Fourier transform infrared (FT-IR) spectroscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM) and gas chromatography (GC). The results showed that CSP-EAE differentiated from CSP-HWE in functional groups and surface morphology leading to its distinct properties. Further research on the precise chemical structures and the unique biological functions of CSP-EAE are currently under investigations in our laboratory. Furthermore, CSP-EAE only showed moderate dose-dependent antioxidant activity *in vitro*. Encouragingly, a combination of CSP-EAE and tumor-derived autophagosome-based therapeutic vaccine (DRibbles) can induce functional 4T1 tumor-reactive $CD8^+$ T cells enhancement. It showed that CSP-EAE could mediate potent autitumor efficacy.

These findings will lay a foundation for future pharmacological and biochemical studies of *Cynomorium songaricum* polysaccharides.

Definitions of botanic garden and conservation of terminological diversity

Andrei Filimonov
Peter the Great St. Petersburg Polytechnic University

Analysis of laws, regulations, reference books and scientific publications reveals that the concept "Botanic garden" has constantly changed throughout more than two centuries (Filimonov, in print). Despite a number of discussions about the concepts definitions, this problem is still very actual (Wyse Jackson, 2009). From our point of view, the main reason for the observed terminological diversity is that most definitions of Botanic Garden were inspired by a local sociohistorical background, rather than by basic features of these institutions. To eliminate the discrepancy mentioned above, we propose the following definition: Botanic garden is a piece of ground, whose boundaries are determined in accordance with local legislation, which is used for the purpose of long-term cultivation and monitoring of properly documented and labelled specimens of wild and cultivated flora (mostly non-native), representing a wide range of taxonomic groups and intended for scientific research and (or) the education.

Research on nutritional components of root of *Apios fortune* Maxim

Shunhua Fu
Zhejiang A&F University

In China, *Apios fortunei* Maxim is rich and is used as food and medicine. But most of it is still in wild and lack of basic research. Here, the general nutrient components, 8 mineral elements and 17 amino acids were studied by the experiment material from 4 sites of different provinces. The results show: The contents of crude protein, crude fiber, polysaccharide and soluble protein, sugar and starch content in it are determined. The results show that the contents of soluble sugar, crude fiber and polysaccharide in different areas are very different, while the difference of starch and protein content is relatively small. The content of soluble sugar, polysaccharide, starch and protein is decreasing with the increase of growth age, and starch is increasing with the increase of year in Pan'an, Zhejiang Province and Shan xian, Shandong Province. The contents of 8 mineral elements in it are determined. The results show that the contents of P, Ca, Mg and K in root of it are rich. P, Mg and Cu are the characteristic elements of it in Shanxian, Shandong Province, and Ca and Cu are the characteristic elements of it in Lanping, Yunnan Province. The element contents of P and K in it of Pan'an, Zhejiang Province, and Shanxian, Shandong Province are significantly decreased with the increase of growth age, and the contents of Ca and Mg are contrary.The microelement content of Fe and Mn increase with the growth age, and the content of Cu and Zn is oppositely trend. In it 15 kinds of amino acids is rich, is lack of Cystine, Methionine. The total amount of amino acids in different sites is ranked as follows: Shanxian, Shandong Province>Pan'an, Zhejiang Province> Lanping, Yunnan Province >Nantong, Jiangsu Province. The total amount of non-essential amino acids is: Shanxian, Shandong Province> Lanping, Yunnan Province >Pan'an, Zhejiang Province>Jiangsu Province; The total amount of essential amino acids in the order: Pan'an, Zhejiang Province>Shanxian, Shandong Province>Nantong, Jiangsu Province> Lanping, Yunnan Province. Among all kinds of amino acids, the Aspartic acid (Asp) is rich mostly and the Lysine is the first limiting amino acid. The ratio of essential amino acids to total amino acids (E/T)and the ratio of essential amino acids to nonessential amino acids (E/N) of 1 year average content of amino acids in Shanxian county in Shandong Province, Pan'an in Zhejiang Province are 32%, 48%, more than 2 year' 8.70%, 12.89%, respectively, which near the FAO/WHO standard (E/T is 40%and E/N is about 60%). According to the result of comprehensive evaluation by principal component analysis, the order of amino acid nutritional value is Shanxian, Shandong Province, Pan'an, Zhejiang Province, Nantong, Jiangsu Province and Lanping, Yunnan Province declinely. In summary, it is rich in nutrient content, beneficial amino acids and abundant mineral elements and it bring the broad development prospects for this resource plant.

The structure and dynamics of natural population of the endangered plant *Tetracentron sinense* Oliv.

Xiaohong Gan[1], *Huaichun Li* [1], *Shan Li*[1]
1. College of Life Science, China West Normal University
2. Key laboratory of southwest China wildlife resources conservation (Ministry of Education)

Tetracentron sinense Oliv. appears to have survived largely unchanged since the early Tertiary, like *Ginkgo* and *Mestasequoia*, and belongs to the family of Tetracentraceae. This species, the East Asian endemic species, a threatened deciduous broad-leaved canopy tree, with a distribution restricted to central and southern China, mainly lived in moist temperate deciduous, or mixed evergreen and deciduous forests or forest edge, above 1100-3500 m sea level. Due to the high demand for medicine, timber, ornamental and scientific research, the destruction of *T. sinense* resources recently reached a very serious degree, resulting in the continuous decrease of remaining wild population and individuals. As a consequence, *T. sinense* was listed in CITES, and listed as a national second-grade protected plant in China. Up to now, the natural population of this species is still at risk of extinction. Previous studies had focused on its systematic status, chemical composition, limiting mechanism of natural regeneration of natural population, but little is known about the survival status and dynamic of natural population of *T. sinense* so far. In order to explore the survival status of natural population and predict the population dynamic in the future, and discuss the protection countermeasures, the age structure and quantitative dynamics of the endangered plant *Tetracentron sinense* Oliv. natural population in Meigu Dafengding Nature Reserve in southwest China were studied through establishment of the time-specific life stable and survival analysis. The results are as follows. (1) Due to the strong screening effect of the environment, there was lack of seedlings, and only a few saplings and arboret, and vast majority of mid-arbors and arbors in natural population, indicting the decline tye of age structure with inverted pyramid character. (2) The life table of *T. sinense* population showed that the life expectancy of *T. sinense* is higher in first and 7th age class, and the survival curve of the population belonged to Deevey type II. The mortality rate and vanish rate curve of *T. sinense* population all showed two peaks in the 6th and 12th age class, so did the mortality density and hazard rate curve. The population survival rate of *T. sinense* decreased monotonically, whereas the cumulative mortality rate increased monotonically. (3) Survival analysis showed that population quantity of *T. sinense* population decreased steadily at earlier stage, and changed smoothly at middle stage, but declined in older stage, resulting in the sharp decrease of population quantity, which may be one of important factors limiting the natural regeneration of *T. sinense*.

Prioritizing fodder species based on traditional knowledge: A case study of mithun (*Bos frontalis*) in Dulongjiang area, Yunnan Province, Southwest China

Yanfei Geng[1,2,3], *Guoxiong Hu*[4], *Sailesh Ranjitkar*[2,5], *Yuhua Wang*[2], *Dengpan Bu*[5,6,7], *Shengji Pei*[2], *Xiaokun Ou*[1], *Yang Lu*[1,2,3], *Xuelan Ma*[2,3], *Jianchu Xu*[2,5]
1. Yunnan University
2. Kunming Institute of Botany
3. Universtiy of Chinese Academy of Sciences
4. Guizhou University
5. World Agroforestry Centre East and Central Asia
6. Institute of Animal Science, Chinese Academy of Agricultural Sciences
7. Hunan Co-Innovation Center of Animal Production Safety, CICAPS

Livestock rearing is one of the oldest and most important types of smallholder farming worldwide. The sustainability of livestock production depends on the efficient utilization of locally available resources. Some traditional methods of raising livestock may offer valuable lessons in this regard. This study documented and evaluated local knowledge of wild forage plants in the Dulongjiang area in Southwest China in the context of rearing mithun (*Bos frontalis*) in order to provide a sound evidence base for tree fodder selection and the establishment of integrated tree-crop-livestock systems. The snowball technique was used to identify key informants with specific knowledge about the topic. Free listing and semi-structured interviews were conducted with 58 households. Participatory investigation and transit walks were used to investigate potential fodder species. Ethnobotanical information was collected, documented and organized. Overall, 142 wild forage plants from 58 families and 117 genera were identified. Species of the Poaceae, Rosaceae and Urticaceae families were most abundant, with 16,14 and 11 species respectively identified as fodder plants. Our results indicated that tree/shrub forage plays a major role in the diet of mithun, unlike that of other ruminants. Mithun prefers to browse and move around the forest in search of food, particularly rough and even barbed leaves. Tree species like *Debregeasia orientalis*, *Saurauia polyneura* and *Rubus* species were identified as being important fodder sources. Farmers in this area have traditionally relied on common property resources such as community-managed forests and grasslands to feed their livestock. Farmers have strong incentive to raise mithuns rather than other livestock species due to Dulong people's cultural preferences. The wide variety of plants cited by the informants demonstrates the importance of traditional knowledge in gathering information about forage resources. This diversity also offers the prospect of identifying promising species which could be used as fodder plants. Identifying such species and tree fodder species in particular could help smallholder farmers to integrate trees, livestock and crops as part of a sustainable farming system.

Regeneration system of *Ammopiptanthus mongolicus* nodes

Qi Guo[1,2], *Peiya Wang*[1,2], *Jun Zhang*[1,2], *Tao Yang*[1,2], *Hui Yang*[1,2]
1. Institute of Biology, Gansu Academy of Sciences
2. Key Laboratory of Microbial Resources Exploition and Application, Gansu Province

A*mmopiptanthus mongolicus* (Masxim.) Cheng f. belongs to the Leguminosae plants, is a national third protection plant, is unique to the desert region of northwest China super xerophytic evergreen broad-leaved shrub, is also a kind of special constructive plants in Alaskan desert, plays a important role in maintaining the local ecological balance. Xinjiang province, Inner Mongolia, Gansu provinc are its main distribution areas. Narrow distribution range and human activities are two of the main causes driving this species to a risk of extinction. At present, many researchers tried to use the tissue culture technology to accelerate the breeding speed to get a number of tube seedlings in a short term. It is a way to protect its germplasm resources and expand its population. Young stem, stem segments and root as explants of A*mmopiptanthus mongolicus* were used in the callus inducition research. But callus differentiation was difficult accompanied by severe browning. Long-term subculture can cause the death of callus to making it impossible to be conserved in vitro. A protocol has been development for the establishment of regeneration system *in vitro* by using *Ammopiptanthus mongolicus* nodes. The number of shoots was highest when the 5-day-old explant cultured on B_5 medium supplemented with 1~2.0 mg•L^{-1}BA. Roots were efficiently established on B_5 medium supplemented with IAA 1.0~2.0 mg•L^{-1} and NAA 0.5 mg•L^{-1}.

Study on the population genetic structure of *Disanthus* (Hamamelidaceae)

Xueying Guo
Guangzhou University

Disanthus (Hamamelidaceae) is an East Asia endemic genus with the distribution pattern of East China and Japan disjunction. *Disanthus cercidifolius* subsp. *longipes* mainly distributes scatteredly in Chinese provinces of Guangdong, Hunan, Jiangxi, and

Zhejiang. *Disanthus* cercidifolius mainly distributes in Central Honshu and Southwest Honshu of Japan. In this study, the population genetic structure of 16 natural populations of *Disanthus* sp. based on the sequences variations of three chloroplast DNA fragments (*psbA-trnH, rps16F-R2, psaA-ycf3*) and nrDNA ITS were investigated. AMOVA analysis base on cpDNA and ITS sequence indicated that obvious genetic differentiation between the Chinese and Japanese subspecies. The result base on cpDNA sequence revealed that genetic variation occurred mainly between groups (53.08%), while 24.11% variation occurred among populations within groups and 22.80% variation occurred among individuals (within populations). The result base on ITS sequence revealed that genetic variation occurred mainly between groups (90.03%), while 5.01% variation occurred among populations within groups and 4.96% variation occurred among individuals (within populations). The total genetic diversity of *Disanthus* sp. is higher (Ht = 0.725), while the average genetic diversity within populations is lower (Hs = 0.148). As Nst is significantly larger than Gst (P<0.01), it demonstrats highly significant phylogeographic structure across the distribution range of *Disanthus* sp.

A floristic geography study of vascular plants in Guanshan mountain

Yi He, *Quanru Liu*
Beijing Normal University

Guanshan Mountain is located in the Loess plateau, China. As this area was governed by three different provinces separately, historically, there has been fewer integrated floristic investigations. Therefore, a detailed floristic research of this region is of great significance to the improvement of floristic data in Northern China, it also helps to solve the controversy on small-scale flora district division and protect plant diversity. In order to figure out the floristic composition and geographical component in this area, we investigated 14 comprehensive line transects, collected 1285 specimens, combining with 19 forest quadrats of 600 m^2 and 6 shrub quadrats of 100 m^2. Based on literatures and field works, we built a database of vascular plants of 12 typical mountain areas in Northern China for comparative study. The main results are summarized as follows: 1. Guanshan Mountain is a comparatively species-rich area. There are 1166 species (including infraspecies taxon) of vascular plants, belonging to 118 families and 480 genera. There are 34 fern species belonging to 22 genera in 11 families, 8 gymnosperm plant species belonging to 6 genera in 4 families and 1124 species of angiosperm plants belonging to 452 genera in 103 families; Families are significantly differentiated, the first 11 largest families contain 586 species; Genera are also differentiated: Big genera are highly developed, while middle and small genera occupy an important position; There are 20 mono-species genera and 46 minor-species genera, comparatively rich; The endemism of this area is pretty low: Only 2 species are endemic, combining with 8 genera, 325 species and no family endemic to China. 2. The geographical components are relatively complicated and diverse. Pteridophyte genera are divided into 6 areal types, mainly worldwide. The number of tropical types is more than that of temperate types; Seed plant families are divided into 11 areal types and 8 subtypes, mainly worldwide. Tropical types are more than temperate types; Seed plants genera are divided into 15 areal types and 7 subtypes, the proportion of temperate genera is as much as 70.79% (except the worldwide types), especially the north temperate type. 3. Comparing with other 11 nearby mountains, Guanshan Mountain is most closely related to Liupan Mountain, rather than Ziwuling Mountain and Huanglong Mountain. At species level, the gini coefficient and species composition analysis show that Guanshan Mountain is the most similar to Liupan Mountain. Cluster analysis and ordination analysis support this as well; At genus level, floristic spectrum shows that it has a much closer relationship with Taibai Mountain (northern slope) and Zhongtiao Mountian, but not quite similar to the Ziwuling Mountain and Huanglong Mountain.

Study on construction of core collection and genetic diversity of mulberry germplasm in northern china

Dechang Hu[1]*, Ping Zhang*[1]*, Jincheng Zuo*[1]*, Zhongli Wang*[1]*,*
Zhaohong Wang[2]*, Chuanjie Chen*[2]*, Yangfang Zhang*[3]
1. Ludong University
2. Sericulture Research Institute of Shandong Province
3. Fujian Academy of Agricultural Sciences

Mulberry (*Morus* L.), an economically important plant used for sericulture, is widely distributed in China with complex genetic backgrounds. In this study, more than 40 phenotypic traits in 560 mulberry samples mainly in northern China from 7 species and 2 varieties were surveyed and complemented. Statistical analysis showed that the mean value of each trait was 2.187 with a standard deviation of 0.922, an average variance of 1.003 and an average coefficient of variation of 47.391, indicating that the mulberry germplasm variation was abundant. The highest genetic diversity index was 1.303 for *M.alba*, followed by 1.077 in *M multicaulis,* 0.869 for *M. atropurpurea*, 0.845 for *M. mizuho*, 0.768 for *M. bombycis* and 0.593 for *M. australi*. The principal component values of the first, second and third phenotypic traits in mulberry were 3.032,1.920,1.609, respectively, which accounted for 10.829%, 6.856% and 5.746% of the total variance. The cumulative contribution of principal components from the first to the eleventh was up to 59.103% of the total variance. Comparison of CV, RPR, VPF, I, Dmax and Dmin of core collections by different strategies could be used as an indicator of the candidate core collection. The result showed that a mulberry core collection had been developed using the following sampling strategy: 5% as suitable total sampling ratio, logarithm proportion as sampling proportion within group and least distance stepwise clustering with group. The DNA of more than 117 the primary core collection of mulberry were collected and used to investigate the genetic diversity by SSR and SRAP Molecular markers. The results showed that many significant genotypic variations in the tested materials. According to the statistical data, the genetic similarity coefficients were calculated and the dendrogram had been constructed by using UPGMA of NYSYS software to take cluster analysis and PCA analysis. The genotypes of the species *M.alba*, *M. atropurpurea* and *M. multicaulis* were in a tangle in the dendrogram, which suggested the level of intraspecific variation was rich among different mulberry species. Both *M. alba* and *M. multicaulis* had close genetic relationship because their similarity coefficients were above 0.82. The current complex genetic background was mainly caused by frequent interspecific hybridization and genetic mutation. Based on the genetic information of molecular markers, 34 genotypes were extracted as the core collections of mulberry, which showed that this sample was a good representation of the population in northern China. With the establishment of core collection for the genus *Morus*, the preservation of mulberry germplasm, evaluation and innovative utilization of the genus, as well as the related researches will be readily accessible.

The botany, traditional uses, phytochemistry and pharmacology of *Abrus* species (Leguminosae) in China

Baokang Huang[1], *Xiao Xiao*[1], *Zhongyuan Xu*[2]
1. School of Pharmacy, Second Military Medical University
2. Nanfang Hospital, Southern Medical University

The genus *Abrus* (Leguminosae) is widely distributed in the tropical and subtropical areas of the world with about 18 species. There are four species of this genus in China, including *Abrus canescens* Baker (*Abrus cantoniensis* Hance), *Abrus madagascariensis* R.Vig. (*Abrus mollis* Hance), *Abrus precatorius* L. and *Abrus pulchellus* Thwaites, which mainly grow in Guangdong, Guangxi, Taiwan, Yunnan, Hainan, and some *Abrus* species in China are important medicinal plants with nutraceutical potential and pharmaceutical functions. The published phytochemical studies of *Abrus* species have shown the presence of more than 243 secondary metabolites belonging to flavonoids, alkaloids, triterpenoid saponins, organic acids, amino acids and aliphatic compounds. A widely range of pharmacological activities of plant extracts and fractions focus on antioxidant, anti-inflammatory, anti-parasitic, antimicrobial, anti-trypanosomal and hepatoprotective function. The active ingredients of flavonoids, alkaloids and triterpenoids are useful marker for the quality evaluation of the herb by HPLC. The toxin abrin possesses both bioactivities and toxicity. The genus *Abrus* possesses chemical diversity and biological activities, and many traditional uses of the Chinese *Abrus* species have been validated by modern pharmacology researches. *Abrus cantoniensis* Hance and *Abrus mollis* Hance, as folk hepatic protective herbs, are promising plants which have attracted much attention owing to their multiple functions. The whole plant of *Abrus cantoniensis* Hance is a valuable traditional Chinese medicine with multiple pharmacological effects. It was firstly recorded in Herbalism Record of Lingnan with Chinese name Jigucao to treat jaundices effectively. Nowadays, it has been widely used both in folk and in clinical to treat jaundice, hypochondriac pain, epi-gastric pain, acute and chronic hepatitis, mastitis and other diseases, especially hepatobiliary disease.

Orthodox behavior of *Camellia sinensis* L. seeds from Jiujiang, China.

Ganesh Jaganathan, *Danping Song, Guorong Wu, Wei Liu, Baolin Liu*
University of Shanghai for Science and Technology

Tea (*Camellia sinensis L.*) is the largest and economically most important plant in the Theaceae family. Tea seeds are mostly classified as recalcitrant, i.e. desiccation-sensitive because drying to lower moisture content in the range of 20-30% moisture content on fresh weight basis (MC) results in mortality. However, tea plants growing in different provinces of China are reported to be survive desiccation, therefore they are also classified as orthodox. The present study was undertaken to verify this suggestion. Fruits of tea from Jiujiang, China were collected at the point of natural dispersal in mid-December, and dried over freshly regenerated silica gel (1:5 ratio) in air-tight containers. The moisture content of the seeds at the time of collection was 35.6% on a fresh weight basis. These seeds survived desiccation to 7.3% with 50% viability, indicating the seeds were not recalcitrant. Dried seeds stored for one-month at various low temperatures lost viability. Seeds stored in liquid nitrogen for one week and three months had 23.3 and 13.3% germination respectively, suggesting that some seeds are able to survive cryopreservation. However, fresh seeds stored at 4ºC for 5 months showed 70% germination, but no seeds germinated after 10 months. The tea seeds from Jiujiang, China are certainly not recalcitrant, and are suggested to be orthodox. Nevertheless, further studies are required to strongly conclude the success of cryopreservation.

Ethnobotanical study on Clusiaceae in China

Yuanyuan Ji[1], *Xinbo Zhang*[1], *Bo Liu*[1], *Ping Li*[1], *Hang Shu*[1], *Chunlin Long*[1,2]
1. College of Life and Environmental Sciences, Minzu University of China
2. Kunming Institute of Botany, Chinese Academy of Sciences

There are about 40 genera and 1000 species in Clusiaceae around the world, in which 8 genera and 87 species occur in China, mainly *Garcinia* and *Hypericum*, distributed in Southern China including Yunnan, Guizhou, Guangxi, Guangdong, Hainan, Fujjian, Taiwan and other provinces. The plants of Clusiaceae can provide edible fruits, drinks, herbal medicines, dyes, oil-bearing seeds and hard wood, widely used by many ethnic groups in China. However, less systematic ethnobotanical study on Clusiaceae in China was conducted. The traditional knowledge of utilization, and diverse culture about Clusiaceae should be investigated. Six fields investigation were ethnobotanically carried out in Yunnan, Guangxi, Guizhou and Hainan in 2012-2016. Informants were from different ethnic groups including Yi, Dai, Hani, Bai, Jinuo, Zhuang, Bulang, Yao, Buyi, Dong, She, Miao and Shui. Literature research, structured interviews, semi-structured interviews, direct observation, key informant interview, focal group discussions and participatory rural appraisal were used to collect the data and information. The main results and conclusions are as below: 1. During the field investigations on Clusiaceae, 17 species including *Garcina hanburyi*, *G. bracteata*, *G. mangostana*, *G. oblongiflia*, *G. paucinervis*, *G. xanthochymus*, *G. xipshuanbannaensis*, *Hypericum beanii*, *H. bellum*, *H. japonicum*, *H. monogynum*, *H. patulum*, *H. sampsonii*, *H. henryi*, *H. stellatum*, *H. kouytchense*, and *Mesua ferrea* had been surveyed. For each species, the distribution, traditional utilization, important values including food, medicine, wood, and ornamentals were recorded. Most Clusiaceae plants in China are wild with limited distribution. The conservation of germplasm resources and cultivation are required. 2. A number of Clusiaceae species have widely been used as folk medicine for a long history in many ethnic groups, especially the genera *Garcinia* and *Hypericum*. The *Garcinia* species are famous traditional Chinese medicine for the treatment of skin ulcer, hemorrhoids, tumor, dense tinea, bruises, bleeding and burns. The *Hypericum* herbs have the effect of heat-clearing, detoxifying, activating blood circulation to dissipate blood stasis, and treat dysentery, hepatitis, jaundice, irregular menstruation, and traumatic injury. Based on photochemical and pharmacological studies, the chemical constituents from Clusiaceae mainly including benzophenones, xanthones, flavones, naphthodianthrone, acylphloroglucinol, coumarin, and volatile oil, have been proven to be with strong biological activities, which support the traditional use of Clusiaceae as herbal medicine in ethnic societies. 3. Biological and cultural diversity have positive correlation. Because of wide utilization and cultural significance, the germplasm resources of Clusiaceae can be saved and developed better if local participation would be adopted. Some local people have learnt rich parataxonomic knowledge of Clusiaceae and recognized ethnotaxa. Such knowledge should be studied further. Based on ethnobotanical investigations and literature studies on Clusiaceae in China, the traditional knowledge had tentatively been recorded. Findings may be helpful for promoting the application and conservation of traditional knowledge of Clusiaceae. Modern ethnobotanical researches on Clusiaceae are recommend for better protecting and developing Clusiaceae plants in China.

The ecological survey and characteristics analysis of *Avicennia marina* and *Excoecaria agallocha* mangrove community in shenzhen dapeng peninsula

Xiaodong Jin

Guangzhou University, Guangdong Province

Mangrove is an important vegetation type occurred in the tropical and subtropical intertidal line, which plays an important role in maintaining ecological balance of coast, and it is of high ecological significance. *Avicenna marina* is a common dominant population in mangroves. In this paper, the basic mangrove community investigation in Baguang of Shenzhen Dapeng Peninsula was conducted, and its ecological characteristic of *Avicenna marina* community was analyzed. Results showed that the species diversity is very low *in Avicennia marina* community, only found a small amount of *Aegiceras corniculatum*, and *Kandelia candel*. In the investigated 1000 m^2 quadrat, the quantity of *Avicennia marina* is more? *Avicennia marina* is absolute dominant in the community, the important value is 291.582. In the age diameter class of community structure: the number of strong trees is 102, the number big trees is 128, the number of deadwood or dead trees are 54; the number of seedlings or saplings is only 5; While other species (*Aegiceras corniculatum* and *Kandelia candel*) have a relatively small number, the number of the young trees, strong tree and the tree are 20,11 and 16 respectively, which spreading to the sea muds of the forest fringe.We can inferred that the *Avicennia marina* community is in recession. The result would provide a guideline for the protection of *Avicennia marina* community and the construction of *Heritiera littoralis* nature reserve. *Excoecaria agallocha* is a common mangrove associates. In this paper, the *E. agallocha* mangrove in Shenzhen Dapeng peninsula was investigated, and the characteristics of communities was analyzed. *E. agallocha* mangrove in Dapeng peninsula was divided into two vegetation types: *E. agallocha - Kandelia candel* community, *E. agallocha - Aegiceras corniculatum* community. *E. agallocha* was the dominant species; the sequence of community from the water to the embankment was *K. candel* ? *E. agallocha-A. corniculatum* ? *E. agallocha*; The species diversity of community was relatively low, the Shannon diversity index range between 0.214-0.591? the Simpson index range between 0.380-0.500; Community buck level structure distribution was showed recession periods, the community age was most in big trees, old trees and strong tree. *A. corniculatum* seedlings was spreading further deep into the sea. The results were showed that *E. agallocha* mangrove in Dapeng Peninsula was one of the rare typical communities in our country, the environment has obvious been seriously polluted by fishponds, reclamation, tourism development and the living garbage pollution threat, and we must start ecological zoning plan to *Excoecaria agallocha* mangrove ecosystem in Dapeng Peninsula as soon as possible.

Rapid and simultaneous analysis of five alkaloids in four parts of coptidis rhizoma by near-infrared spectroscopy

Jintao Xue

Xinxiang Medical University

Near-Infrared Spectroscopy (NIR) was used to develop a method for rapid and simultaneous determination of 5 active alkaloids (berberine, coptisine, palmatine, epiberberine and jatrorrhizine) in different parts (rhizome, fibrous root, stem and leaf) of Coptidis Rhizoma. A total of 100 samples from 4 main place of origin was collected and studied. With HPLC analysis values as calibration reference, the quantitative analysis of 5 marker components was performed by two different modeling methods, partial least-squares (PLS) regression as linear regression and artificial neural networks (ANN) as non-linear regression. The results indicated that the 2 types of models established are robust, accurate and repeatable for five active alkaloids, and the ANN model was more suitable for berberine, coptisine and palmatine while the PLS model was for epiberberine and jatrorrhizine. The performance of the optimal model was achieved as follows: the correlation coefficient (R) for berberine, coptisine, palmatine, epiberberine and jatrorrhizine was 0.9958,0.9956,0.9959,0.9963 and 0.9923, respectively; the root mean square error of validation (RMSEP) was 0.5093,0.0578,0.0443,0.0563 and 0.0090, respectively. Furthermore, the content of 5 active alkaloids in 4 parts of Coptidis Rhizoma and 4 main origin of place was analyzed and compared by the established NIR model for the comprehensive exploitation and utilization of plant resource of Coptidis Rhizoma. This work demonstrated that NIR spectroscopy may be a promising method as routine screening for off-line fast analysis or on-line quality assessment of traditional Chinese medicine (TCM).

Alternative approaches to cryopreserve Aster altaicus Kitam, an endangered species

Haeng-Hoon Kim
Sunchon National University

Aster altaicus var. *uchiyamae* Kitam is an endemic and endangered species in urgent need of a comprehensive conservation strategy. The objective of this study was to develop complementary cryopreservation protocols, i.e., cryopreservation of dried seeds and droplet-vitrification of in vitro shoot tips. Seeds were cryopreserved after been desiccated to 4.6% moisture content (MC; 19 h over activated silica gel), and seedling emergence was recorded after 2 and 4 weeks. Shoot tips of in vitro plants were cryopreserved using a droplet-vitrification method following optimization of preculture, osmoprotection, and vitrification solution (VS) treatment steps. The standard protocol included preculture with 10% sucrose and 17.5% sucrose for 55 h and 17 h, respectively, followed by osmoprotection with C4-35% (17.5% glycerol + 17.5% sucrose) for 30 min, and cryoprotection with either B5-80% (40% glycerol + 40% sucrose) for 60 min or A3-90% (37.5% glycerol + 15% dimethylsulfoxide + 15% ethylene glycol + 22.5% sucrose) for 20 min. The first count germination rate of cryopreserved seeds dried for 2-19 h, at seed MC of 11.3-4.6%, was comparable to that of the fresh seeds (52.4%). But the final count emergence of cryopreserved seeds dried for 6-19 h, at MC of 7.2-4.6%, was lower than that of fresh seeds. Hence, the hydration window for cryopreserving *A. altaicus* seeds was 8.0-11.3%. In droplet-vitrification methods, preculture and osmoprotection were not critical for the regeneration of cryopreserved *A. altaicus* shoot tips. B5-80%, 80% dilution of PVS3, was comparable to PVS3 in liquid nitrogen survival and regeneration, which indicated that *A. altaicus* shoot tips were sensitive to the osmotic stress induced by highly concentrated VS. A3-90%, a modified PVS2 produced significantly higher regeneration of cryopreserved shoot tips than did the original PVS2 (54.5% vs. 38.8%, respectively). Several ex situ complimentary conservation approaches were successfully developed, including cryopreservation of desiccated seeds and a droplet-vitrification method for in vitro shoot tips.

Traditional plant-derived pesticides to control rice pests in Dong communities communities, Guizhou, China

Qiyi Lei[1,2], *Jiangju Zhou*[2], *Xingyuan Li*[2], ***Chunlin Long***[1,3]
1. College of Life and Environmental Sciences, Minzu University of China
2. College of Life and Environmental Sciences, Kaili University, Guizhou
3. Kunming Institute of Botany, Chinese Academy of Sciences, Kunming

Chemical pesticides have resulted in serious environmental pollution, while botanical pesticides have received widespread attention because of their advantages. More than 1000 plant species have been reported with insecticidal effects. However, only 20 species have been used. In 2015-2016, we conducted field works in three Dong villages (Kengdong, Huanggang and Kendong) in Liping County, southeast Guizhou, China. Traditional knowledge of plant pesticides against rice pests had been collected using semi-structured interview, key informant interview, participatory observation and field test. Results showed that the Dong people have used 15 plant species for controlling pests of vegetables and rice. They are mainly *Derris trifoliata, Cinnamomum camphora, Brucea javanica, Nicotiana tabacum* and others. The local people prepared traditional botanical pesticides according to the proportion of different plant materials to control different pests of vegetables and rice. These plant pesticides showed strong activities against rice planthopper (*Nilaparvata lugens*, *Sogatella furcifera* and *Laodelphax striatellus*), *Chilo suppressalis* and *Tryporyza incertulas*, in which control rate in rice planthopper reached 97.82% while for *Chilo suppressalis* and *Tryporyza incertulas* it reached 95.64%. The utilization of traditional knowledge of local plant-derived pesticides in ethnic communities has shown great development potential. Unfortunately, such local plant-derived pesticides and associated traditional knowledge are becoming endangered. It is of great significance and urgencies to carry out further investigation of and studies on these plant-derived pesticides for sustainable development of agriculture and the safe production of food.

The comparison of the soil physical and chemical properties among different cinnamomum camphora forest types

Hanbing Leng, *Shucheng Feng*
Shanghai Botanical Garden

Urban soil is the foundation of plant growth, affecting the growth status and landscape of plants directly. However the ecological function of soil is disappearing due to increasing urbanization after the long-term interruption of human activity. The natural physical and chemical property of soil has been damaged arising from soil pollution, variation of soil characteristics and *et al.,* Artificial forest with the function of restoration and reconstruction to urban ecological system can strengthen the integration of vegetation, soil and other organisms. Therefore 3 different *Cinnamomum camphora* forest types (pure forest on bare soil, pure forest only with grass, mixed forest planting with grass and shrubs), common species communities in Shanghai, were analyzed, based on field sampling and laboratory test. We explored the effect of different forest types on the change pattern of soil physical and chemical properties. The aim is to provide scientific guidance for urban landscaping application. The result showed that: 1) Significant differences were found in bulk density, non-capillary porosity, maximum water capacity, capillary water capacity, field capacity and soil water storage capacity under different forest types. Mixed forest planting with grass and shrubs presented better aeration and water-holding capacity in soil. 2) There were significant differences in organic carbon contents, total nitrogen contents, hydrolysis nitrogen contents and available phosphorus contents among different forest types. Mixed forest planting with grass and shrubs contained highest carbon and nitrogen contents in soil while more available phosphorus contents was distributed in pure forest only with grass. 3) The observation in this study showed a significant negative correlation between bulk density and non-capillary porosity, maximum water capacity, capillary water capacity, field capacity, soil water storage capacity, soil organic carbon contents, total nitrogen contents, total phosphorus contents and hydrolysable nitrogen contents. Soil organic carbon had a positive significant correlation with total porosity, maximum water capacity, capillary water capacity, field capacity, total nitrogen contents and hydrolysable nitrogen contents. These findings indicated that the compound plantation structure (arbor-shrub-herb type) had the plant root more uniformly distributed in the vertical and horizontal level and increased the input of understory vegetation litter fall to the most extent. And the lower bulk density and higher organic carbon contents caused by this kind of structure played an important role in improving soil physical and chemical properties as well as promoting the soil nutrient cycling.

Effects of progressive drought stress on the accumulation of flavonoids in the growth of radix astragali

Guangyue Li, Yuehua Liu, ***Guilin Chen***
College of Life Science, The Good Agriculture Practice Engineering Technology Research Center of Chinese and Mongolian Medicine, Inner Mongolia University

The plants defense environment changes by producing secondary metabolites and physiological and biochemical reactions. Flavonoids play an important role in plant response to abiotic stress and have tissue specificity. Radix Astragali is a traditional Chinese herb, it has successfully evolved in arid and semi-arid environments. The plant growth usually be suppressed in humid environment. It is mainly distributed in the north and northwest of China. Now, many farmers have begun to cultivate them because of shortage of wild resource. Therefore, it is important to understand the accumulation of flavonoids in different organs of Radix Astragali under drought stress, and to understand the main synthetic sites of isoflavones glucoside, which is of great significance to improve the comprehensive utilization of Radix Astragali. The dynamic of physiological state and content of calycosin-7-o-β-D-glucoside and calycosin in root, stem and levaes were studied, use the seedlings of *Astragalus membranaceus* var. *mongholicus* (Bge.) Hsiao (*A. mongholicus*) and Astragalus membranaceus Bunge (A. membranaceus), under the continuous drought stress, by pot culture simulated drought conditions, at greenhouse in Inner Mongolia University. calycosin-7-o-β-D-glucoside and calycosin are distributed and obvious difference in the three different parts, which the content of calycosin-7-o-β-D-glucoside was leaf > stem > root. The content of calycosin-7-o-β-D-glucoside (0.4mg/g DW) in the leaves of *A.membranaceus* was higher than that of *A. mongholicus* (0.25mg/g DW). However, calycosin are only distributed in stems and leaves of seeding in two different species, which the content of calycosin (0.22mg/g DW) in the leaves of *A. membranaceus* was higher than that of *A. mongholicus* (0.13mg/g DW). What's more, the contents of calycosin-7-o-β-D-glucoside and calycosin were increased during 8-12 d in leaves, but the calycosin-7-o-β-D-glucoside was no significant change in roots of two different species under drought stress. Those results indicated that the responses to drought stress were different in *A. membranaceus* and *A. mongholicus*, and the distribution and content of calycosin-7-o-β-D-glucoside and calycosin were different in different organs of two different species. What's more, moderate drought stress could promote the accumulation of calycosin-7-o-β-D-glucoside. In addition, some studies have shown that the key enzymes and glycosyltransferase gene expression of calycosin-7-o-β-D-glucoside in the leaves of Astragalus membranaceus were significantly higher than those in other organs. Moreover, the differences in the content of different organs in the three-year-old *A. mongholicus* were found. Thus, the leaves may be the main synthetic site of the calycosin-7-o-β-D-glucoside.

Cloning and analysis of Phenylalanine Ammonialyase Gene (*CiPAL*) in *Clematis intricata* Bunge

Ting Liu, Hongjiao Li, Xingjiao Sun, Tebuqin Borjigin, ***Xiao Li***
Inner Mongolia Medical University

Clematis intricata Bunge was one of the traditional Mongolian medicinal plants with the drug name "Temuri-aoriyanggu"and it commonly used in compound preparations which have the function against lump, tumor, dyspepsia, edema, wound, hemorrhoids, *etc. Clematis intricata* contained several flavonoids with the pharmacological action of liver protection, anti-inflamatory, antioxidant, anti-tumor, *etc.* Phenylalanine ammonia-lyase, a key enzyme of plant secondary metabolism, catalyzed the first reaction in the biosynthesis from L-phenylalanine to a wide variety of natural products (flavonoids included) based on the phenylpropane skeleton. Phenylpropanoids metabolic products could further form flavonoids via the metabolic pathway. In this study, phenylalanine ammonialyase gene, named asCiPAL, was isolated from *Clematis intricata* Bunge.The full-length of CiPALis 2386 bp obtained by RT-PCR and RACE, which includes 78 bp of 5'untranslated region, 190 bp of 3' untranslated region and 2118 bp complete open reading frame (ORF) encoding 705 amino acids. The protein formula was $C_{3382}H_{5395}N_{937}O_{1035}S_{26}$, the molecular weight and theroreticalisoelectric point (pI) of the deduced CiPAL protein were 76.6kDa and 6.10, respectively .The amino acid sequence analysis showed that there are three domains of PAL-HAL, PLN02457 and pheamlyase, belonging to the superfamily of cleavage enzymes. And an enzyme active site sequence (GTITASGDLVPLSYIA) at position 187-202 of CiPAL which belongs to a typical PAL family member. It was highly homologous to other PAL proteins from different species, up to 85%. Phylogenetic tree analysis indicated that CiPAL was closely related to PAL of Caprifoliaceae and Berberidaceae. Real-time PCR analysis showed that CiPAL expressed in root, rhizome, stem, leaf, bud, flower and seed tissues at different levels, and the expression was highest in seed that is more 10 times than that in leaf. And we will make further plant secondary metabolism research of *Clematis intricata* Bunge based on the result in this study about the characteristics of CiPAL.

Assessment on forest fragmentation of National Forest Na-

ture Reserves in China

Yao Li[1], *Xiangming Xiao*[1,2]
1. Fudan University
2. University of Oklahoma

Forests produce half of net primary production in the world, and play an important role in the global carbon cycle, water and heat fluxes, biodiversity, and soil and water conservation. The information of forest area, spatial distribution and fragmentation of forest is needed to assess the biodiversity conservation and ecosystem services. In this study, using the forest fragmentation model and 50-m forest cover generated by analyses of MODIS and PALSAR images, a forest fragmentation map of China in the year of 2010 was built at six different fragmentation levels including interior forest, perforated forest, edge forest, patch forest, transitional forest and undetermined forest. We explored the forest fragmentation status in 114 national forest nature reserves of China. Our results show that in national forest nature reserves of China, the patch forest accounts for the largest proportion (16.20%), and the perforated forest area accounts for the second largest proportion (15.82%), while interior forest is the smallest (3.11%) (except the undetermined forest). In most of protected area, the areas proportion of six different fragmentation levels forest accounts for 30% (in entire protected area, core area, buffer area and experimental area). Overall, our results clearly show that the forest fragmentation occurs extensively and varies substantially in national forest nature reserves of China, and therefore provide basic information to reduce forest fragmentation and avoid further losses of forests in the future.

Preliminary study on vascular plant specimen collected by emile licent in North China (1914-1936)

Li Yong
Tianjin Natural History Museum

Emile Licent (1876-1952), a french Jesuits missionary, doctor of zoology in French Academy of Sciences and a biologist, created the first comprehensive natural science museum in north China--The Hoangho Paiho Museum (former Tianjin Museum of Natural History), was known for its abundant collections. In 1914, Emile Licent came to China and since then, worked in China for 25 years. Travelling almost every region of north China, he collected a large amount of specimens of geology, paleontology and flora and fauna, among which the paleontological fossils in Cenozoic era won him international fame. In 1938, he returned to France and settled down in Paris. Most Valur specimens collected by E.Licent in Northern China are kept in Tianjin Natural History Museum. Others were collected in Paris, London and America. There are about 40,000 specimen collected in TIE (Herbarium code of Tianjin natural history museum), which belong to 1201 generas and 210 families. Some of them were identified by Handel-Mazzetti, parts of them were collected and research by France and Russia' botanist.

Gap Analysis with spatial conservation prioritization for Conservation initiatives in Southeast Asia region

Bo Liu, *Hongfeng Wang, Zheping Xu, Maofang Luo, Qinwen Lin, Keping Ma**
Institute of Botany, Chinese Academy of Sciences

The Southeast Asia region contains four global biodiversity hotspots: Sundaland, Wallacea. Philippines and Indo-Burma; however, these hotspots and the biodiversity they support are under the constant threats of human destructive exploration activities and economic development. Conservation strategies based on the geographic patterns for conservation gaps could improve the effectiveness of policy and management of nature reserves conservation initiatives for Southeast Asia at the broad scale. This paper aims at establishing and optimizing an ecological network for conservation in this region based on large-scale gap analysis. Gap analysis has been used to identify priorities for species and habitat types. We also replicated the analysis by using Species Distribution Models (SDMs) as biodiversity features to evaluate the robustness and utility of our environment-based analysis. Based on current available red list data and nature reserve list in this region, results showed, the 100 most threatened animal and plant species in this region are under comprehensive protection. However, there are still some protection gaps, and these identified gap areas will provide a scientific basis for further planning and development of nature reserves.

Cryopreservation of shoot-tips of *Populus euphratica* domant buds by encapsulation-vitrification

Yanping Liu
Tarim University College of life Science

Shoot-tips of *Populus euphratica* domant buds were successfully cryopreserved by using encapsulation-vitrification. Domant shoot-tips were encapsulated 3% calcium alginate beads. The main factors influencing the viability such as sucrose concentration, preculture time, different vitrification solution and the time beads in vitrification solution were studied. The results show that the high viability can be obtained when alginate beads were precultured for 24h in the 0.8mol/L sucrose. The beads were dehydrated with vitrification solution [40%Gly + 45% (0.4mol/L) Suc + 10%PEG (4000)+5%DMSO]for 30 min at 25℃ .Under optimum conditions, the viability of domant shoot-tips can reach 77% at the most.After cryopreservation, the dorman t shoot-tips could regrow directly and the genetic stability was maintained.

Efficient *in vitro* propagation method on shoot multiplication of *Paphiopedilum parishii* and *P. charlesworthii*

Bo Long[1], *Sven H. Wagner*[2], *Wenjun Su*[1], *Jichen Wei*[1], *Dexi Kong*[1]
1. School of Life Sciences, Yunnan University, Kunming, China
2. Sails For Science Foundation

Paphiopedilum plants needs four to five years to generate a new plant in the wild. The native plant supply cannot satisfy the horticultural market demands. In the China's Biodiversity Red List Species—Higher Plant, *P. parishii* (Rchb. f.) Stein is treated as Critically Endangered, *P. charlesworthii* (Rolfe) Pfitzer is treated as Endangered. *Paphiopedilun parishii* is also evaluated as Critically Endangered in China's Red List Species, only have one location, is seriously threaten species. Urgent protection and more in depth investigation for its propagation is now needed. In order to conserve these species and avoid further destruction on remaining plants at natural habitats, propagate *in vitro* is rather needed. The effects of various plant growth regulators (PGRs) on the frequency of shoot organogenesis in *P. parishii* and *P. charlesworthii* were investigated. The combination of 6-BA 1 mg/L with NAA 0.5 mg/L is optimal for the shoot multiplication on *P. charlesworthii*. An average shoot length of 156%. The longest shoot was achieved at an average of 1.60 cm through a combination of 6-BA 8 mg/L with NAA 0.5 mg/L with just 56% shoot multiplication. *P. parishi* incubated only in the presence of 2 mg/L ZT + 0.5 mg/L NAA, showed a 33% increase in the frequency of shoot organogenesis, the new shoot reached up to 0.4 cm after 10 months of incubation. Our methods may prove to be of value for both, horticultural and conservation purposes.

This research was funded by a grant from the National Natural Science Foundation of China (31100249).

Selection of native tree species for subtropical forest restoration in Southwest China

Yang Lu

Kunming Institute of Botany, Chinese Academy of Sciences

The use of native species in forest restoration has been increasingly recognized as an effective means of restoring ecosystem functions and biodiversity to degraded areas across the world. However, successful selection of species adapted to local conditions requires specific knowledge which is often lacking, especially in developing countries. In order to scale up forest restoration, experimental data on the responses of native species to propagation and restoration treatments across a range of local conditions are required. In this study, the restoration potential of 34 native tree species was evaluated based on nursery research and field planting experiments at a highly degraded site in a subtropical area of southwest China. We examined species performance in terms of germination rates as well as survival rates and growth two years after planting. Of the 34 species examined, 25 had a germination percentage greater than 50%. Survivorship ranged from 0 to 97% across species and was greater than 50% for 20 species. Mean monthly growth increments varied between species. Pioneer species performed well, and 14 mid- and late-successional species performed reasonably well to very well in this study. However, the remaining 16 mid- and late-successional species performed poorly. These results indicate that carefully selected mid- and late-successional species can be effectively incorporated into mixed species plantings. This data can be used to inform restoration planning, helping to identify suitable species and so enhance the biodiversity and resilience of restored forests.

Diversity of Tibetan incense plants in China

Binsheng Luo[1]*, Feifei Li*[1,2]*, Chunlin Long*[1,3]

1. College of Life and Environmental Sciences, Minzu University of China

2. Chinese Research Academy of Environmental Science

3. Kunming Institute of Botany, Chinese Academy of Sciences

Burning incense plants for smoke to worship and communicate with gods is a traditional religious custom in Tibetan area in China. In order to comprehensively and deeply understand the relative culture from the ethnobotanical angle, several times of field investigations during 2012 to 2013 were carried out in some Tibetan areas including Muli county, Kangding county, Danba county in Sichuan province and Lhasa, Mainling County, Nyingchi County and Gongbo'gyamda County in Tibet. Semi-structured interviews and random interviews were conducted to 53 people including local Tibetans, monks, incense merchants. In total, 97 species of incense plants, from 34 families and 20 genera, and their relative information were collected. In addition, 14 species were endangered, 27 species were medicinal plants and 13 species were endemic species of Tibetan. Otherwise, the importance, protection and sustainable utilization of incenses plants had been discussed, the difference of incense plants among Tibetan nationality and other ethnic groups were analyzed in the end as well. This research not only helped to record the endangered traditional Tibetan Knowledge, but also laid a foundation for future development of incense plants.

Dormancy and germination of *Firmiana danxiaensis*

Xiaoying Luo[1]*, Qianmei Zhang*[2]*, Hai Ren*[2]*, Guohua Ma*[2]

1. Shaoguan University

2. South China Botanical Garden, CAS

Firmiana danxiaensis H. H. Hsue & H. S. Kiu (family Sterculiaceae) was listed as a Second Class Key Protected Wild Plant of China in 1999 and in the Conservation Program for Plants with Extremely Small Populations in China in 2012. Its distribution is restricted to Danxia landform, including Danxiashan National Nature Reserve (DX) and Cangshizai County Nature Reserve (NX) at Shaoguan City, South China. *Firmiana danxiaensis* grows on red cliffs which formed by sandy conglomerates and shallow soil layers. In order to conserve this species, we studied its germination methods. We collected ripe seeds of *F. danxiaensis* from DX and NX on August, 2016. The seeds were globose and yellowish-brown, ca. 6.23 mm (NX) to 6.89 mm (DX) in diameter, 92.28 g (NX) to 141.79 g (DX) in 1,000-grain weight, 4.92% (DX) to 8.44% (NX) in the percentage of empty seeds, 11.01% (NX) to 11.36% (DX) in water content, and 58.44% (NX) to 82.89% (DX) in seed viability. Germination test was carried out with total 12 treatments, including four temperatures (25,25/35,15/25 and 10/20℃ (night /day)), and three photoperiods (24 h light, 24 h dark, 12 h light /12 h dark). The highest average germination rate was 1.48% at 25/35°C, which was significantly lower than the seed viability (58.44%-82.89%). According to this result, we deduced that the seed was dormant. The results also indicated that illumination had no effect on seed germination and 25/35 ℃ treatment was the suitable germination condition with the shortest germination time lag and the fastest growth rate. The water absorption rate (WAR) of CK (intact seed) was about 20% when it achieved constant weight in 48 h. The WAR of ZK (puncture the seed hole) reached 120% (DX)-140% (NX) in 96 h and saturation has not yet reached. The WAR of QK (shuck the seed coat) was about 130% (DX)-170% (NX) in 48 h. These results suggested that the seed coat was a physical obstacle on water absorption, and resulted in seed dormancy. To break dormancy, six treatments were conducted, including 1) soak the seeds into 98% H_2SO_4 for 1 h; 2) hot and cold water alternation (90℃ /5 min transfer to 0℃ /5 min); 3) 4℃ storage for 7 days; 4) soak the seeds into 500 mg/L GA_3 and 500 mg/L 6-BA for 24 h at 50℃ , respectively; 5) soak into water at 50℃ ; 6) CK. The 98% H_2SO_4 treatment turned out to be an effective way to break the dormancy of the seeds. Those germination methods are helpful for the conservation of this species.

Flexibility of resource allocation in a hermaphrodite-gynomonoecious herb through deployment of female and male resources in perfect flowers

Jannathan Mamut[1], *Ying-Ze Xiong*[2], *Dun-Yan Tan*[1], *Shuang-Quan Huang*[2]

1. Xinjiang Key Laboratory of Grassland Resources and Ecology and Ministry of Education Key Laboratory for Western Arid Region Grassland Resources and Ecology, College of Grassland and Environment Scienc

2. Institute of Evolution and Ecology, School of Life Sci

Premise of the study: It has been hypothesized that two flower types permit flexible allocation of resources to female and male functions, yet empirical evidence for the sex allocation hypothesis remains scarce in gynomonoecious species. To characterize resource allocation to pistillate and perfect flowers and allocation of perfect flowers between gynomonoecious and hermaphrodite individuals, we examined the flexibility and whether female-biased allocation increases with plant size in the hermaphrodite-gynomonoecious herb Eremurus anisopterus. Methods: Frequency of gynomonoecious individuals, flower production and plant size were investigated in different populations. Floral allocation was compared among the three flower types of E. anisopterus. Key Results: Frequency of gynomonoecious plants varied from 2% to 17% in nine populations. Only larger plants produced female flowers at the bottom of racemes. Both female and perfect flower production tended to increase proportionately with plant size in gynomonoecious individuals. Female flowers did not produce less biomass than perfect flowers from hermaphroditic or gynomonoecious plants. However, both female and perfect flowers from gynomonoecious individuals had lighter stamen but larger pistil mass than perfect flowers from hermaphrodites. Conclusions: Although the prediction of an increase in female flower number with plant size was not observed in E. anisopterus, the flexibility of sex allocation in gynomonoecious species was confirmed in that gynomonoecious individuals had a female-biased floral allocation compared to hermaphroditic individuals. Such comparisons of gynomonoecious to hermaphroditic individuals permit us to unveil a sexual adjustment strategy, flexibility of sexual investments within plants.

Population of rare species *Alcea hyrcana* (Grossh.) Grossh. in Azerbaijan

Naiba Mehdiyeva [1], *Gulnara Osmanova*[2], *Rena Abdiyeva*[3]

1. Institute of Botany of Azerbaijan National Academy of Sciences

2. Mari State University, Russian Federation

3. Institute of Botany of Azerbaijan National Academy of Sciences

Alcea hyrcana (Grossh.) Grossh. - Hyrcanian hollyhock (Malvaceae family), rare species of Azerbaijan is classified as ?endangered? (EN B2ab (ii, iii, iv) according to the IUCN Red List. The height of perennial herb is 35-85 (100) cm. Leaves are petiolate, floccose, rounded, heart-shaped, 5-7 lobed with irregular dentated blunt lamina. The nimbus is pink and petals on the top are daedalous, up to 400 mm long. Seeds are brown, covered with rare short hairs. Flowering in June-August, fruiting in July-August. Reproduced by seeds. Xerophyte, heliophyte grows in lowland and mountainous parts of the Lankaran area, on seaside sands in psammophyte-littoral groupings and in the foothill forests. The plant has decorative and medicinal value. Researches of coenopopulation (CP) *A. hyrcana* were carried out in the territory of Hirkan National Park in 2015-2016. Characteristic type of vegetation of the Hirkan National Park is forest with edificators of *Quercuseta, Parrotieta, Populuseta, and Pterocarieta*. Individuals of *Alcea hyrcana* were studied in the composition of association *Parrotia persica+Zelkova carpiniefolia+Punica granatum*. Components of association are *Albizzia julibrissin* Durazz.*, Ficus hyrcana* Grossh.*, Filago arvense* L.*, Pimpinella peregrina* L.*, Sedum lencoranicum* Grossh., *Allium lenkoranicum* Miscz. ex Grossh., *Celtis caucasica* Willd., *Pteris cretica* L., *Pteridium tauricum* V. Krecz., *Plantago media* L. *etc.* According to the classification ?delta-omega?, CP of this species in this area is young (Δ - 0,078, ω - 0,144) and presented by individuals of pregenerative (97%) and generative periods (3%) with domination of individuals of the pregenerative period (juvenile (j) - 39 individuals, immature (im) - 23, virginile (v) – 2). High values of the recovery index (Ir) 32.0 and substitution (Is) 30.0 evidences of active self-maintenance of this CP. Ontogenetic spectrum of CP is left-sided. Evaluation of ontogenetic state *A. hyrcana* indicates that CP of plant develops normally and as it grows in a protected area it is not subjected to the negative anthropogenic influence. However, due to the affection of the surrounding vegetation with fungal diseases there is high probability of destruction of vegetative and generative organs. *A. hyrcana* could adversely affect the favorable development of this type CP in the future.

Comparative biogeography of Australian plants

Daniel Murphy[1], *Darren Crayn*[2]

1. Royal Botanic Gardens Victoria

2. Australian Tropical Herbarium

The Australian flora has been the subject of many historical biogeographic analyses undertaken using a comparative approach. In this talk we review and summarise the main results of these analyses, illustrate the broad ecological and historical patterns that are emerging, and discuss the future directions and value of a comparative approach, using plant groups in Australia. Our review highlights the existence of five ecologically-based biomes; a Northern Australia monsoon tropical savanna biome; a centrally located and massive arid biome; mesic biomes of peripheral southern parts of the continent; and an aseasonal wet biome along the eastern coastal parts of Australia. Furthermore we point to some consistent patterns and results for Australian plants including: (1) temperate southeast-southwest disjunct pattern; (2) the arid zone has a complex history; (3) the McPherson-Macleay zone (central eastern coast) zone is contentious; (4) Tasmania is sister to the rest of Australia; (5) northern and southern Australia show an early break in connectivity; and (6) immigration into northern Australia is strong and mostly recent. However, we also noted that within Australia there are multi-layered and complex historical distributional patterns of endemism of plants, including some human-mediated, pre-human and ancient (relictual) distributions apparent. Australian plant historical biogeography now sits at a crucial point in history. Two major recent developments are driving a step change in the discipline. First, the availability of enormous geospatial datasets based on digitised collections data (e.g. Australia's Virtual Herbarium and the Atlas of Living Australia) have catalysed methodological developments that utilise these data for defining areas (phytogeographical regionalisation) and discovering patterns of phylogenetic endemism and diversity. Secondly, new genomic approaches have increased both the range of herbarium specimens that are amenable to DNA analysis and the volume of characters for analysis which is chipping away at one of the largest impediments to historical biogeography—the availability of phylogenies for many key Australian plant lineages.

Quantitative assessment of priority for rare and endangered plants in Yerengu Nature Reserve of Hubei

Qianqian Peng
Hubei University

Based on sample-plot survey and sample-line survey, rare and endangered plants resources in Yerengu Nature Reserve of Hubei Province was investigated, and the priority conservation of rare and endangered plants was quantitative analyzed by 5 synthetical indicators like threatened coefficient, genetic coefficient, species value coefficient, comprehensive evaluation value, protect status coefficient and breeding difficulty coefficient, and basing on 15 individual indicators. The results showed that: There were 31 species of rare and endangered plants belonging to 30 genra of 26 families; 5 species was ranked as the first grade for conservation priority, 14 species as the second grade, 8 species as the third grade, and 4 species as the fourth grade; Most rare and endangered plants distributed at the altitude of 1,000-1,600 m, and the distribution is concentrated.This research result is more realistic and effective, which provides a scientific basis for the management of the protected area to make the protection plan of the rare and endangered plants in the area.

Study on spatial distribution of *Lithocarpus* in China

Lichuan Qiu
Taiyuan Normal University

Fagaceae has many species which are important in subtropical evergreen broad- leaved forest. The character and range of the forest in Chinaare more prominent and larger than those of other place in the world. Fagaceae has 7 genus. *Lithocarpus* is one of them. The number of its species is more than that of other genus inChina. Spatial distribution characters of *Lithocarpus* will be helpful for protecting and restoring Fagaceae and vegetation. The paper provides basis of plant spatial distribution with GIS. Its spatial data is gotten from Flora Republicae Popularis Sinicae, Scientific Database of China Plant Species and so on. The data is made and analysed in ArcGIS 9.2, including map and attributes inChina. The map is composed of counties. The attributes are species of *Lithocarpus*. There is 136 species in *Lithocarpus*. *Lithocarpus* is mainly distributed in the south ofChina. It is from the most northern Wenxian to the south of the Sanya and from the most eastern Ningbo to the west of the Nielamu. It spans latitude from 33°20' to 18°9'N and a large longitude from 122°8' to 85°27'E. *Lithocarpus* accounts for 24% of China's counties, 51% of Fagaceae's counties. The number of species in Pingbian is more than that in other counties. The south of Yunnan is the centre of species diversity. Ranges of species are different in *Lithocarpus*. A few species are widely distributed, such as *L. hancei*, *L. harlandii*, *L. henryi*, *L. litseifolius*. Their distribution is close to the range of *Lithocarpus*. These species are more adaptable to environment than others. Fagaceae and vegetation will be restored by these species. Most species are distributed in a limited range. Some species distribute mainly in Yunnan. They are *L. amygdalifolius*, *L. fenestratus*, *L. truncates*, *L. dealbatus*, *L. grandifolius*, *et al.,* Some species are only in Yunnan, such as *L. fohaiensis*, *L. mairei*, *L. microspermus*, *L. xylocarpus*. Some species are limited in a place. Most of these species are in the south of Yunnan. They are *L. cryptocarpus*, *L. tabularis*, *L. leucodermis*, *L. tephrocarpus*. Yunnan is the most important place of *Lithocarpus* inChina. It should be protected. Some species are limited in island, such as *L. elaeagnifolius*, *L. obovatilimbus* in Hainan and *L. kawakamii*, *L. lepidocarpus*, *L. nantoensis* inTaiwan. We should protect these species which are in limited range. Spatial distribution of *Lithocarpus* is studied in quantification with GIS. Its range may be showed by longitude and latitude. The distributed counties and diversity centre of *Lithocarpus* may be showed and gotten by spatial distribution map.

Current status of *ex situ* conservation of medicinal plants in China

Ling Que, *Guang Yang*
(State Key Laboratory of Dao-di Herbs, National Resource Center for Chinese Materia Medica, China Academy of Chinese Medical Sciences

Ex situ conservation of plants is an emergency protection method to prevent endangered species from extinction. In order to balance the relationship between resource conservation and exploitation, it is necessary to grasp the status quo of *ex situ* medicinal plants in China. Based on Chinese Union of Botanical Gardens and Chinese Union of Medicinal Plant Gardens, this paper studied the *ex situ* conservation medicinal plant types. The results showed that there are more than 5,700 species of medicinal plants in China, and the *ex situ* conservation and breeding mechanism of medicinal plants are still immature. There are a large number of medicinal plants subject to natural environmental restrictions are not *ex situ* conservation, but many common medicinal plants are over-protected. This paper is of great reference value for improving the protection system of medicinal plants and improving the efficiency of *ex sit*u conservation.

Diversity of the *Cynomorium songaricum* rhizosphere microbial community under natural condition

Mengyun Ren
Hainan University; Chinese Research Academy of Environmental Sciences

Many studies have shown that rhizosphere soil microbial communities are crucial to plant growth, health, and stress resistance and numerous studies have implicated desertification as a cause for loss of biodiversity. In this study, 16S ribosomal RNA amplicon sequencing was used to determine the taxonomical structure of the microbial communities of the typical holoparasite psammophyte *Cynomorium songaricum*. The α-diversity and β-diversity were then calculated using QIIME. The gallic acid, protocatechuic acid, catechin, and phloridzin contents in *C. songaricum* from 18 fields were determined using high-performance liquid chromatography. The relationship between the chemical components and the microbial genetic composition is critical for understanding how microbes on the *C. songaricum* community affect its medicinal function. *Proteobacteria*, *Actinobacteria*, *Euryarchaeota*, *Bacteroidetes*, *Firmicutes*, *Gemmatimonadetes*, *Nanohaloarchaeota*, *Acidobacteria*, *Thaumarchaeota*, and *Saccharibacteria* were the most abundant phyla in the rhizosphere of *C. songaricum*. The gallic acid, protocatechuic acid, catechin, and phloridzin contents showed regional differences. However, principal coordinates analysis indicated strong interspecific patterns of microbial rhizosphere communities. Variance partitioning canonical correspondence analysis indicated that environmental factors and chemical composition exerted strong influences on the structure of the rhizosphere microbial community and explained 38.18 and 24.68% of community variances between samples, respectively. Our results showed strong interspecific clustering of the microbial rhizosphere communities of *C. songaricum*. Annual precipitation explained most of the variation in the composition of microbial rhizosphere communities of *C. songaricum*, followed by altitude and pH, annual mean temperature, gallic acid, catechin, protocatechuic acid, and phloridzin. Desertification was shown to have complex effects on microbial communities in the northwest of China.

Hotspots within hotspots: Identifying plant diversity and endemism centers in tropical Asia

*Ke Tan, **Ming-Xun Ren***
Hainan University

Southeast Asia is the home of diverse tropical plants and is the main part of Indo-burma biodiversity hotspot. This region is mostly consisted with islands and peninsulas, which makes the habitats and species distributions largely fragmentedly. The information about geogaphical locations of species diversity, especially the endemic plants, is crucial to to detect biodiversity hotspots for conservatio priority. Collection data from two species-rich tropical families, i.e. Dipterocarpaceae (560 spp.) and Malpighiaceae (80 spp.) were used to explore patterns of biodiversity at 1 × 1 latitude/longitude grid resolution, with the main goal of identifying the occurrence of centers of species richness and endemism. For each grid cell, species richness (total count of species), weighted richness (down-weighting each species by the inverse of its range) and endemism proportion were calculated. Grid cells within the top 10% of highest values of weighted richness were considered centers of endemism. Our results identified six centers of species diversity and endemims, two are islands, i.e. Sri Lanka and Borneo, two are in Thailand, respectively in north (upper reaches of Chao Phraya River) and south (Siam Bay), the other two are in Southwest China, roughly corresponding to river valleys of Hongshuihe River (upper reaches of the Pear River) and Nujiang River (upper reaches of Salween River). The river and the monsoon climate can facilitate northward spreads of tropical plants, which facilitated the process of speciation near river valleys in Thailand and China. This research can provide an overview of approaches to identifying specific biodiversity hotspots of high conservation priorities.

Carotenoid profiling in the peel and pulp of selected banana (*Musa* spp.) varieties

Ou Sheng
Institute of Fruit Tree Research, Guangdong Academy of Agricultural Sciences

Bananas (*Musa* spp.) are not only one of the most popular fruits but also important staple food in some tropic countries. Carotenoid in pulp of banana fruits is an important source of vitamin A. While little is reported on carotenoid in peel, which is traditionally recognized as byproduct of food industry and may be a potential source of antioxidant compounds. Here we determined and reported carotenoid content and composition in both peel and pulp of 36 different banana cultivars. A total of 3 and 8 carotenoid components were identified in pulp and peel, respectively. The results show that carotenoid ranged from 0.18 to 36.82μg/g FW in pulp and 0.9 to 16.2 μg/g FW in peel. Vitamin A values as retinol activity equivalents (RAE) in the pulp ranged from 0.003 to 1.85 μg/g. This report represents the first comprehensive assessment of carotenoid profiling in both fruit peel and pulp of 36 white to orange types of bananas and demonstrates banana peel product is also a valuable source with great nutritional properties.

2. Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, China

Plants in *Acorus* are not only important traditional herbal medicines, but also beautiful ornamentals. In China, the history of *Acorus* used as ornamental can be tracked back to 2000 years ago. Initially, *Acorus* was a courtyard ornamental. Until Tang and Song dynasties, it was grown as an indoor ornamental such as potted plant. There are 3 species in the genus *Acorus*, in which *Acorus tatarinowii* is widely used for ornamental purpose. *Acorus* plants are perennial and evergreen, with aromatic leaves and rhizomes. Because of their unique biological characteristics, they are regarded as symbolic and holy plants which have been endowed with the exorcism roles in traditional Chinese culture. They are also praised as elegant ornamental plants symbolized the moral integrity of indifferent to fame and wealth and resist severe coldness. With strong viability and resistance to stress, *Acorus* can be transplanted at any time and grown easily in adequate humid and shady environments. The reserves of them are extremely rich. *Acorus* plants have the functions of purifying environment by absorbing the formaldehyde, benzene and other indoor decorating pollution. Therefore it is very suitable to grow *Acorus* indoors. According to their horticultural characters and cultural values, we strongly recommend *Acorus tatarinowii* and *A. gramineus* being popularized as indoor ornamentals, while *A. calamus* can be cultivated as a courtyard ornamental plant.

Park “Presidio” (San-Francisko, USA) - unique botanical object

Mikhail Shustov[1], *Vladimir Shatko*[1], *David Gunn*[2], *Betty Withrow*[2], *Gideon Dollarhide*[3], *Anna Erst*[4]
1. Main Botanical Garden named after N.V. Tsitsin, RAS
2. Missouri Botanical Garden
3. Botanical Garden, The University of California, Berkeley
4. Central Siberian Botanical Garden, SB RAS

In the framework of the Russian-American project “Conservation of rare and endangered species of plants and a comparative study of the North American and Eurasian Flora” in August 2016 in San Francisco (USA), we visited the park, “Presidio”, located on the northern tip of the San Francisco Peninsula and included in Golden Gate National recreating Area since 1994. The park was founded in 1776 on the territory of the military base and the US Army hospital. Plants were brought from all subtropical regions of the world available to the US Army. For 240 years it was formed unique botanical object of world importance. Because the jurisdiction of the US Army, its territory was not studied by botanists properly. It is found out from scientific literature and the Internet information available. The list of plants is far fromcomplete. According to our preliminary assessment there are more than 200 taxa. The age of some exotic species (such as *Cupressus macrocarpa* Hartw., *Quercus ilex* L., *Eucalyptus globosus* Labill., *Cryptomeria japonica* (L.) K. Koch is 200 - 250 years, and many of them are almost never found in the territory of California. Sothe park is not only of historical, but the scientific importance. The most common species are: *Cedrus deodara* (Roxb.) G. Don, *C. atlantica* (Endl.) Manetti ex Carriere, *Eucalyptus globosus* Labill., *E. oblique* L’Her., *E. robusta* Sm., *Cupressus macrocapa* Hartw., *Pinus radiata* D. Don, *P. contorta* Douglas, *P. canariensis* C. Sm., *Araucaria araucana* (Molina) K. Koch, *Phoenix canariensis* Chabaud, *Jubaea chilensis* (Molina) Baill., *Ficus macrophylla* Desf. ex Pers., *Hydrangea macrophylla* (Thunb.) Ser, species and varieties *Pittosporum, Cistus.* Also there some exotics, rarely met in landscaping of California: species, forms and varieties *of Quercus, Banksia, Hebe, Magnolia, Ceanothis, Ilex, Cotoneaster, Ligustrum, Arbutus, Iochroma, Abelia, Hydrangea, Agave, Pyrus, Malus, Prunus, Lagerstroemia, Washingtonia, Melaleuca nesophila* (F.Muell.) Kuntze, *Cyathea cooperi* (W. J. Hook. ex Muell.) Domin. and *etc.* So according to assortiment of plants and their age the park “Presidio” is unique botanical object.The park deserves the scientific investigations and conservation efforts.

The lichens in Red Books of the Ulyanovsk and Samara regions of Russia

Mikhail Shustov
Main Botanical Garden named after N.V. Tsitsin, RAS

The Red Book of the Ulyanovsk region includes 32 species of lichen. Some of them are located at the southern borders on the plain: *Phaeophyscia constipata* (Norrl & Nyl.) Moberg, *Cladonia acuminata* (Ach.) Norrl, *C. decorticata* (Flörke.) Spreng., *C. caespiticia* (Pers.) Flörke, *C. turgida* Hoffm., *Lecanora cenisia* Ach., *Melanelia panniformis* (Nyl.) Essl., *M. sorediata* (Ach.) Goward et Ahti, *Immersaria cupreoatra* (Nyl.) Calat & Rambold, *Umbilicaria deusta* (L.) Baumg., *Bryoria capillaris* (Ach.) Brodo et D. Hawksw., *B. furcellata* (Fr.) Brodo et D. Hawksw., *B. fuscescens* (Gyeln.) Brodo et D. Hawksw., *Hypogymnia tubulosa* (Schaer.) Hav., *Platismatia glauca* (L.) W.L. Culb. et C.F. Culb. Some lichens are found at the northern borders: *Cladonia subrangiformis* Sandst, *Lecanora bolcana* (Pollin.) Poelt, *Neofuscelia ryssolea* (Ach.) Essl, *Xanthoparmelia camschadalis* (Ach.) Hale, *Rinodina terrestris* Tomin, *Fulgensia fulgens* (Sw.) Elenkin, *Ramalina capitata* (Ach.) Nyl. in Cromb, some species – at the western border: *Aspicilia transbaicalica* Oxner, *Lasallia pensylvanica* (Hoffm.) Llano, *Lecanora crustacea* (Savicz) Zahlbr. Some lichens characterized by widely dispersed distributions have isolated habitats in the territory of the Ulyanovsk region: *Flavopunctelia soredica* (Nyl.) Hale, *Cladonia portentosa* (Dufour) Coem, *Bryoria subcana* (Nyl ex Stizenb.) Brodo et D. Hawksw, *Ramalina polymorpha* (Lilj.) Ach., *Dimelaena oreina* (Ach.) Norman, *Rinodina milvina* (Wahlenb.) Th. Fr., *Lasallia rossica* Dombr. The Red Book of Samara region consists of 7 species of lichens and 27 species are recommended. The main part of them on the territory of the Samara region have isolated areas of their habitat on the southern borders on the plain: *Phaeophyscia constipata*, *Rinodina turfacea* (Wahlenb.) Körb, *Leptogium tenuissimum* (Dicks.) Körb, *Physconia muscigena* (Ach.) Poelt, *Romjularia lurida* (Ach.) Timdal, *Rinodina oxydata* (A. Massal.) A. Massal. Some species: *Glypholecia scabra* (Pers.) Müll. Arg., *Rinodina lecanorina* (A. Massal.) A. Massal., *R. terrestris* are located on the northern borders of their habitats. Of particular interest has the lichen *Lobaria pulmonaria* (L.) Hoffm. In 30-ies of XX century, it was found in the Zhiguli occasionally, but now it is not found. Some lichens in Samara region have isolated areas of their habitat on the southern borders of the spread on the plain: *Cladonia arbuscula* (Wallr.) Flot, *C. rangiferina* (L.) Weber ex F.H. Wigg., *Cetraria islandica* (L.) Ach. At the same time *Psora decipiens* (Hedw.) Hoffm. is located on the northern border. Such lichens as *Rusavskia elegans* (Link) S. Kondr. & Kärnefelt and *Dermatocarpon miniatum* (L.) W. Mann have single habitat in the Samara region. All these lichens in Ulyanovsk and Samara regions are rare in need to be protected. Of particular importance to the protection is the fact that most of them are climatic relicts of floras of different periods. Thus, in the Red Book of the Ulyanovsk and Samara regions includes 39 species and 27 species of lichen are recommended. The conservation of them is the most important task of the state.

The lichens of the Privolzhskaya upland

Mikhail Shustov

Main Botanical Garden named after N.V. Tsitsin, RAS

The Privolzhskaya upland is a part of the Eastern - European (Russian) plain whish looks like a plato spreaded in the meridian direction along the Volga river with an area of more than 165 thousand square kilometers. Flora and vegetation of the Privolzhskaya upland attracted attention of the greatest Russian botanists of the XIX - XX centuries in relations to the fact that the region territory was covered only partly by the Quaternary glaciers. The possibility of preserving the Tertian flora and vegetation or their elements on the Privolzhskaya upland is of a primary importance for understanding historical processes of forming flora and vegetation of the Russian plain. Lichens flora of the Privolzhskaya upland represents a complicated heterogeneous complex of different geographical lichen groups. There were distinguished 9 geographical elements in the investigated flora. Lichens flora of the Privolzhskaya uplands can be characterized as nemoral - boreal with a great extent of arid, hypoarctomontanous, montanous and arctoalpine as well as suboceanic and alpine species. There were distinguished 12 arealogic groups in the regional flora of the lichens. The areological analysis exposes a number of species, which deserve a special study. The results of the geographical analysis of the Privolzhskaya upland lichens flora, to a certain extent, do not correspond to modern conditions of the regional nature. It is indicative of a long and complicated history of the investigated flora formation process that took place from the end of Paleogen and was not interrupted by the Quaternary glaciers. The Privolzhskaya upland lichens flora include species, the specific features of their spreading all around the world and growing on the Privolzhskaya upland at present time, as well as paleogeographical data allow to specify those lichens as climatic relicts of the next geological periods: the Early - Middle Miocene, the Late - Miocene, the Early - Middle Pliocene, the Late Pliocene, Eopleistocene, the Early - Middle Pleistocene, the Late Pleistocene, Holocene. The Privolzhskaya upland lichens flora has been continuously developing since the Late Paleogene. The specific features of the lichens spreading all around the world and growing on the Privolzhskaya upland at present time, as well as paleogeographical data allow to specify the following main stages of regional lichensflora formation: the Early - Middle Miocene, the Late - Miocene, the Early - Middle Pliocene, the Late Pliocene, Eopleistocene, the Early - Middle Pleistocene, the Late Pleistocene, Holocene. There are reasons to suppose that further evolution of lichens flora of the Privolzhskaya upland will occur in the way of developing desert-steppe-xerophytic elements and decreasing forest mesophytic elements on the basis of its general degradation, impoverishing and simplification. The unique lichens flora of the Privolzhskaya upland is subject to the negative effect as a result of economic activity. The modern condition of the regional lichens flora represents a serious concern. It is vitally important to work out the Federal programme for preserving natural objects located on the territories, including the Privolzhskaya upland, that served as refuges during the Quaternary glaciers and conserve relicts of different periods.

Map the distribution of *Phragmites australis* based on Generlized Additive Models

Chuangye Song[1], *Chong Huang*[2]

1. Institute of Botany, Chinese Academy of Sciences

2. Institute of Geographical Sciences and Nature Resources, Chinese Academy of Sciences

This study aims to present a vegetation mapping approach based on generalized additive model and then map *Phragmites australis* in the Yellow River Delta. Reflectance values of Spot and Landsat images were respectively employed as predictive variables to calculate the occurrence probability of *Phragmites australis*. The predictive variables were selected into the GAMs based on F-test. The fitness of the GAMs was assessed by model deviance and area under curve of receiver operating characteristic curve (ROC). Maximized sensitivity approach was used to select the threshold to transform the projected occurrence probability to presence/absence map. The results indicated that near infrared band and visible red band were the most important variables in the fitted GAM of Spot 5. And for Landsat 5, visible blue, thermal infrared and near infrared bands were the most crucial predictive variables in the fitted GAM. The fitted GAMs gave relatively high sensitivity compared with previous researches (the maximized sensitivity are 0.74 and 0.82 for GAM based on Spot 5 and Landsat TM respectively). We hope this research could provide some references for regional vegetation mapping.

Identification of *Senecio vulgaris* L. (Asteracea) by DNA Barcodes

Xindong Hou[1,2], *Dayong Han*[1], *Zhongsai Tian*[1], ***Dandan Cheng***[1,2]

1. School of Environmental Studies, China University of Geosci-

ence (Wuhan), Wuhan, China
2. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, China

A lack of species identification tools has hindered progress in understanding and managing biological invasions. Compared to traditional methods, DNA barcodes have proved to be efficient for plants species discrimination and identification using short and standardized genomic regions. Five DNA regions, namely, rbcL, matK, ITS, ITS2, and psbA-trnH, have been recommended as primary DNA barcodes for plants. *Senecio vulgaris* (Asteraceae), originated in Europe and a widely-distributed weed in temperate regions, has been listed as one of the invasive plants in China. Plants of *S. vulgaris* are morphologically similar to native plant species such as *Senecio dubitabilis*. Hence, it is important to discriminate *S. vulgaris* from other *Senecio* species by DNA barcoding. Here we used three plants from each of 6 invasive (European) and 6 invasive (Chinese) *S. vulgaris* populations and isolated ITS, trnH - psbA and rbcL sequences from the 36 *S. vulgaris* plants. Then we downloaded related sequence of 5 composite species from the NCBI database. Using MEGA we built NJ phylogenetic tree with the three kind of sequences, respectively. The result showed that ITS correctly identified plant samples at genus level and roughly at the specie level. In addition, *trnH - psbA* displayed a variable ability to discriminate related species within different genera. However, *rbcL* was unable to distinguish plant from different genera. Generally, neither of the three genes could identified *S. vulgaris* plant samples from different populations. This study provides an empirical paradigm in identification of invasive plants species and barcoding analysis in composite species.

Pollinators and their foraging behaviors on a medicinal parasitic plant, *Cynomorium songaricum*

*Dehui Wang, Le Feng, **Guilin Chen***
College of Life Science, The Good Agriculture Practice Engineering Technology Research Center of Chinese and Mongolian Medicine, Inner Mongolia University

Cynomorium songaricum, belonging to genus *Cynomorium*, family Cynomoriaceae, is a commonly used medicine in traditional Chinese medicine and Mongolian medicine. It is aholoparasitic plant that mainly parasitizes the root of *Nitraria*. *C. songaricum* is mainly distributed in dry, rocky, or sandy soils of northern hemisphere and plays an important ecological role in windbreak and sand fixation. It is distributed in China, Afghanistan, Mongolia and Iran. In recent years, wild *C. songaricum* resources are threatened by extinction due to its slow growth rate and overexploitation. In addition, people pay more attention to a higher economic value of *Cistanche deserticola* Y.C.Ma which has a same living environment with *C. songaricum*. So its survival becomes more difficult. It is important to understand the pollination biology for its reproduction. *C. songaricum* is a cross flower pollination of insects that has been mentioned, but who pollinators are involved in pollination and how they pollinate is still poorly understood. To reveal the pollination of *C. songaricum*, we carried out two periods of 3 days investigation of pollinators during flowering in May 2016 in Zuo County, Alashan City, Inner Mongolia Municipality, China (N39°36'E105°05'). We used photo, video and visual measurement to observe *C. songaricum* populations visitors. We recorded the species, quantity and visiting frequency of all pollinators from 07:00 hours until 18:00 hours in sunny days, and made specimens of pollinators to identify. In order to identify which volatile components of the flowering *C. songaricum* has an chemical temptation effect on the pollinators, we used petroleum ether to extract the base, stem and inflorescences of flowering *C. songaricum*., respectively. The extract was divided into three portions, and the chemical constituents of each portion were determined by GC-MS. The result shows that Main pollinators of *C. songaricum* included Coleopteran (Tenebrionidae), Diptera (Calliphoridae, Sarcophagidae, Muscidae, Tachinidae) and Hymenoptera (Formicidae), total of 9 species of insects, sometimes we can see a few *Phrynocephalus versicolor* on it. The change trend of the number of pollinators exhibits as follows: an average of 6.65; numbers/individual/h at 7:00-9:00, an average of 3.18 numbers/individual/h at 9:00-11:00, an average of 3.4 numbers/individual/h at 11:00-12:00, an average of 6 numbers/individual/h at 12:00-14:00, an average of 5.26 numbers/individual/h at 14:00-16:00, an average of 4.18 numbers/individual/h at 16:00-18:00. The duration of pollinator exhibits as follows: Coleopteran's duration is 9s-2min, Diptera's duration is 4s-7min, Hymenoptera's duration is 5s-4min. Petroleum ether extract of *C. songaricum* mainly contains alkanes, esters, ethers, aldehydes and ketones, total of 56 substances. The following studies, investigation of *C. songaricum* pollinators, confirmation of pollination insects, tendency of pollination insects on petroleum ether extract, and other research, will be carried out by us in this year.

Influence of Aitrogen addition on the primary production in Inner Mongolia degraded grassland

Jing Wang
Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences

Irrational utilization and global climate change have caused degradation of grassland ecosystems in northern China with low soil fertility, decreased vegetation coverage and productivity. Nitrogen addition has been suggested an effective way to enhance restoration of those degraded grassland. In this study, we selected a typical steppe with three different degrading levels, including lightly, moderately and heavily degraded communities, in East Ujimqin, Inner Mongolia. Our objectives of this study were to examine how nitrogen (N) addition can enhance restoration of those degraded grassland. Treatments with four levels of N addition (0,5.0,10.0 and 20.0 g $N\cdot m^{-2}\cdot a^{-1}$) were conducted to each of the three degraded communities from 2014 to 2015. Nitrogen was applied as urea in June of both years. Aboveground biomass was collected at the species level in 1 m × 1 m plot in August each year, all species biomass was summed as net primary production, and biomass of plant functional groups was calculated by perennial rhizome grasses, perennial bunchgrasses, perennial forbs, shrubs and semishrubs, annuals and biennials. Our results showed that the high (20.0 g $N\cdot m^{-2}\cdot a^{-1}$) and medium level N addition (10.0 g $N\cdot m^{-2}\cdot a^{-1}$) significantly increased the aboveground biomass of the slightly degraded community by 53.1% and 51.6% compared with no N addition. N addition had no significant effects on the moderately and heavily degraded communities. N addition with high and medium levels increased aboveground biomass of perennial rhizome grasses by 45.1% and 47.7%, but decreased that of perennial forbs by 37.4% and 42.1% at the slightly degraded community. Our results indicated that N addition could increase the growth of perennial rhizome grasses, and the growth of perennial forbs was suppressed consequently. Our results suggest that even the application of N fertilizers can only be helpful to restoration of those slightly degraded grasslands. Besides, N addition had no significant effects on species richness in different degraded communities indicating the fact that the study may not last long enough. For the purpose of increasing aboveground biomass of degraded grassland, we should not only consider the type and quantity of fertilization, but also the attribute of the degraded communities. In addition, the response of degraded community in biomass may strongly be impacted by degrading level of studied grassland.

The response of vegetation to the Younger Dryas event in the Hengduan Mountains region

Xia Wang[1,3]*, Yifeng Yao*[1]*, Alexandra H. Wortley*[2]*, Yufei Wang*[1]*, Stephen Blackmore*[2]*, Chengsen Li*[1]

1. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences, Beijing, P.R. China

2. Royal Botanic Garden Edinburgh, 20a Inverleith Row, Edinburgh, United Kingdom

3. University of Chinese Academy of Science

The Hengduan Mountains region, located at the southeastern margin of the Tibetan Plateau, is one of the 34 biodiversity hotspots in the world. It is a hot topic whether the climate fluctuation caused by Quaternary glaciation and inter-glaciation has affected the distribution pattern of plants and vegetation in this region. Here we present a high-resolution pollen and loss on ignition record from Haligu wetland on the Jade Dragon Snow Mountain, one of the highest peaks in the Hengduan Mountains region, to reveal the dynamic vegetation change during late glaciation. The result shows that the vegetation was dominated by needle-leaved forest during 12.9 and 12.4 cal. ka BP with high relative abundance of *Abies* and *Picea*, indicating a cold and dry climate. Between 12.4 and 11.9 cal. ka BP, it was needle-leaved forest (mainly *Pinus*, *Abies*), with slightly decreasing of *Abies* and *Picea* and distinctly increasing of *Tsuga*, implying a cold and humid condition. From 11.9 to 11.2 cal. ka BP, the vegetation was still dominated by needle-leaved forest, while the relative abundance of *Picea* increased and *Tsuga* decreased. The climate became cold and dry again. The period of 12.9 to 11.2 cal. ka BP corresponds to the YD event. The quantitative climate analysis shows that the climate fluctuated frequently during this period, with several striking cooling events and a maximum decreasing amplitude of 7.2℃. From 11.2 to 10.0 cal. ka BP, the vegetation was replaced by *Pinus* forest. Coniferous trees (*Abies*, *Picea* and *Tsuga*) decreased sharply, along with large increasing of broad-leaved trees (*Betula*, *Corylus*, *Carpinus*, *Carya* and *Quercus*), suggesting a warm and dry climate. Between 10.0 and 9.1 cal. ka BP, the vegetation was dominated by *Pinus* forest. *Abies* pollen continued to decrease, accompanied by increasing of *Tsuga*, indicating a warmer and wetter climate compared to the preceding stage.

A062

Bacterial diversity and community structure along different depth in the rhizosphere soil of *Ferula*

Xiuling Wang

College of life science, Shihezi University

Ferula is an important national herbal medicine, the vast majority of Ferula are grow in the wild. There is little artificial large-scale cultivation of history. The diversity of rhizosphere microorganisms had an important influence on the growth and development of *Ferula*. Rhizosphere microorganisms generally several times or dozens of times of the none rhizosphere microorganisms, and rhizosphere microorganisms promote the growth of plants. Different types of plants generally have specific root microbial communities. In order to explore the specificity of different kinds of *Ferula* rhizosphere microorganisms, we analyzed the 4 kinds of *Ferula* species (*Ferula lehmannii*, *Ferula ferulaeoides*, *Ferula gracilis*, *Ferula syreitschikowii*) and different depth rhizosphere soil microbial diversity that distributed in northern of the Xinjiang Uygur Autonomous Region, China. In this paper, 4 kinds of the *Ferula* are all belong to the class of ephemeral plants. Stratified sampling (3-5cm, 20cm, 40cm) was carried out in the rhizosphere soil of different kinds of *Ferula*, and the rhizosphere microbial diversity of different kinds of Ferula roots was studied. The experiment was carried out by high throughput sequencing of the V4 region of the rhizosphere soil microbial 16SrRNA to obtain the information of the phylum, the class, the order, the family, the genus and species of the rhizosphere soil. We have compared the rhizosphere soil microbial diversity index with the soil simple depth and species of *Ferula*, and find that the richest six Phylum are *Proteobacteria, Actinobacteria, Gemmatimonadetes, Bacteroidetes, Acidobacteria, Cyanobacteria* in ferulic rhizosphere soil bacterial community, no matter relative or absolute abundance. The distribution of *Gammaproteobacteria* is stratified Evidently and the least distribution is the first layer.

A simple method for lichenized fungi preservation

Youzhi Wang

Institute of Microbiology Chinese Academy of Sciences

Lichens are symbiotic association formed by fungi and algae or cyanobacteria, and traditionally treated as lower plants. The lichenized fungi mostly belong to ascomycota and a few to basidiomycota. Lichens are difficult to culture artificially and its slow growth is a major obstacle for further study of lichens on other sides such as experimental biology. First of all, the focus was spotted on the isolation and culture and preservation of lichenized fungal strains. A simple method for preservation was introduced here. The lichenized fungus was inoculated in liquid malt extract media (Malt extract 3%, Mycological peptone 0.5%, Distilled water) for shaking cultivation for at least one month till mycelial pellets were formed. The mycelial pellets were then transferred to a tube with 8 cm high and 2 cm in diam. and with 5 ml of 10% glycerin in it, after then kept it at 4 °C. Because of the lichenized fungi are usually not sporulated, their thalli are used for preservation. Lichenized fungi usually grow slowly. With a long time of flask shaking culture, dense mycelial pellets were formed. A fungus can be kept alive for at least 3 years in a protectant solution of 10% glycerin in a laboratory refrigerator. Non sporulated and fast growing fungi can grow in 10% glycerin at 4°C, therefore are not suitable to preserve by this method. They are usually preserved in liquid nitrogen. So, this method is suitable for the non sporulated and slow growing fungi.

Protozoa communities of bryophytes and their biomonitoring for heavy metall pollution in the Carlin Gold Mines in Guizhou

Zhihui Wang[1], *Qimei Wu*[1,2], *Zhaohui Zhang*[1,2]
1. Guizhou Normal University
2. Guizhou Key Laboratory for Mountainous Environmental Information and Ecological Protection

The protozoan communities of bryophytes in mines are unique and special, but they have been little studied from the Carlin Gold Mines in China. Supported by the National Natural Science Foundation of China (NSFC. No. 31360035; No. 31360043), we carried out some ecological surveys at Carlin Gold Mines of karts area in Guizhou. The results showed that 56 species were identified in bryophytes and 25 species in top soils, and the community composition had great differences. The similarity of protozoan community in bryophytes and topsoils in NGM (Nipu Gold Mine) and ZGM (Zima Gold Mine)was less than the similarity in NGM (Nipu Gold Min) and WGGM (Wangjiawan Gold Mine), and the similarity was higher in NGM and WGGM. It indicated that different district and types of gold mine affected their community structure. Colpoda simulans is a very common species on both on bryophytes and topsoils. By using a community diversity index and redundancy analysis (RDA), the protozoa communities living on mosses and their relationships with heavy metal pollution were investigated from slags, orebodies, abandoned ores and nearby naked limestones in the Carlin gold mineralized area in the southwestern Guizhou. The protozoa species had an abundance range from three individuals/g to 482 individuals/g fresh weight of bryophytes. The slag sites were most severely contaminated by heavy metals. The structure of the protozoa community of bryophytes was dramatically affected by heavy metal pollution. Some species were found to be sensitive or resistant to heavy metal pollution. Therefore, the protozoa communities of bryophytes could be used to biomonitor heavy metal pollution in gold mineralized ecosystems.

High genetic diversity and structural differentiation in fragmented populations of wild barley (*Hordeum brevisubulatum*)

Wanli Guo
Zhejiang Sci-Tech University

Hordeum brevisubulatum (Trin.) Link., tolerated diverse abiotic stresses, is a wild barley species widely distributed in Songnen Plain of China. However, many populations of the wild barley were fragmented and/or dispeared during the last few decades mainly due to anthropogenic effects. The decrease in fragmented populations may affect the genetic diversity and structure of the populations, and in turn their survival potential. Five fragmented and four unfragmented populations (FP and UFP) in Songnen Plain were analyzed using two types of DNA marker namely, amplified fragment length polymorphism (AFLP) and sequence-specific amplified polymorphism (SSAP). The genetic diversities (0.162_{AFLP} and 0.239_{SSAP}) of five FPs [SB1, SB2, DBS, QZJ and QG] were higher than those (0.126_{AFLP} and 0.20_{SSAP}) of four UFPs [SS1, SS2, FY1 and FY2], although the later one (the UFPs) had large population size. Moreover, the 5 FPs also showed higher population genetic differentiation (G_{ST}, 0.197_{AFLP} and 0.192_{SSAP}) comparing with 4 UFPs (0.086_{AFLP} and 0.108_{SSAP}). The habitat fragmentation could improve the genetic variability, and lead to heterogeneous impact on different genome regions in *H. brevisubulatum*.

Dynamic comparative analysis on antioxidant activity and phenolic compounds of *Chrysanthemum Indicum* and *Opisthopappus shih*

Dongwei Wei[1], *Wuyong Sun*[2], *Jing Sun*[1], *Yaping Zhou*[1]
1. Henan Agricultural University
2. Henan Entry-Exit Inspection and Quarantine Bureau

Chrysanthemum indicum (*C. indicum*) is widely used as a health food and as a popular herb in China for many centuries. *Opisthopappus Shih* (*O. shih*) often takes the place of *C. indicum* in functional tea or medicine prescriptions in place of origin. In this paper, dynamic comparative analysis on phenolics and antioxidant activity of aqueous ethanol extracts of *C. indicum* and *O. shih* were investigated. Antioxidant properties of plant extracts were investigated using DPPH and ABTS radical scavenging capacity assays. Total phenolics and total flavonoids were measured using Folin-Ciocalteau and aluminum chloride colorimetric methods respectively. An HPLC method was used to simultaneously quantify five phenolic compounds including chlorogenic acid, luteolin, rutin, quercetin, and apigenin. Results indicated that Trolox equivalent antioxidant activity (TEAC) values had extremely large variation during plant growth. The most abundant phenolics and potent antioxidant activity appears at vegetative growth stage. Antioxidant activities and phenolics of *O. shih* were higher than that of corresponding parts of *C. indicum* at the same collection time. Health-promoting properties of *O. shih* may be much better than its related genera *C. indicum*. The whole plants of *O. shih*, especially its leaves and flowers are good candidates to obtain nutraceuticals and functional food ingredients.

Observations on female gametophyte and embryo of the critically endangered species *Isoetes orientalis*

Hongyu Wei, *Jinghong Liu*, ***Baodong Liu****

Harbin Normal University, Key Laboratory of Plant biology, College of Heilongjiang Province, Harbin

Isoetes orientalis was special ancient vascular plants of China, which was a new species isolated from *I. sinensis*. *I. orientalis* was critically endangered and had great significance in vascular plant evolution. However, its reproduction and endangered mechanism was unclear. With the advantages of implementation of artificial breeding and acquisition of adequate materials, the development of female gametophyte and embryo using thin sectioning were observed. The main results were as follows: Megaspore germinated after 3-5d, female gametophyte was circular with internal structure of uniform and formed a number of archegonias. There were neck cells, two neck canal cells and one egg in the archegonia. The abdominal wall cells were transformed from vegetative cells. Most of the female gametophytes only developed into one embryo, occasionally the coexistence of two embryos. With the first primordium rapid growth, primitive cells of ligula began to cleft horizontally. The ligula of the first primordium not only protected itself but also provided nutrition for the second and third ones. The early primary axis in embryonic development rotated to 30°-40°. It were speculated that the block of gametophyte development, the instability of genital differentiation, egg or reproductive helper cell abortion and embryo differentiation stopped and so on might be the causes of abortion. The double also reported and discussed the protective function of early leaf tongue on embryonic development and its phylogenetic significance.

The population genetic structure and conservation strategies of *Camellia chekiangoleosa* analysed by SSR Markers

Qiang Wen[1,2], *Li-An Xu*[2], *Wen Cai Zhou*[1], *Lin Chu Xu*[1]
1. Jiangxi Academy of Forestry
2. Nanjing Forestry University

Camellia chekiangoleosa Hu. (Theaceae), a member of genus *Camellia*, is endemic to the south of China. It has high values in ornamentals and edible oil use. This tree may be used as the important parent in hybridization for breeding ornamental camellias and important edible oil varieties in the hill country. Although the resource distribution of *C. chekiangoleosa* is mostly in the wild or semi-wild states, but its natural habitat has been increasingly fragmented due to human activity and other reasons. It was found out that the distributions, areas and resource quantities of *C. chekiangoleosa* are reducing rapidly, close to be in imminent danger through field surveys of germplasm resources and literature comparative analysis. Therefore it is urgent and necessary to do a systematic research on its current status quo and the genetic diversity so as to propose conservative strategies to protect it. In this study, based on 454 sequences of Camellias, microsatellite was mined to develop a batch of SSR markers. Meanwhile, the low-copy nuclear genes were obtained by RACE for the phylogenesis of Sect. *Camellia* and the molecular screening of *C. chekiangoleosa* and its close relative species was carried out using the introns 12-16 and 23 of the RPB2 gene of nuclear DNA. Subsequently, combining with the results of phylogenesis and screening the authenticity of the population of *C. chekiangoleosa*, the population genetic structure of 12 natural populations of *C. chekiangoleosa* was studied by 16 polymorphic SSR markers to reveal the genetic diversity and to investigate the effects of natural and artificial selection, genetic drift and other factors on the genetic structure. Compared with other species, the low genetic diversity of *C. chekiangoleosa* was found (h=0.596). The characteristic of diversity distribution is that: the populations located in the range of Huaiyu and Wuyi mountain chain had highest diversity level (such as Damao, Sanqing and Gutian) and it may be the diversity distribution center of *C. chekiangoleosa*, in complete contrast to the population located Hengshan mountains chain, where the diversity level was lowest, and the population located east to the center (such as Wuyalin and Xiapu) had medium level of diversity. The population had obviously genetic structure and had a high level of genetic differentiation. The variation among populations was about 24% of the total (FST=0.234, GST=0.239). It may be caused by habitat fragmentation and isolation, small population scale, bottleneck experienced (such as Hengshan and Lingshan), the inbreeding and little gene flow (Nm=0.796), *etc*. It is urgent to make the reasonable protection strategy. For the higher diversity populations such as the damao, shanqing and gutian, in situ conservation of forest genetic resources may be realized by establishing nature reserves to cut down the damage. And for the lower genetic diversity populations such as Hengshan and Fuan, the species recovery should be promoted by reintroduction. In addition, for lower diversity distribution area, such as Midwest of Jiangxi to Hunan, it is suggested to rich resources by the introduction method.

Genetic diversity of *Ophiocordyceps sinensis* and its host moths on the Qinghai-Tibetan Plateau as rewealed by ITS and *COI* sequences

Hai-Jun Wu, *Yi-Jian Yao*
State Key Laboratory of Mycology, Institute of Microbiology, Chinese Academy of Sciences, Beijing, China

Ophicordyceps sinensis, one of the most valuable medicinal fungi in China, is a native fungal parasite of the ghost moth larvae in Hepialidae (Lepidopterra). It is restricted to the Qinghai-Tibetan Plateau from 3,000 meter altitude upwards to the snow line. The annual yield of the fungus has gradually declined in recent decades and it has been listed as a state protected species in China. In this study, a total of 221 individuals of the fungus collected from 43 counties on the Plateau, covering the known distribution area of the species, were used for analyses of the genetic diversity of both the fungus and its moth hosts by sequencing the gene fragments of nrDNA ITS from the former and mitochondrial *COI* from the latter. A total of 18 ITS haplotypes and 81 *COI* haplotypes were detected. Analyses of ITS haplotypes revealed that high nucleotide diversity was located in the Aba and Garzê area in Sichuan and the Nyingchi area in Tibet. The same pattern was followed by the analyses of *COI* haplotypes. Based at 97% sequence similarity cut-off, a total of 15 distinct *COI* OTUs were identified. Among them, 11 OTUs could be named at the species level by the Blast search in Gene Bank, while there was no match sequence for the other four OTUs. The congruence of both ITS and *COI* analyses indicted the true diversity of the fungus and its hosts and also the close link between both fungus and moth populations. The results presented here provided useful information for understanding the genetic diversity of *O. sinensis* and also provide valuable information for protection and sustainable use of this treasure fungal resource.

Identifying *Camellia oleifera* Abel. germplasm accessions with inter-simple sequence repeat (ISSR) markers

Hua Cheng[1,2], ***Jun Xiang***[1,2], *Linling Li*[1,2]
1. Economic Forest Germplasm Improvement and Comprehensive Utilization of Resources of Hubei Key Laboratories
2. College of Life Sciences, Huanggang Normal University

The diversity and genetic relationship among and within major populations of *Camellia oleifera* 109 strains were analyzed using ISSR markers. The result showed, 23 ISSR primer, which selected from 49 primers, yield about 487 legible bands of which 335 were polymorphic markers, and the ratio of polymorphism was 68.86%; Base on the bands, the genetic similarity coefficient ranged from 0.61 to 0.93 using NTSYS2.10e software. When coefficient was 0.75,109 cultivars were divided into 11 categories and categories I contain 79 varietys by UPGMA cluster analysis. The test variety divided into 7 subgroup when categories is 0.75, which show a close genetic relationship. The results wil provide a theoretical foundation for the identification of *Camellia oleifera* cultivars, and for the efficient of their germplasm resources.

The conservation biology of *Iris ensata* in East Asia

Yue-E Xiao, *Shu-Cheng Feng, Guang-Qi Zhao*
1. Shanghai Botanical Garden Shanghai, China;
2. Shanghai Engineering Research Center of Sustainable Plant Innovation, Shanghai 200231, China

Iris L., with about 280-300 species, is the largest genus in the Iridaceae and is believed to have originated in the temperate northern hemisphere. *Iris ensata* Thunb., a member of series *Laevigatae* (Diels) G. H. M. Lawr. (subgenus *Limniris* (Tausch) Spach section *Limniris* Tausch), is native to China, Japan, Korea, and Eastern Russia. This species is one of the most widely cultivated, hybridized, and important horticultural species and has more than 5000 cultivars known as ‘Japanese Iris’ (English name) or ‘Hanashobu’ (Japanese name). However, excessive agricultural reclamation has resulted in habitat destruction and habitat fragmentation of natural populations. Thus, it makes sense to precede the conservation biology of *Iris ensata* in East Asia. Firstly, we investigated morphological variation of wild *I. ensata* in East Asia in the past ten years. There are plentiful phenotypic variations in floral size, type and color in East Asia. The floral size differs from 5 to 12 cm. The vertical, horizontal and intermediate floral types between vertical and horizontal type of *I. ensata* are common in the field, while it was reported that pentamerous flowers were only found in North Honshu. In contrast, there are abundant flower color forms intra-species *I. ensata*, including dark-purple, fuchsia, tawny, pink and white except common different shades of purple and bluish violet. Among these forms, tawny, the pink and white forms are very rare, which can be found in North East of China, central Honshu and north of Honshu. Furthermore, the genetic from 48 natural populations in East Asia were tested by the applicability of nine nuclear microsatellites (nSSR) loci. Moderate genetic diversity ($H_E = 0.618$, $Ho = 0.618$) and high genetic divergence ($F_{ST} = 0.245$, $P < 0.001$) were detected at the species level based on nSSR datasets. The genetic diversity level of South Korea populations was significant higher than those of other regions ($P < 0.05$). Remarkable genetic sub-structures were detected in Tianmu Mts., Japan, and South Korea. Finally, the conservation strategy of *I. ensata* in East Asia was proposed based on information of phenotypic variation and genetic diversity.

Ethnobotanical study on medicinal plants used by the Buyi people in eastern Yunnan

Yong Xiong[1], *Xueyi Sui*[2], *Selena Ahmed*[3], ***Chunlin Long***[1,3]
1. College of Life and Environmental Sciences, Minzu University of China, Beijing, China.
2. Sustainable Food and Bioenergy Systems Program, Department of Health and Human Development, Montana State University, Bozeman, MT, USA.
3. Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, China.

Background: The Buyi is an ethnic group in southwest China. They have developed their own medicinal knowledge over a long history. The medicinal plants used traditional by one branch of them located in Luoping county (Yunnan province) serve as an inseparable part of the whole Buyi medicinal cultures. Previously, no detailed literature, concerning its traditions and using of plants has been recorded in this area. The objective of this paper is to document the medicinal plants and associated traditional knowledge.Methods: The investigations were conducted in 4 different villages in Lubuge Township of Luoping County, through ethnobotanical approaches: participatory observation, semi-structure, ranking exercise, key information interview, focus group discussion, participatory rural appraisals (PRA). Results: A total of 122 ethnomedicinal plant species belonging to 64 families were used by the local healer to cure different diseases. Among these plants, 56 species were documented to have medicinal values for the first time, compared with all existed Buyi medicinal literaures. The most frequently used medicinal part was leaf (24.9%) and the most common preparation was decoction. Medicinal plants were mainly used to treat rheumatism, trauma and injuries. Medicinal plants were used other purposes which were edible, fodder, fence and ornamental, *etc.* Conclusion: Due to the similarities in terms of living habits and environmental factors, these Buyi marginal regions may contribute to the integrity of Buyi medicinal knowledge, which should not be ignored. Buyi medicines have multiple uses, and some have poisonous too. The paper results showed that the traditional Buyi culture played a positive role the utilization of Buyi medicine. However, the ethnomedicinal knowledge and experiences are facing the danger of extinction due to several factors, which indicates the requirement for extensive investigation and relative compulsory policies to ensure their conservation and sustainable development.

Reactive oxygen species induced by cold stratification promote germination of *Hedysarum scoparium* seeds

Liqiang Su[1], Qinying Lan[2], Hugh W. Pritchard[3], Hua Xue*[1], Xiaofeng Wang*[1]
1. National Engineering Laboratory for Tree Breeding, College of Biological Sciences and Biotechnology, Beijing Forestry University, No.35, Tsinghua East road, Beijing, 100083, PR China
2. Key Laboratory of Tropical Forest Ecology, Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Germplasm Bank, Mengla, 666303 Yunnan, PR China
3. Royal Botanic Gardens, Kew, Wakehurst Place, West Sussex, RH176TN, UK

Seed germination is comprehensively regulated by multiple intrinsic and extrinsic factors, and reactive oxygen species (ROS) are relatively new among these factors. However, the role and underlying mechanisms of ROS in germination regulation remain largely unknown. In this study, we initially found that cold stratification could promote germination and respiration of Hedysarum scoparium seeds, especially at low temperature. We then noted that a ROS environment change induced by hydrogen peroxide (H_2O_2) or methylviologen (MV) could similarly promote seed germination. On the other hand, the ROS scavenger N-acetyl-L-cysteine (NAC) suppressed germination of cold-stratified H. scoparium seeds, indicating a stimulatory role of ROS upon seed germination. An increased accumulation of O2- was detected in embryonic axes of cold-stratified seeds, and stratification-induced ROS generation as well as progressive accumulation of ROS during germination was further confirmed at the cellular level by confocal microscopy. Moreover, protein carbonylation in cold-stratified seeds was enhanced during germination, which was reversed by NAC treatment. Finally, the relationship between ROS and abscisic acid (ABA) or gibberellin (GA) in germination regulation was investigated. ABA treatment significantly inhibited germination and reduced the H_2O_2 content in both cold-stratified and non-cold-stratified seeds. Furthermore, we found that cold stratification mediates the down-regulation of the ABA content and increase of GA, suggesting an interaction between ROS and ABA/GA. These results in H. scoparium shed new light on the positive role of ROS and their cross-talk between plant hormones in seed germination.

Polycyclic natural products and their anti-AD activities of two medicinally important plants in the genus *Hypericum*

Yongbo Xue*, Yi Guo, Na Zhang, Shuangshuang Xie, Yonghui Zhang*
School of Pharmacy, Tongji Medical College, Huazhong University of Science and Technology

Hypericum is one of the largest genus in family Guttiferae, many species of which have been applied as folk medicines throughout the world. For instances, *Hypericum perforatum*, also known as “St John’s Wort”, is utilized externally for wound healing and internally to relieve the symptoms of neurological disorders. The extract of St John’s Wort (ESJW) can alleviate mild to moderate depression that is mainly attributed to the inhibition of various neurotransmitter receptors and exerts versatile biological properties including anti-inflammatory, cytotoxic and neuroprotective properties. Polycyclic prenylated acylphloroglucinols (PPAPs) are usually characterized by a highly oxygenated and densely substituted bicyclo[3.3.1]nonane-2,4, 9-trione or other related core structures that were decorated with isoprenyl, geranyl, and acyl groups. Over the past decades, almost 300 structurally complex PPAPs endowed with different skeletons have been reported. PPAPs are mainly isolated from the plants of the Guttiferae family and exhibit a wide variety of bioactivities, such as antitumor, antibacterial, antioxidant, anti-HIV, and anti-neurodegenerative. In light of their complexstructures and potential biological activities, PPAPs have attracted great interest from the scientific community due to their intriguing molecular structures and interesting pharmacological effects. Alzheimer’s disease (AD) is one of the most common disease found in people live with dementia. Most recently, the World Alzheimer Report 2015 demonstrated that at present there are over 46 million people live with dementia worldwide, and this number is estimated to increase to 131.5 million by 2050. Aimed to discover more bioactive polycyclic natural products from the genus of *Hypericum* collected in central China regions, our group previously reported the isolation of a large number of PPAPs from *H. sampsonii*, *H. attenuatum*, *H. japonicum* and *H. ascyron*. Currently, the chemical study by our research group on two species of *Hypericum*, *H. longistylum* and *H. perforatum*, led to the isolation of 40 new PPAPs with diverse carbon scaffolds, along with 20 known ones. Some of the new isolates exhibited significant inhibitory activities against protein phosphatase 2A (PP2A) and beta-secretase (BACE1) enzymes in Alzheimer’s disease. The finding will provide new insights into the skeletal diversity of PPAPs and natural PP2A and BACE1 inhibitors.

Dynamic characteristics of *Rhododendron maculiferum* community in Shennongjia

Linsen Yang
Administration of Shennongjia National Park, Shennongjia, China

A study was conducted on the sub-alpine *Rhododendron maculiferum* community in Shennongjia via ten 400 m^2 quadrats. There were 84 plant species of 58 genera and 32 families in ten quadrats. Rosaceae is the most in woody layer with 19 species. *Fargesia* had the highest importance value in the shrub layer. *Fragaria orientalis*, *Rubus fockeanus* and *Asteropyrum peltatum* were common in the herb layer. On average, there were 6 species in the tree layer, 15 species in the shrub layer, and 20 species in the herb layer, and the total was 38 species. The species richness of tree layer and shrub layer decreased with altitude, while the species richness of the herb layer slightly changed. In the tree layer most individuals were in the 5-8 cm diameter class, accounting for 61.3% of the total, and 80.9% of the individuals were in the 4-7 m height class. The ratio of the dead standing trees and the living is 7.1%, and the dead standing trees of *Rhododendron* accounted for 86% of the total number of dead standing trees. 70.8% of the dead standing trees of *Rhododendron* were in 3-4 cm diameter class, indicating that under high crown closure the objects of the self-thinning process in the community is mainly saplings. With the rise of altitude, the population density decreased and the community levels tend to be simple. The anophanerophyte accounting for 31% and hemicryptophyte for 27.4% are the main elements of the community. This life form structure adapted to the local conditions of long cold winter and humid climate. The north temperate genera is dominant in the flora, which is of obvious temperate attribute. Upper *Abies fargesii* layer disappeared after disafforestation decades ago, so the *Rhododendron maculiferum* at under layer developed into the single dominant species. Thence the species diversity of the tree layer, shrub layer and herb layer decreased, and the average tree height became smaller. The *Rhododendron* community at prime period is relatively stable, while the invasion of trees like *Abies* and *Betula utilis* in the community or on the edge promotes the succession. The gaps caused by the dead wood is the main impetus for the regeneration. There is an evolution tendency that *Abies fargesii* will replace *Rhododendron*. *Fargesia murielae* inhibited the renewal of *Rhododendron*. However, the death and regeneration of *Fargesia* since the 1990s have promoted the regeneration of *Rhododendron* to a certain extent.

Dye plant resources in Liangshan Yi autonomous prefecture

Bei-Xi Zhang[1], *Bin-Sheng Luo*[1], *Qu-Ye Diri*[1], *Chun-Lin Long*[1,2]
1. College of Life and Environmental Sciences, Minzu University of China, Beijing 100081, China
2. Kunming Institute of Botany, Chinese Academy of Sciences, Kunming 650201, China

Natural dyes have attracted more and more people's attention. Yi, an ethnic group in China, is remarkable for their traditional knowledge of dye plants. Based on literatures review and ethnobotanical investigation on traditional dye plants and their dyeing processing knowledge in Liangshan Yi Autonomous Prefecture, Sichuan Province of Southwest China, we systematically collected and identified seven species of commonly-used local dyeing plants. They are *Juglans regia*, *Coriaria nepalensis*, *Toxicodendron vernicifluum, Rubia cordifolia*, *Coptis chinensis*, *Rumex dentatus*, and *Polygonum tinctorium*. The process of traditional dyeing was recorded as well. By interviewing with indigenous Yi people, it was found that local farmers are the main user of dye plants and holders of associated dye knowledge. The current situation of local dye plants was analyzed. Results showed that traditional knowledge associated with dye plants was becoming endangered. This study can not only help saving the traditional knowledge related to dye plants, but also provide informative knowledge for future sustainable development of local dye plants.

Alpinia officinarum rhizomes of different varietas can be applied personalizedly

Chunrong Zhang, *Xiaomin Tang, Xuanxuan Cheng, Liming Pan, Quan Yang*
Guangdong Pharmaceutical University

Alpinia officinarum, known as lesser galangal, is a herbaceous plant in the Zingiberaceae family. It originated in China and is cultivated in Southeast Asia. The rhizomes, valued for their sweet spicy flavor and aromatic scent, have been used as spice and perfumes in Asia and Europe for more than 2000 years. In China, the rhizomes are also used as a traditional Chinese medicine in curing epigastric pain, vomiting, dyspepsia, gastric and duodenal ulcer, chronic gastritis, acute gastroenteritis, *etc.* Some new usages such as additives for feed and cosmetics, fresh keeper for fruit, vegetable and meat, are also found out. The long history of huge market demand has nearly exhausted the natural resources. Resources available on the market are all domestic. There are four *A. officinarum* varietas which are named Niu Jiang, Fengwo Jiang, Ji Jiang and Zhutou Jiang in China. In most places, Niu Jiang or Fengwo Jiang, which is in higher yield, is vegetatively propagated for years and years. This is disadvantageous to population evolution and new varieties formation. In our present work, macroscopic characteristics of the rhizomes were identified among the four varietas. Niu Jiang is in the highest yield and tastes sweet spicy with a little bitterness. Fengwo Jiang smells the strongest aromatic and tastes sweet spicy with no bitterness. Zhotou Jiang tastes less spicy. Ji Jiang is in the lowest yield and has the lest water content. These scent and flavor differences indicate that the *A. officinarum* rhizomes of different varietas can be applied personalizedly. For example, Niu Jiang and Fengwo Jiang can be used as medicines and perfumes. Fengwo Jiang and Ji Jiang are good for food additives. Zhutou Jiang is better for spice. To reveal their differences in chemical compositions, metabolome analysis will be in our later research.

The exploration of the water use pattern of populus euphratica in different ages at the Tarim River downstrean

Jiang Zhang
Shihezi University

Water is one of the factors that affect the growth and reproduction of vegetation in terrestrial ecosystem, and it is also a key factor to control the structure and dynamics of the vegetation community. Especially in the arid area, it will be the key factor to limit growth of piant.And it is important for explain the spatial and temporal distribution of vegetation under the global climate change that expound the utilization pattern of plant's water.The stable hydrogen and oxygen isotope technique used in the research of water source determination in plants mainly focus on two aspects, one is the gradient of soil water by absorption of plants; the other is the main source of water absorbed by the plants and their contribution degree.Compare the water of the plant xylem with the water in the growth environment, using two or more isotope mixing models to determine the water utilization of plants of different water sources and the relative contribution of plant water, can also study it's changes in time and space. $\delta^{13}C$ can not only reflect the carbon isotope ratio of atmospheric CO_2, also reflect the value of Ci/Ca.According to the definition of water use efficiency, water use efficiency of plant relate to Ci and Ca, so ^{13}C can indirectly reveal the long period of plant water use efficiency.A large number of studies have confirmed that the $\delta^{13}C$ is highly related to

WUE, which can be used as an effective indicator to measure the water use efficiency of plants in the long term.Therefore, we measure and analyze soil moisture and δD, $\delta^{18}O$ of the soil water, groundwater and xylem and $\delta^{13}C$ of leaf, which analyze the mean depth of water uptake of different ages of Populus euphratica, and discuss the water use patterns and he adaptation mechanism in the arid environment, which provide scientific basis for the formulation of ecological water in lower reaches of Tarim River and restoration of Populus euphratica forest.

Altitudinal variation of the reproductive strategies and the future distribution prediction of *Primula florindae*

Jie Zhang[1], *Xianfeng Jiang*[1], *Lingling Chen*[1], *Qingjun Li*[2]
1. Xishuangbanna tropical botanical garden
2. Yunnan University

The alpine ecosystem harbours extremely high biodiversity, however, the harsh environment factors seriously impact the growth and reproduction of plants, such as low temperature, strong wind, intense radiation, frequent rain and snow. In particular, the reproductive season shows striking sensitivity to surrounding conditions, at the same time, plants can also integrate various strategies for acclimatization. The flower, as a reproductive organ, exhibits floral traits variations in different altitudinal conditions, so it is of great importance in reproductive strategies research. *Primula florindae*, which distributes from 3100 m to the treeline (4350 m) in the Sygera Mountains, as an endemic species in the Qinghai-Tibet Plateau, is an ideal material for exploring the relationship between elevation and reproductive strategies. In this research, we select flowering phenology, floral display traits, pollinators, sex allocation, and natural seed set as characters, by comparing these characters among five populations along altitudinal gradients, we highlight three conclusions: (1) Initial blooming time of *P. florindae* did not show a correlation with elevation: the middle elevation population bloomed earliest and the highest population bloomed last. Nevertheless, with the increase of elevation, flower longevity and floral display area of both morphs of *P. florindae* increased significantly, but varieties of pollinators decreased, and both morphs tend to allocate more resources to assure female sexual function. Overall, reproductive strategies of *P. florindae* were affected by biotic and abiotic factors generated by the altitudinal gradients, but varying responses among the traits studied resulted in the intraspecies variation of reproductive strategies. (2) With the increase of elevation, flower number of *P. florindae* significantly diminished but both herbivory number and rate also reduced, so effective fruit number of all populations showed no distinct disparity, and there were also no significant differences in seed number, showing that by shaping corresponding reproductive strategies to different environment, *P. florindae* guaranteed breeding success, and then stablized population in all elevations. (3) Climate change will have profound and lasting impacts on the distribution of *P. florindae*, the lower altitudinal limit may shift up, but sandy soils at higher elevations are unfavorable to its growth, while the temporal-spatial distribution of pollinators under climate change are still unknown. We predict the lower altitudinal limit of *P. florindae* will move up to middle elevation and result in a decrease in its distribution over the next 100 years.

EST-SSR marker based DNA fingerprinting for cultivar Identification and genetic diversity analysis of *Elymus sibiricus* germplasm in China

Junchao Zhang, *Wengang Xie, Xuhong Zhao, Zongyu Zhang, Yongqiang Zhao, Yanrong Wang*
The State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University

In this study, EST-SSR markers were used to analyze the genetic diversity of 52 *Elymus sibiricus* accessions, and construct the DNA fingerprinting profiles of 7 *E. sibiricus* cultivated accessions and cultivars in China. A total of 204 bands were generated from 20 EST-SSR markers with an average of 10.2 bands. 176 (86.27%) bands were polymorphic, indicating a high level of polymorphism. The primers Elw404 and Elw195 could easily distinguish 7 cultivated accessions and cultivars from other materials. The molecular variance analysis (AMOVA) showed that genetic variation was greater within geographical regions (73.94%) than between them (26.06%) in *E. sibiricus*. The structure analysis suggested that the 52 accessions were clustered into five groups, similar to result of principal coordinate analysis (PCoA). Wild accessions (NPB=174, PPB=85.29%, I=0.2966, H=0.1798, Na=1.8529) possessed higher genetic diversity when compared with cultivars and cultivated accessions, suggesting wild accessions could be used as important genetic resources for future breeding programs. Furthermore, ex situ and in situ conservation strategies were suggested for *E. sibiricus* germplasm. The results of the present study showed that EST-SSR markers were efficient in assessing the genetic diversity and identifying cultivars.

The first flowering plant on Mars

Huien Zhao
Beijing Forestry University

Mars is the most Earth-like planet in the solar system. Modern-day Mars is a harsh place for life where frigid temperatures, intense radiation, highly oxidizing soil and extreme aridity combine to present significant obstacles to any potential extant life forms. Lichens were regarded as the survivors on Mars since some lichen species are able to live under harsh conditions, characterized by low temperatures, aridity and high UV radiation fluxes and several lichens are even able to survive simulated and real space conditions. Redesigning living organisms to survive on Mars were proposed recently. Here we think that amphiploid somatic transgenic multigeneric hybrids of Anthemideae and *Saussurea* within Asteraceae might be the first flowering plant colonized on Mars without any protection. There are many elite genetic resources distributed in Polar Regions, high mountains, deserts or cracksn within Ajania group. We can get Multi-generic hybrids with embryo rescue using the related genera distributed in harsh environments within Asteraceae-Anthemideae-Artemisiinae. Further more, Somatic transgenic multigeneric hybrids of Anthemideae and Saussurea could be produced using transgenic multigeneric hybrids with diverse genes from extremophiles. At last, Amphiploid somatic transgenic multigeneric hybrids of Anthemideae and Saussurea could be bred which might be suitable on Mars.

A brief report of pilot province in the Fourth National Survey of Chinese Materia Medica Resources: Hebei Province

Lin Pei[1], ***Lin Li***[2], *Pei He*[1], *Hong-Zhu Liang*[2], *Xu-Hong Duan*[1,2], *Shuo Shi*[2], *Jian-Cheng Zhao*[2]
1. Institute of Traditional Chinese Medicine
2. Hebei Normal University

Traditional Chinese medicine resources are one of the important strategic resources of the country. With the rapid development of Chinese medicine industry in recent years, great changes in the medicinal resources of China in terms of types, distribution, reserves and quality, have taken place. The national level's census of traditional Chinese medicine had carried out for three times. And the lasted census was carried out in 1983-1987, nearly 30 years ago. Problems such as Chinese traditional medicine resource status were not clear and lack of exchange of resources information still exists. Based on this situation the State Administration of Traditional Chinese Medicine organized the Fourth National Survey of Chinese Materia Medica Resources. The preparatory work started from 2009, and formal work began in 2011. Hebei Province and other 15 provinces, as the second batch of pilot provinces, carried out the program in 2012. 280 professional fellows from different research units, including Hebei University of Chinese Medicine, Hebei Normal University, Hebei Academy of Agriculture and Forestry Science and Chengde Medical University, constituted 16 survey teams arranged by Administration of Traditional Chinese Medicine of Hebei Province. The survey was carried out since 2013. According to the technical regulations, the survey teams carried out field investigations and got plentiful data. In the program, 1,317 quadrat were investigated, 1,975 species medicinal plants were collected, of which 265 were important traditional medicine. More than 20,000 specimens were made and 9,500 specimens were submitted to the National Resource Center for traditional Chinese medicine. 807 medicinal materials of 120 species and 2,335 collections of seeds of 788 species were also submitted. The traditional Chinese medicine raw materials quality monitoring and technical service center was established. The monitoring stations in Anguo City and Julu County have been put into use. In the circumstance of the survey, the Chinese Medicine Resources Center of Hebei Province was established; specimens of medicinal plants and crude drug materials would be well stored in it. More than 10 papers related to the survey were published. Through this survey, a group of technical backbone was growing up. A foundation for the following work of the survey was made.

Our work was supported by Special Fund on Public Health from the Central Finance "Resource survey and monitoring on original plant of essential medicine", award No. Cai She[2011]76 and the Special Fund of the National Traditional Chinese Medicine, award No. 201207002.

1. Institute of Botany, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences
3. Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences

China's biodiversity loss is serious, but the available protection resources are very limited. It is a more realistic and efficient way to concentrate the limited resources on the important biodiversity regions. And the construction of a key biodiversity areas evaluation index system which is operational and consistent with the specific situation of our country is the prerequisite and basis for setting the protection priority area. Based on IUCN's Key Biodiversity Areas (KBA) evaluation criteria and relevant studies, we build the China's KBA evaluation index system by considering the scientificity, operability and availability of data. Then, the key biodiversity areas of China were identified and GAP analysis was also carried out, which would be helpful to the formulation of effective policies and the rational allocation of resources.

Canopy seed bank of *Sophora alopecuroides* L. in Ili River Valley

Ying Liu[1,2], *Yu Zhao*[1,2]
1. Biology and Geography School, Yili Normal University
2. University and College Key Lab of Natural Product Chemistry and Application in Xinjiang

Sophora alopecuroides is a tipical perennial clone and dominant species in the Ili River Valley, which is a familiar kind of poisonous and harmful plant in this area. Just because of its typical canopy seed bank, this project take *S. alopecuroides* as the research object. By using the the field study method in desert steppe of Huocheng county, an experiment was conducted to study the size and composition, seed vigor, Supplementary effect on soil seed bank, and the retention ratio dynamics of *S.alopecuroidesopy*'s canopy seed bank. The result showed that canopy seed bank possess 271.50±124.43 beans/m^2, the maximum was 489.00 beans/m^2. *S.alopecuroidesopy*'s canopy seed bank was composed of two parts: the whole seeds, moldy and rotten seeds. The number of whole seeds reached 144.07±137.93 beans/m^2, and its percentage was 53.06%. Retention ratio reached 25.01±16.92, the maximum was 51.46, and the minimum was 4.29. After mechanical damage, germination rate reached 76.98±11.89%, seed vigor index was 72.44±39.01, which indicated that canopy seed bank could keep higher seed vigor. Canopy seed bank lasted for nine months, the retention rate was about 25 percent at the beginning of March of the next year. Even in May or June, some certain degree of seeds still stained in the canopy. As a result, canopy seed bank could be an effective supplement to the soil seed bank, and both of them performed effective supply bank of propagules during the population regeneration and community succession. The results would be helpful to systematically understand the reproductive characteristics, reveal the bio-ecological mechanism of its malignant invasion, and provide theoretical support for scientific management of grassland ecosystem in the Ili River Valley.

Jujube tea processing and its antioxidant activity

Xiaomin Lu, Xu Yan, Xu Liu, Yuemeng Cao, Yacui Wang, Xiaoyue Ma, ***Zhihui Zhao***

Horticulture College, Agricultural University of Hebei

Chinese jujube (*Ziziphus jujuba* Mill.), a native plant ofChina, belongs to the Rhamnaceae family and has been cultivated for over 3000 years. InChina, its fruits are used in traditional medicine exhibiting tonic activity. Chinese jujube plant tree has abundant flowers in its fruit development stage. The flowers of Chinese jujube have mild but amazing smell. We collected fresh jujube flowers at June 2015, fresh red jujube fruits at September 2015 and bought fresh fruits of apple, mango, pawpaw, pineapple, kiwi, longan, Hami melon and flowers of rose. And then some of jujube fruits were dried by oven, the others and other fresh fruits, flowers were lyophilized. We mixed different fruits and flowers with jujube fruits, flowers as fruit teas. Eight different products of jujube teas we processed were used for the evaluation. These processed products were evaluated on the basis of their appearance, taste, components and antioxidant activities. The results showed the eight products contained titratable acid of 1.98%-11.33%, reducing sugar of 2.93%-5.6%, soluble sugar of 6.22%-51.33%, polysaccharides of 0.37%-0.77% and vitamin C of 9.81mg/100mg -38.60 mg/100mg based on the dried weight. Two products with more kiwi fruits mixed had good taste and higher antioxidant activities and they had higher contents of titratable acid and soluble sugar. So, we made two jujube tea products with good taste and higher antioxidant activities.

The aasis of city for research and conservation of endangered species in East China—Hangzhou Botanical Garden

Chuan Chen, *Jinliang Yu, Ting Wang, Yahong Gao*

Hangzhou Botanical Garden, Hangzhou, China

Hangzhou Botanical Garden founded in 1956 is located within the World Cultural Heritage Site—Hangzhou West Lake Scenic Area, covering an area of 248.46 hectares. Besides 14 specialized gardens, such as classification garden, economic plants garden, bamboo garden, medicinal herb garden, endangered trees garden, *Acer* and *Rhododendron* garden, *Osmanthus* garden, 4,836 species of living plants are *ex-situ* conserved in Hangzhou Botanical Garden, of which more than hundreds tree species are endangered and endemic to China. One of our main missions is research and conservation for endangered species of East China on which many strategies, managements and studies have been conducted. Having scientific content, park appearance and cultural connotation, the garden is not only a comprehensive botanical garden, but also the oasis of East China for endangered species.

Chemical constituents from leaves of *Taxus chinensis*

Aiping Meng, Juan Li, ***Sheban Pu***

China Pharmaceutical University

A new compound, (*E*)-1-methoxy-3-*O*- (*p*-coumaroyl)-*myo*-inositol (1), and 13 known compounds, *p*-hydroxybenzaldehyde (2), *p*-hydroxybenzoic acid (3), palmitic acid (4), protocatechuic acid (5), sciadopitysin (6), ginkgetin (7), sequoiaflavonoids (8), taxacin (9), 10-deacetylbaccatin III (10), 5-deacetyltaxachitriene B (11), makisterone C (12), 7-β-xylosyl-10-decetyltaxol (13), taxiphyllin (14) were isolated from leaves of *Taxus chinensis* (Pilger) Rehd. The structure of the new compound was elucidated by analysis of spectroscopic data. Compoud 12 was isolated from the genus *Taxus* for the first time, and compounds 2,3, 8 were isolated from *Taxus chinensis* (Pilger) Rehd for the first time.

The genetic diversity research of the national protect plant *Bhesa sinica*

Zehua Ma

Guangzhou University

In this paper, the ISSR molecular marker technology is applied to the study on genetic diversity of 2 wild *Bhesa Sinica* populations. Using the optimized reaction system, 5 ISSR primers were screened out to amplify on 2 natural populations of a total of 18 samples in the distribution area, and amplified 69 bands in total. Using PopGene 32 for data analysis, the results show that: the genetic diversity of *Bhesa Sinica* ranks in the middle level at the species level, the percentage of polymorphic loci (*PPB*) is 69.57%, Nei's gene diversity (*He*) is 0.1310, and Shannon's information index (*Hsppo*p) is 0.2438; however the genetic diversity at population level is relatively low, (*PPB*) is 49.28%, and Shannon's information index (*Hpop*) is 0.2071. The total population gene diversity of *Bhesa Sinica* (*Ht*) is 0.1512, gene diversity within populations (*Hs*) is 0.1310, the coefficient of genetic differentiation (*Gst*) is 0.1333, that is, the variation within population accounted for 86.67% while variation among populations accounted for 13.33%. Gene flow among populations of *Bhesa Sinica* (*Nm*) is 1.6259, which has prevented the population differentiation caused by genetic drift. By comparing the coefficient of genetic differentiation (*Gst*), gene flow among populations (*Nm*) and the percentage of polymorphic loci (*P*), low genetic diversity is one of the causes of *Bhesa Sinica* on the verge of extinction. Based on the relationship between genetic identity and genetic distance, NTSYS software, version 2.01 is applied to 2 *Bheas Sinica* populations of 18 samples to make UPGMA cluster analysis, the results show that: the individuals of 2 *Bhesa Sinica* populations basically clusters according to geographical distance . The results show that, as a result of the genetic variation mainly existed among individuals within populations, a large number of samples should be taken within different populations by the *ex situ* conservation in order to achieve the preservation of genetic diversity of *Bhesa Sinica* in maximum.

Local habitat disturbance best predicts biological indices of mosses and vascular plants in Ohio (USA) Wetlands

Martin Stapanian[1], *Brian Gara*[2], *William Schumacher*[2], *Jean Adams*[1]
1. U.S. Geolgical Survey
2. Ohio Environmental Protection Agency

Loss of wetland habitats and their associated biological communities is a major environmental concern. Quality assessment indices (QAIs) and indices of biological integrity (IBIs) are useful for assessing the responses of taxa to wetland habitat quality and land use in the surrounding landscape. Mosses and vascular plants have been shown to be reliable indicators of wetland habitat delineation and environmental quality. Knowledge of the best ecological predictors of the quality of wetland moss and vascular plant communities may determine if similar management practices would simultaneously enhance both populations. We used Akaike's Information Criterion to identify models predicting a moss quality assessment index (MQAI) and a vascular plant index of biological integrity based on floristic quality (VIBI-FQ) from 27 emergent and 13 forested wetlands in Ohio, USA. The set of predictors included the six metrics from a wetlands disturbance index (ORAM) and two landscape development intensity indices (LDIs). The best single predictor of MQAI and one of the predictors of VIBI-FQ was an ORAM metric that assesses habitat alteration and disturbance within the wetland, such as mowing, grazing, and agricultural practices. However, the best single predictor of VIBI-FQ was an ORAM metric that assessed wetland vascular plant communities, interspersion, and microtopography. LDIs better predicted MQAI than VIBI-FQ, suggesting that mosses may either respond more rapidly to, or recover more slowly from, anthropogenic disturbance in the surrounding landscape than vascular plants. These results supported previous predictive studies on amphibian indices and metrics and a separate vegetation index, indicating that similar wetland management practices may enhance three vastly different wetland biological communities (amphibians, vascular plants, and mosses). This may lead to more efficient use of available resources by wetland management agencies.

In vitro root induction of *Gyrinops walla* (Gaertn.) using micropropagated multiple shoots

Arosha Nirmal Buddhapriya Welle Hewa Kankanamge, *Sandun Kumari Senarath Wathuge Thamara Priyanthie*
University of Sri Jayewardenepura

Gyrinops walla (Thymelaeaceae) is one of the major sources which provides agarwood resin for the manufacture of valuable perfumes and also for medicinal purposes. This species is naturally grown in the Southeast Asia and the Indian Subcontinent regions. In Sri Lanka, *G. walla* distributed through the humid lowland forests as evergreen trees with tall, strait and slender trunk. The reddish brown latosolic soil is more favourable for the growth of *G. walla* and their roots were adapted for that. Development of plant tissue culture protocol for mass propagation of *G. walla* has been started as a solution for scarcity of natural population due to slow natural growth and illegal felling. Multiple shoots of *G. walla* were induced using *in vitro* germinated seedling parts with optimized Murashige and Skoog (MS) medium supplemented with plant growth regulators. Eight weeks old *G. walla* multiple shoots were used for the *in vitro* root induction. Healthily grown multiple shoots were carefully separated into single shoots. Then the shoots were transferred to half strength MS medium supplemented with different concentrations of indole-3-acetic acid (IAA) (0.0-2.0 mg/L), indole-3-butyric acid (IBA) (0.0-2.0 mg/L) and 1-naphthaleneacetic acid (NAA) (0.0-2.0 mg/L) separately. There were fifteen replicates in each treatment for root induction. Cultures were incubated for 18 hour photoperiod at 25 ± 1°C and observed weekly over a period of ten weeks. Mean number of roots and mean root length were measured by taking rooted plantlets out of the culture vessels before being transferred for acclimatization, after ten week period. Like naturally grown *G. walla* plants, micropropagated plantlets show tap root system which was characterized by having one main root (the taproot) from which smaller branch roots emerge. All tested treatments including plant growth regulator free medium (control) induced roots. Half strength MS medium supplemented with 1.0 mg/L IBA was found to be the most effective treatment in stimulating roots with the highest mean number of roots per shoot (5.2 ± 0.5) and highest mean root length (8.6 ± 0.2 cm). Conclusively, micropropagated *G. walla* plantlets were managed in acclimatization process.

Diversity of Arecaceae in Amapá: The beginning

Tonny Medeiros
Instituto de Pesquisas Científicas e Tecnológicas do Estado do Amapá

The palm trees (Arecaceae) form a group with high species richness in the Amazon Forest. They are widely distributed, occurring mainly in the tropics and subtropics, in diverse habitats and at different reliefs, including the maritime borders to interior regions, emphasizing that there is a gradient of density and decreasing wealth from the Andes to the Atlantic Coast. In many neotropical forests, palm trees stand out for the abundance and richness of species, both in the sub-forest and in the upper strata. The great abundance and diversity of the palm trees in these forests indicate that they are elements of great importance in the structure and functioning of ecosystems. In addition to its ecological importance, the number of basic products for human subsistence is higher in the Arecaceae family than in any other family of plants. Studies in the Amazon have shown that these plants account for between 6 and 7% of the total aerial biomass of the forest, but their fruits rich in lipids and carbohydrates contribute about 60% of the energy content of all fruits produced. The number of species is considered floating and controversial, since specialized literature estimates quantities ranging from 2,500 to 3,500, with approximately 230 genera. In general, the Brazil is considered the third richest country in native palm diversity, with around 37 genera and 288 species. The Amazon flora has a significant number of palms, the surveys already recorded about 232 species and 32 genera, considering that other species are to be discovered and de-

scribed as new regions are explored. Although research on Arecaceae has advanced in the last decades, most of the phytosociological studies carried out in the Amazon use criteria for inclusion in samplings of individuals that exclude palm trees. When these are included, few species are mentioned due to the minimum diameter and the difficulties in the collection and herborization procedures, as a consequence, the available data on floristic composition and palm dynamics are still very scarce. This is the case of the state of Amapá that concentrates one of the largest biodiversity in natural environments, since it is part of two geographical domains, the Amazonian and the oceanic. But little is known about the diversity and richness of palm trees. The Amapá presents most of its territory converted into protected areas, but it is the only Brazilian state in which there is no official list of plants, due to several factors, but mainly due to the incipience in botanical collections in certain places, as pointed out, in recent studies that in Brazil among the priority regions for botanical inventories is included the Tumucumaque Mountains National Park, located in the State of Amapá. Records point to about 36 species and 11 genera: *Astrocaryum*, *Bactris*, *Desmoncus*, *Geonoma*, *Hyospathe*, *Manicaria*, *Mauritia*, *Mauritiella*, *Oenocarpus*, *Socratea*, *Syagrus*, from palm trees of the Amapá. Facing the diversity of Arecaceae in the Amazon, this number denotes the need for studies with the family on diversity, wealth and biotic associations.

Ethnobotany in the Amapá: Situation and perspective

Raullyan Silva

Instituto de Pesquisas Científicas e Tecnológicas do Estado do Amapá

The ethnobotanical and ethnopharmacological studies are important to provide information on the extent and intensity of traditional use of plant resources by the population and in recent years there has been an increase in this type of study in Amapá state providing information about medicinal plants, ornamental, toxic and food through various sources such as academic work in its various levels, as well as through scientific papers published in scientific journals. This whole arsenal of scientific information that could (and should) serve to support more accurate studies for the development of natural products phytochemical in the discovery of new bioactive substances and production of new drugs, the improvement of existing drugs, the production of insecticides, repellents and phytocosmetics, but unfortunately this wide range of information, though important, are not systematized, leaving to be effectively useful for their applicability purposes. Therefore, this research aimed to make the state the rescue of art ethnobotany and ethnopharmacology produced in Amapá. How to collect and record data instrument was used a form to register to published works as well as a portable scanner was used to make the digital recording information in a practical, direct and safe, and then transported for processing database. They recorded 231 species included in 76 families and 184 genera. The families with the highest number of species were Fabaceae, Lamiaceae, Asteraceae, Solanaceae, Arecaceae and Rutaceae. The genera that had the highest number of species were: *Citrus, Piper, Bauhinia, Capsicum, Ocimum* and *Solanum*. Regarding the growth habit of the plant species recorded, there are the woody plants, followed by those of herbaceous, shrub, the habit of scandent and sub-shrubs. It was demonstrated the wealth of plant diversity known and used by the residents of communities in the state of Amapá, making a motivating factor to broaden and deepen research in agricultural sciences, forestry, ethnobotanical and pharmacological.

Flavonoid-containing plants of flora of Azerbaijan and prospects of their use

Eldar Novruzov [1], *Elnura Jafarova*[2], *Mehriban Zulfugarova*[1], *Aydan Zeynalova*[1]

1. Institute of Botany Azerbaijan National Academy of Sciences

2. Genetic Resources Institute of the Azerbaijan National Academy of Sciences

Investigation of biologically active substances (BAS) in plant sources has always been a topical issue of plants resources. Among the BAS of plant origin, flavonoids occupy a special place. Flavonoids, including numerous and varied in structure phenyl-chromone derivatives have strong anti-allergic, anti-carcinogenic, anti-inflammatory, antiviral and other properties. This is due to the presence in their molecules reactive hydroxyl and carbonyl groups. Flavonoids unlike phenolic antioxidants (tocopherols), except direct antiradical action, are capable of binding to a metal ion with a variable valence and form chelate complexes, which leads to the inhibition of free radical processes. Besides inhibiting monoamine oxidase, inhibit reactive oxygen species, which is very promising for the treatment of certain neurodegenerative diseases, inhibit lipid peroxidation, thus preventing cardiovascular diseases, promote the stabilization of production collagen, inhibit platelet aggregation and stimulate the endothelium of prostaglandins, reduce the rate of cancer cell division, can inhibit carcinogenesis. In the analysis of official sources of drugs found that there are 140 trade names of drugs based on flavonoids. According to pharmotherapetic actions flavonoid drugs grouped as angioprotectors, gepatoprotektory, hypnotics, sedatives, cardiac, improve of cerebral and peripheral circulation, and others.

In the study of flavonoid-containing plants of flora of Azerbaijan revealed that 364 species belonging to 110 genera and 46 families contain flavonoids. Of these, 314 species of flavonoid is installed for the first time. Content of flavonoids depending on characteristics of plant species in fruit varies from 9.4 to 2710.5 mg%, in the flowers of 51.9 to 5213.4 mg%. Most are rich in flavonoids species of the family Rosaceae, Eleagnaceae, Asteraceae, Apiaceae, Hypericaceae, Polygonaceae, Fabaceae, Berberidaceae, Salicaceae, Sambucaceae, Punicaceae. Most rich content of flavonoids in the flowers are considered the following: *Salix caprea* L. – 1011.3 mg%, *Populus transcaucasica* A. Jarmol. - 2115.5 mg%, *Berberis iberica* Stev.et Fisch. ex. DC. - 1018.6 mg%, *Crataegus pentagyna* Waldst.et Kit – 1117.9 mg%, *Crataegus caucasica* C.Koch – 1025.8 mg%, *Hippophae rhamnoides* L. – 1513.1 mg%, *Helichrysum plicatum* DC. - 5213.4 mg%, *Helichrysum callichrysum* DC. - 3758.9 mg%, *Helichrysum azerbaidzhanicum* D. Sosn. - 3570.4 mg%, *Tragopodon gramnifolius* DC. - 1034.5 mg%, *Spartium junceum* L. – 2211.6 mg% . It was found that the content of flavonoids depends on soil and climatic conditions and the members of the phytocenoses and qualitative composition is a biological feature of the type acquired in the course of evolution, and not subject to change. The regularities flavonoid-containing types of vertical zonation and botanical and geographical areas. It was found that with increasing altitude above sea level increases the number of flavonoid-containing species. By saturation different lower and middle belts. Flavonoid-containing plants are concentrated in the Greater Caucasus, Nakhchivan Autonomous Republic and Talysh. From the researched types more than 90 types as on content, high-quality structure, and also on raw material stocks it is possible to carry to perspective for receipt of medicines, dietary supplements, and also for increase in biological value of food and cosmetic products.

Genetic diversity assessment of under-exploited African plants for genetic improvement and food security

Conrad A. Omonhinmin, *Jacob O. Popoola, Fisayo Daramola, Samuel A. Ejoh, Omolola E. Omotosho, Raphael Mordi, Ayoola Ayodeji, Olugbenga Taiwo*
Covenant University, Ota, Ogun State,

Climate change, loss of natural habitats and environmental degradation due to developmental drives are major factors accelerating the alarming rate of plant and animal diversity loss. Changes in consumer demand and the use of only a few species, varieties and breeds have also exacerbated genetic erosion. Above all, a North-South dichotomy in research focuses on global production of food, medicine etc, have relegated African plants to the background, creating the “Orphan plants or crops” of today. The pressure on forest lands, forests and the effects of unsustainable use of forest resources, pose a grave concern on the loss of potentially important plants species; and with only an estimated one percent (1%) of the over 80 000 tree species studied so far, efforts to carry out proper genetic diversity and conserve valuable food, spices, beverage and medicinal resources of African plants that are endemic, indigenously cultivated and an integral part of the way-of-life of Africans stand to offer the only true food security antidote for Africa. The present study focuses on a solution-based research effort on improved genomic information generation on indigenous but under-exploited African plant species. In our present research effort, we have commenced the genetic diversity study of 30 indigenous plants across Northern and Southern Nigeria. The survey spanned 192 communities, in 101 Local Government Areas of 35 States and the Federal Capital; generating a total of 682 accessions of 30 plant species. The research proposes to generate reliable molecular information on the plants applying rbcL sequencing and DNA barcoding tools. The results will impact immensely on biodiversity conservation of the species, draw the attention of global researchers and developmental organizations to these plants as well as directly affect other core SDG targets like; Poverty, Hunger and Food security, Health, Energy, Economic growth, Inequality, Gender equality and Women empowerment, Sustainable consumption and production, Climate change, Forest desertification and partnership.

Tropical tree genomics reveals fragmentation of the African rainforest during the ice ages

Rosalia Piñeiro
Royal Botanic Gardens, Kew

The fossil record in tropical Africa suggests that dry conditions during the Ice Ages caused the contraction of rainforests in favour of savannahs. This seems to explain why the African rainforest harbours less species than rainforests in South America and South East Asia. Based on the rate of endemic species, the location of forest refugia has been proposed. However, to what extent the forest was fragemented, where it survived, and the timing of demographic events remain unknown. In order to address these questions, genomic data from 250 trees of six rainforest tree species were generated using nuclear microsatellites and Genotyping by Sequencing (GBS). Phylogenomic reconstructions, Bayesian clustering, and GIS tools showed congruence of the intraspecific genetic discontinuities across species in Central Africa, pointing at common barriers to gene flow. Demographic model tests revealed the intraspecific gene pools diverged during the Pleistocene (<2Myr ago), so that intraspecific differentiation is the appropriate scale to test the effect of Pleistocene dry periods on tree populations. Demographic tests revealed clear genetic signals of population expansion in both taxa, possibly following bottleneck events after forest fragmentation.

The genus *Lejeunea* in Eocene amber from Baltic in the west coast of Russia

Wei Cao, *Yuanxin Xiong, Xianzhen Luo, Hongying Tan, Degang Zhao*
College of Life Science, Guizhou University

A sterile liverwort inclusion in a piece of Eocene amber which collected from Baltic and deposited in in Guizhou University Museum, is described and assigned to the extant genus *Lejeunea*. Cenozoic ambers are a valuable source of bryophyte inclusion and provide evidence for the presence of numerous extant genera of leafy liverworts in the Eocene and Oligocene. Most Eocene amber inclusion of liverworts come from Baltic. Some of these inclusions do not match the morphology characteristics due to morphology stability of liverworts over a period of 15-20 million years. The inclusion resembles a complex of extent Russia *Lejeunea* species (*L.cavifolia*, *L. japonia*, *L. otiana* and *L. alaskana*) that share a small size, ovate to obovate leaf lobes with rounded apices, leaf lobule not reduced, first tooth spreading towards leaf apex. It is impossible that the sample can be definited to one of these species due to lack of several diagnostically relevant charaters such as perianths and oil bodies. The inclusion is clearly different from the extinct species *Lejeunea* palaeomexicana from Mexican amber, so the *Lejeunea* species first occurred in the Baltic.

Molecular systematics and biogeography of genus *Saussurea* DC. (Asteraceae)

Yousheng Chen, *Qian Yuan*
Institute of Botany, Chinese Adademy of Sciences

Saussurea DC., one of the largest genera of Asteraceae tribe Cardueae, includes approximately 460 species, and is a typical group occurs in the Northern Hemisphere. Previous molecular systematics studies showed that the subgenera and sections in genus *Saussurea* are mostly not monophyletic, and genus *Saussurea* needs a more nature classification system. Besides, the origin and evolution, the present distribution pattern of *Saussurea* is not clear. In the present study, *Saussurea* species have been sampled in a large scale, and their phylogenetic relationships were reconstructed using molecular phylogenetic analyses and ancestral character reconstruction methods. Meanwhile, the origin and evolution, and the mechanisms of shaping the present distribution pattern in this genus were also discussed based on our phylogenetic framework. 1) Molecular phylogeny. We sampled 441 accessions belong to 263 species in *Saussurea* most representing the species diversity and geographical distributions. Molecular phylogenetic analyses based on two nuclear genes (ITS and ETS) and seven plastid genomic regions (*ycf1, rpl32-ndhF, psbA-trnH, trnL-F, rbcL, trnY-rpoB, trnL-rpl32*) provided a relatively better phylogenetic framework: (1) the species of *Saussurea* formed a highly supported monophyly, and the sister group is *Polytaxis*. (2) traditional taxonomy system of genus *Saussurea* was broken completely; (3) and *Saussurea* should be divided into five clades. 2) The evolution history of several morphological characters. Seven morphological characters (habitat, stem obviously or not, stem has wing or not, leaf shape, inflorescence, involucre shape, the density of hairs on involucral, phyllary reflexed or not) have been used to reconstruct their evolutionary pattern. The results show that these morphological characters which were usually used to classify and identificate *Saussurea* species originated many times, and have experienced convergence evolution. 3) Biogeographical history of *Saussurea.* Based on the phylogenetic tree, molecular dating analysis was done using BEAST, and ancestral area reconstruction was done by three methods: S-DIVA, DEC and S-DEC. The results indicated that (1) *Saussurea* might originate from Hengduan mountains during late-Miocene; (2) The first divergence of *Saussurea* fell at ca. 7.66 Mya, affected by the third major Qinghai-Tibetan Plateau (QTP) uplifts; (3) the forth QTP rapid uplift since 3.6 Mya might driven the radiation and diversification of *Saussurea*. (4) the global temperatures drop significantly from late Miocene might result in dispersal to other mountains the QTP and Hengduan mountains; (5) *Saussurea* might arrive at North America during Pleistocene.

Holly leaf epidermal cell classification by the LeNet CNN model

Yuan Liu[2], *Jingyao Tu2, Miao Ma*[1,2], ***Yuli Chen***[1,2]
1. Key Laboratory of Modern Teaching Technology, Ministry of Education
2. Shaanxi Normal University

The worldwide genus *Ilex* Linnaeus is of very important economic, ornamental and medicinal value, and encompasses more than 500 species of dioecious shrubs and small trees distributed in tropical to warm temperate regions. However, extant *Ilex* species have extremely high intraspecific variability in leaf morphology, which resulted in a heated controversy on the intrageneric taxonomy and systematic relationships. The leaf epidermal characteristics of hollies (such as stomatal apparatus, anticlinal wall and epidermal hairs) can be proved to objectively circumscribe the phylogenetic relationships of different taxa and hence has great potential for understanding the classical taxonomy, paleobotany and phylogenetics. Understanding the variable, complex cuticle characters of holly leaves is one of the most challenging problems in phytotomy. Machine learning offers opportunities to deal with large numbers of microscopic images, to discover novel cuticular features of the intrageneric taxa that may have phylogenetic significance, and to use those characters to classify unknowns. Here, we tested whether a LeNet Convolutional Neural Networks (CNN) model (LeCun *et al.,* 1998) could use a database of 196,211 *Ilex* leaf anatomical images (including upper and lower epidermis) from 101 species of the subgenus *Ilex* (sections *Lioprinus*, *Paltoria*, *Ilex* and *Pseudoaquifolium*) and subgenus *Prinos* to learn features of botanical subgenera, sections and species, then classify novel images. Convolutional Neural Networks (CNN) is a kind of multi-layer neural networks trained with back-propagation algorithm. In this paper, we employ the classical deep LeNet CNN model to identify the database of holly leaf cuticle images (Li *et al.,* 2010) as shown in Table 1. The LeNet CNN model consists of convolution layers and subsampling (pooling) layers alternately, and ends with a fully connected layer. We conducted five experiments for the four sections and one subgenus, respectively. For each experiment, we further performed three sub-experiments for analyzing upper, lower and mixed epidermal cells, respectively. All of the images in the database are separated as the training and validation sets. Our experiments are carried out under the Matconvnet toolbox (http://www.vlfeat.org/matconvnet/). The input of the LeNet model is a holly leaf cuticle image. The output of the model is a vector of elements whose amount is identical to the species number. The element values indicate the probabilities of the input image belonging to the corresponding species. The species with the highest probability is regarded as the predicted result. The accuracy rates of the five experiments showed that the LeNet CNN model has a good performance on the classification of holly leaf cuticle images. Among the four sections and one subgenus of holly, the best accuracy rate reaches 95% and the lowest one is 79% as shown in Table 2. Therefore, the LeNet CNN model is likely to prompt recognition and interpretation of a wealth of cuticle characters. With assistance from computer vision, cuticles are poised to make numerous new contributions to systematic and paleobotanical studies.

Oligocene *Acer* fruits from the Ningming Basin in Guangxi, South China

Yunfa Chen[1], *Qi Wang*[2], *Qian Hu*[1], *Yongqing Liufu*[1], *Zhiming Xie*[1]

1. Guangxi Museum of Natural History

2. Institute of Botany, Chinese Academy of Sciences

Acer ningmingensis sp.nov. is described for asymmetric samara from the Oligocene Ningming Formation in Guangxi Zhuang Autonomous Region, South China. Fruits samaroid; nutlet at basal end; nutlets 0.7 to 0.8 cm long, 0.4 to 0.5cm wide, outline elliptic; nutlet flattened or very thin; attachment scar 0.4-0.5cm long, attachment angle 30°to 45°, nutlet angle 20°to 25°; veins on nutlet obscure, nutlet surface nearly smooth; proximal margin of nutlet either not or only slightly expanded beyond proximal margin of wing; wing 3.0-3.4cm long, 0.9-1cm wide; wing apex narrowly rounded and conspicuously inclining to proximal side; proximal margin broadly concave, distal margin broadly rounded - broadly convex, forming a broadly shallowly V-shaped sulcus with nutlet; proximal margin with 5 prominent veins coalesced along the wing proximal margin, extending from apical margin of nutlet; wing veins diverging from proximal margin at angles of 20° to 40°, nearly straightly extending toward distal margin, the angles increasing from the apex to the base, dichotomizing 2 to 4 times, few anastomoses. The winged fruits described in this paper are similar to the fossils of *Acer stewarti* in the North America. However, the nutlet outline of *Acer stewarti* is circular, concave-convex, and wing proximal margin straight, veins in wing body dichotomizing more (5 to 6 times). The present fossil differs from modern *Acer laxiflorum* fruit in Guangxi, South China which is characterized by straight proximal margin and much bigger attachment angle (>70°). The fossil is the lowest latitude Oligocene *Acer* documented in China, even in Asia, and the only recorded Oligocene *Acer* samaras from a tropical zone today. It suggests that, plant *Acer* had been widely distributed in the Oligocene in Northeast Asia and East Asia, and the climate of the Ningming area in the Oligocene would be cooler than at present.

Species richness and distribution of *Plagiochila* (Plagiochilaceae) in Mt. Apo and Mt. Limbawon, Mindanao, Philippines

Fulgent Coritico, *Victor Amoroso*

Central Mindanao University

There is a limited study regarding the hepatic flora in the Philippines. One of the largest genera of the liverworts (hepatics) is *Plagiochila*. It is one of the main components of bryophyte communities in tropical mossy forests. This research was conducted to determine the species richness and distribution of *Plagiochila* (Plagiochilaceae) based on field surveys from the two mountain ecosystems in Mindanao, viz., Mt. Apo and Mt. Limbawon and available herbarium data. A total of fourteen species are known from these mountains, *viz*, *Plagiochila arbuscula*, *P. blepharophora*, *P. dendroides*, *P. frondescens*, *P. fusca*, *P. javanica*, *P. massalongoana, P. philippinensis*, *P. propinqua*, *P. renitens*, *P. salacensis*, *P. sciophila*, *P. trabeculata* and *P. sp*. This is about 28% of the total number of species found in the Philippines. The richness of *Plagiochila* is comparatively similar in Mt. Banahao, Luzon and comparatively higher in Mt. Makiling, Mt. Pulog, and Mt. Data in Luzon Island. Majority of the species observed are closely related to the species found in the neighboring island of Mindanao such as Java, Sumatra and Borneo. Assessment of the species revealed one endemic species, *P. philippinensis*. The study obtained the first records of *P. arbuscula, P. frondescens, P. javanica, P. massalongoana, P. philippinensis, P. salacensis, P. sciophila, P. trabeculata* for the island of Mindanao and one possible new species.

Identification of 220 strains of *Alternaria* in China

Hui Deng, *Yan Min Hou, Yong Chun Niu*

Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences

Alternaria is a genus with abundant saprophytic, endophytic and pathogenic species associated with various plant substrates. According to DNA-based studies during recent years, *Alternaria* is currently divided into 26 sections. To identify 220 strains of *Alternaria* preserved in Agricultural Culture Collection of China (ACCC), morphological and molecular phylogenetic analysis were studied on them. All of the 220 strains were sequenced by the glyceraldehyde-3-phosphate dehydrogenase (GPDH) gene, and some strains were sequenced by the translation elongation factor1-a (EF-1a) gene, RNA polymerase second largest subunit (rpb2) or *Alternaria* major allergen gene (Alt a 1) regions. The data show that the 220 strains are identified as species in six sections, sect. *Alternaria*, sect. *Brassicicola*, sect. *Panax*, sect. *Porri*, sect. *Pseudoulocladium*, sect. *Ulocladium*. There are six species in sect. *Alternaria*, *Alternaria alternata*, *A. burnsii*, *A. gossypina*, *A. jacinthicola*, *A. longipes*, and one possible new species of six strains isolated from various plants in Hainan and Guangdong provinces.

Taxonomic and systematic studies on Acanthaceae from China

Yunfei Deng

Key Laboratory of Plant Resources Conservation & Sustainable Utilization, South China Botanical Garden, Chinese Academy of Sciences

Acanthaceae is a tropical family of about 230 genera and 4500 species. In mostly recent publication of Volume 19 of *Flora of China*, 35 genera and 304 species were recognized. After completing the treatment for *Flora of China*, the relationships among Chiense Acanthaceae were studied, some genera were re-delimited, and the thorough taxonomic revision was carried out. Six chloroplast DNA regions and one nuclear region were used in the phylogenetic study, the result indicated that Acanthaceae from China can be divided into four subfamilies, viz. Nelsonioideae, Avicennioideae, Thunbergioideae and Acanthoideae. Acanthoideae can be divided into four tribes, viz. Acantheae, Ruellieae, Andrographideae and Justiceae. The subdivision at subtribal level within Ruellieae and Justiceae are also discussed. The generic circumscription of *Ruellia* and *Strobilanthes* in broad sence is supported, but *Justicia* is a polyphyletic and the treatment in broad sense is not supported and further studies need be done. *Leptosiphonium venustum* might be treated to be a new genus *Psendosiphonium* Y.F. Deng *et al.,* ; the species of *Echinacanthus* from China and Vietnam are quite different from the type of the genus and should be described as a new genus *Sinoacanthus* Y.F. Deng *et al., Justicia grossa* and *J. microdonta*, two species previously placed in the genus *Justicia* might be moved from Jusciciinae to Isoglossinae and *Tetramerium*-lineage, and they present two un-described new genera, *Hanseniacanthus* Y.F. Deng and *Wuacanthus* Y.F Deng *et al.,* respectively. Two genera *Asystasiella* and *Haplanthus* are resurrected. *Cystacanthus* is merged with *Phlogacanthus*. After the treatment of the family Acanthaceae for *Flora of China*, 10 new species were discovered, 6 names were reduced to the synonymy. Consequently, 40 genera and 308 species are currently recognized.

A094

Molecular phylogeny of *Cladrastis* clade and resurrection of *Platyosprion* (Leguminosae: Papilionoideae)

Lei Duan[1], *Jun Wen*[2]
1. South China Botanical Garden
2. Smithsonian Institution

Based on sequence data of nuclear ITS and plastid *matK*, *trnL-F* and *psbA-trnH* markers, the phylogeny of *Cladrastis*, *Pickeringia* and *Styphnolobium* in the tribe Sophoreae was inferred. The results showed these three genera form a clade, phylogenetically away from the rest of Sophoreae. *Cladrastis* is polyphyletic, which is redelimited to include *C. delavayi*, *C. kentukea*, *C. shikokiana* and *C. wilsonii*. *C. chingii*, *C. parvifolia* and *C. scandens* are treated as synonyms of *C. platycarpa*. The genus *Platyosprion* is resurrected on the basis of *C. platycarpa*. The monophyly of *Pickeringia* and *Styphnolobium* are supported, and two subgenera were recognized within *Styphnolobium*.

Genomic SSR in *Gentiana lawrencei* var. *farreri*: Characterization, marker identification and transferability in its congeneric species

Peng-Cheng Fu[1], *Shan-Shan Sun*[1], *Yan-Wei Cheng*[1], *Hui-Yuan Ya*[1], *Shi-Long Chen*[2]
1. Luoyang Normal University
2. Northwest Institute of Plateau Biology, Chinese Academy of Sciences

Gentiana lawrencei var. *farreri* T. N. Ho is a popular perennial herb in the Qinghai-Tibetan Plateau (QTP) alpine meadow and has been used in traditional Chinese and Tibetan medicine. Reliable and highly polymorphic molecular markers are required for genetic diversity and conservation studies in this species. In this study, enriched DNA libraries of *G. lawrencei* var. *farreri* were used for high-throughput microsatellite development by 454 FLX+ platform. We obtained 87,097 reads with an average length of 809 bp. The total size of examined sequences was 23,848,926 bp, from which 6,381 SSRs were identified. Of these sequences, 4,831 contained SSRs, with 24.07% featuring more than one SSR. Only 23.37% SSRs were present in compound formation. SSRs with repeat motifs of 2–3 bp (di- and tri-nucleotide repeats) accounted for 97.05% of SSRs. Tri-nucleotide repeats were the most abundant. The predominant motif was (AAC/GTT)n and (AG/CT)n. A total of 3031 primer pairs were designed and 96 were selected for validation. After screening using a series of criteria, a set of 20 fluorescently labeled primer pairs was further selected and screened for polymorphisms in two populations of *G. lawrencei* var. *farreri* and two populations of *G. veitchiorum*. The average number of alleles per locus was 15.2 in the two taxa. Among the four populations, mean observed and expected heterozygosities ranged from 0.222 to 1 and 0.221 to 0.914, respectively. Of the 20 loci, 12 showed significant deviation from Hardy-Weinberg equilibrium (HWE) in one or more populations and only one locus showed significant deviation from HWE in all the four populations. Finally, removing linked loci, a set of 17 unlinked loci was in HWE. The genetic clustering showed that the four populations from two taxa should be grouped into two clusters, indicated the 20 SSRs could be reliable for species delimitation of the two taxa. In conclusion, the newly identified SSRs should be useful for study about genetic diversity, gene flow and evolution in *Gentiana*.

A096

The complete chloroplast genome sequence of *Gentiana lawrencei* var. *farreri* (Gentianaceae) and comparative analysis with its congeneric species

Peng-Cheng Fu[1], *Shan-Shan Sun*[1], *Yan-Zhao Zhang*[1], *Shi-Long Chen*[2]
1. Luoyang Normal University
2. Northwest Institute of Plateau Biology, Chinese Academy of Sciences

Background. The chloroplast (cp) genome is useful in plant systematics, genetic diversity analysis, molecular identification and divergence dating. The genus *Gentiana* contains 362 species, but there are only two valuable complete cp genomes. We report the characterization of complete cp genome of *G. lawrencei* var. *farreri*, which is endemic to the Qinghai-Tibetan Plateau (QTP). Methods. Using high throughput sequencing technology, we got the complete nucleotide sequence of the *G. lawrencei* var. *farreri* cp genome. The comparison analysis including genome difference and gene divergence was performed with its congeneric species *G. straminea*. Results. The cp genome of *G. lawrencei* var. *farreri* is a circular molecule of 138,750 bp, containing a pair of 24,653 bp inverted repeats which are separated by small and large single-copy regions of 11,365 and 78,082 bp, respectively. The cp genome contains 130 known genes, including 85 protein coding genes (PCGs), eight ribosomal RNA genes and 37 tRNA genes. Comparative analyses indicated that *G. lawrencei* var. *farreri* is 10,241 bp shorter than its congeneric species *G. straminea*. Four large gaps were detected that are responsible for 85% of the total sequence loss. Further detailed analyses revealed that 10 PCGs were included in the four gaps that encode nine NADH dehydrogenase subunits. The cp gene content, order and orientation are similar to those of its congeneric species, but with some variation among the PCGs. Three genes, *ndhB*, *ndhF* and *clpP*, have high non-synonymous to synonymous values. There are 34 SSRs in the *G. lawrencei* var. *farreri* cp genome, of which 25 are mononucleotide repeats: no dinucleotide repeats were detected. Comparison with the *G. straminea* cp genome indicated that five SSRs have length polymorphisms and 23 SSRs are species-specific. The phylogenetic analysis of 48 PCGs from 12 Gentianales taxa cp genomes clearly identified three clades, which indicated the potential of cp genomes in phylogenetics. Discussion. The "missing" sequence of *G. lawrencei* var. *farreri* mainly consistent of *ndh* genes which could be dispensable under chilling-stressed conditions in the QTP. The complete cp genome sequence of *G. lawrencei var. farreri* provides intragenic information that will contribute to genetic and phylogenetic research in the Gentianaceae.

Gene flow results in high genetic similarity between *Sibiraea* (Rosaceae) species in the Qinghai-Tibetan Plateau

Peng-Cheng Fu[2], *Qing-Bo Gao*[1], *Fa-Qi Zhang*[1], *Rui Xing*[1], *Jiu-Li Wang*[1,3], *Hai-Rui Liu*[1,3], *Shi-Long Chen*[1]

1. Northwest Institute of Plateau Biology, Chinese Academy of Sciences

2. Luoyang Normal University

3. University of Chinese Academy of Sciences

Studying closely related species and divergent populations provides insight into the process of speciation. Previous studies showed that the *Sibiraea* complex's evolutionary history on the Qinghai-Tibetan Plateau (QTP) was confusing and could not be distinguishable on the molecular level. In this study, the genetic structure and gene flow of *S. laevigata* and *S. angustata* on the QTP was examined across 45 populations using 8 microsatellite loci. Microsatellites revealed high genetic diversity in *Sibiraea* populations. Most of the variance was detected within populations (87.45%) rather than between species (4.39%). We found no significant correlations between genetic and geographical distances among populations. Bayesian cluster analysis grouped all individuals in the sympatric area of *Sibiraea* into one cluster and other individuals of *S. angustata* into another. Divergence history analysis based on the approximate Bayesian computation method indicated that the populations of *S. angustata* at the sympatric area derived from the admixture of the 2 species. The assignment test assigned all individuals to populations of their own species rather than its congeneric species. Consistently, intraspecies were detected rather than interspecies first-generation migrants. The bidirectional gene flow in long-term patterns between the 2 species was asymmetric, with more from *S. angustata* to *S. laevigata.* In conclusion, the *Sibiraea* complex was distinguishable on the molecular level using microsatellite loci. We found that the high genetic similarity of the complex resulted from huge bidirectional gene flow, especially on the sympatric area where population admixtures occurred. This study sheds light on speciation with gene flow in the QTP.

Systemetics and taxonomy of the genus *Sinoacanthus* (Acanthaceae)

Chunming Gao[1], *Yunfei Deng*[2]

1. Binzhou university

2. South China Botanical Garden

Sinoacanthus, a new genus of Ruellinae in Acanthaceae restircted to Sino-Vietnamese karst flora, and including three species, S. *longipes*, *S. longzhouensis* and *S.lofouensis,* is segregated from *Echinacanthus.* There are some differences between *Sinoacanthus* and *Echinacanthus* based on the morphological, pollen and molecular characters. Firstly, the inflorescence of *Echinacanthus* is thyrsus, but, the *Sinoacanthus* is cyme. Then, *Sinoacanthus* has appendaged anthers with two appendages per thecae (*S. lofouensis* has one two-in-one appendaged per thecae based on our study). But, *Echinacanthus* species have appendaged anthers with one appendaged per thecae. Furthermore, pollen aperture of *E. attenuatus* arranged on the band and reticulate exine, pollen aperture of Chinese pants are located in pseudocolpi and perforate surface. Finally, *Echinacanthus* is included in subtribe Petalidiinae and *Sinoacanthus* is a member of subtribe Erantheminae based on our phylogenetic relationship. *Sinoacanthus* in Subtribe Erantheminae of Ruellinae. The new genus, *Sinoacanthus,* is a monophyletic group based on our molecular study. Furthermore*, Sinoacanthus longzhouensis* formed sister group with the clade of *Sinoacanthus longipes and Sinoacanthus lofouensis*. *Sinoacanthus* is a typical genus of Sino-Vietnamese karst flora. The there species have Relatively independent niche. *Sinoacanthus longzhouensis* is distributed endemic to Guangxi, Guangdong of China. It grows in limestone hills in forests (300-400m). *Sinoacanthus longipes* is distributed Guangxi, Yunnan of China and Vietnam. It grows in of limestone hills in forests (500-2000m). *Sinoacanthus lofouensis* is a species endemic to Guangxi, Guizhou in China and grows in limestone hills in forests about 500-1000m. It may be an examples in the development of Sino-Vietnamese karst.

A099

Population genetic differentiation and taxonomic suggestions of two highly fragmented *Saxifraga* species endemic to the Qinghai-Tibetan Plateau

Qingbo Gao[1], *Yan Li*[1,2], *Zhuoma Gengji*[1,2], *Shilong Chen*[1]

1. Key Laboratory of Adaptation and Evolution of Plateau Biota, Northwest Institute of Plateau Biology, Chinese Academy of Sciences, Xining 810001, Qinghai, China

2. University of Chinese Academy of Sciences, Beijing 100039, China

Saxifraga pasumensis and *S. umbellulata* are two narrowly distributed and well isolated species endemic to the Qinghai-Tibetan Plateau (QTP). Taxonomy of *S. pasumensis* is still in controversy. In this study, three chloroplast DNA fragments (*rbcL*, *trnL-F*, *trnS-G*) and nuclear ribosomal DNA internal transcribed spacer (ITS) were employed to study genetic structure across 104 individuals from 12 populations of *S. pasumensis* and *S. umbellulata*, including one population which was recognized as a novel species, *S. banmaensis*. Chloroplast DNA (cpDNA) phylogenies revealed two well supported clades, corresponding exactly to the two species as identified based on morphology. Topology of ITS phylogenies was largely congruent with that generated from cpDNA haplotypes, but with minor conflicts which might be caused by incomplete lineage sorting. Analyses of molecular variance based on both cpDNA and ITS datasets revealed that most variance was detected between species (92.31% for cpDNA; 69.78% for ITS), suggesting high differentiation between *S. pasumensis* and *S. umbellulata*. Analyses of molecular clock and S-DIVA suggested a vacariant allopatric speciation of the two species at ca. 4.37 Ma, coinciding with the most recent uplift event of the QTP. Vacariance associated with QTP uplifts should also be responsible for intraspecific divergence in *S. pasumensis*. However, intraspecific divergence of *S. umbellulata* was most likely triggered by Quaternary glaciations. The extremely low gene diversity within populations of *S. pasumensis* could have resulted from both fragmentation and human collection due to its medical utilization. Combining morphological characteristics, biogeographic distribution and our molecular results, *S. pasumensis* is better to be treated as a species instead of a variety, and *S. banmaensis* should be treated as a synonym of *S. pasumensis*.

Liliaceae Juss. in the Azerbaijan flora

Parvana Garakhani[1], *Tariyel Talibov*[2]

1. Institute of Botany of Azerbaijan National Academy of Sciences

2. The Institute of Bioresources of Nakhchivan Division of Azerbaijan National Academy of Sciences

Some researchers of the recent years studying Liliaceae Juss. stated that extent of this family is disputable and consists of genera of different origins in the heterogeneous content. Modern systematists determined several evolution branches within the family and accepted them as independent families. Representatives of the family are encountered in many areas of world. Liliaceae Juss. species are distributed in the forests, lowlands, even in the deserts. Lilies is not only grass plants, it has shrub and/or tree representatives in Africa. Species from the family are decorative plants. Liliaceae Juss. of Azerbaijan flora is divided into several genera: *Tulipa* L., *Gagea* Salisb., *Lilium* L., *Fritillaria* L., *Liloydia* Reichenb. Among these genera *Tulipa L.* is are clearly distinguished with its decorative capasities. Tulipa comprises up to 100 species in the world and 7 in Azerbaijan. In recent years, based on the detailed results, 2 new species recorded and the taxon number of this family increased up to 9 species. *Fritillaria* L. is represented with 8 species, 1 sub-species in the Azerbaijan flora. *Lilium* L. comprises 2 species, 2 sub-species. *Liloydia* Reichenb. is represented with 1 sub-species, and *Gagea* Salisb. with 18 species in the Azerbaijan flora. Many of the species included to the family Liliaceae are endemic and rare species. These species are included to the 2nd editon of the Red Book of the Republic of Azerbaijan (2013). These species are as followings: *Fritillaria caucasica* Adams – ENA1c:B1ab (iii). Rare species of Azerbaijan; *Fritillaria gibbosa* Boiss. (Rinopetalum gibbosum Boiss.) Losinsk et Vved. – VUA2c+3c. Rare species of Azerbaijan; *Fritillaria grandiflora* Grossh. – CRB1ab (v). Endemic species of Azerbaijan; *Fritillaria kotchyana* Herb. – ENA2c. Rare species of Azerbaijan; *Gagea glacialis* C.Koch.– NT. Rare species of Azerbaijan; *Lilium ledebourii* (Baker.) Boiss. – ENA2c. Rare species of Azerbaijan, endemic species of Caucasus; *Tulipa biebersteiniana* Schult.et Schult. – VUA2c+3c. Rare species of Azerbaijan; *Tulipa biflora* Pall.– VUA2c+3c. Rare species of Azerbaijan; *Tulipa echleri* Regel. – VUA2c+3c. Rare species of Azerbaijan, endemic of Caucasus; *Tulipa florenskyi* Woronov. – VUA2c+3c. Rare species of Azerbaijan, endemic of Caucasus; *Tulipa gesneriana* L. – VUC2a (ii). Rare species of Azerbaijan; *Tulipa julia* C.Koch. – VUA2c+3c. Rare species of Azerbaijan, endemic of Caucasus; *Tulipa karabachensis* Grossh. – DD. Rare species of Azerbaijan; *Tulipa schmidtii* Fomin. – NT. Rare species of Azerbaijan.

Floral ontogeny in *Idesia Polycarpa* (Flacourtiaceae)

Li-Ping Ge

Shanxi Agricultural University

Idesia traditionally belongs to the family Flacourtiaceae. *Idesia Polycarpa*, only species of the genus *Idesia*, is recently concerned and utilized as a kind of biomass energy tree because its seeds can produce more oil. However, there are still many disagreement of classification on the family Flacourtiaceae among different taxonomist, and more phylogenetic analyses show that the family is not a monophyletic group, consequently some former members of Flacourtiaceae are moved into other different family according to new research results. Floral organogenesis has been shown to be valuable in elucidating phylogenetic position for generic and supra-generic taxa, but the floral ontogeny in *Idesia* has not been reported so far. The present work aims to provide data of floral ontogeny for the *Idesia Polycarpa*. The dynamic process on the floral organogenesis both female and male flowers of *Idesia Polycarpa* were examined respectively using scanning electron microscopy (SEM). Both female and male flowers, sepals are initiated successively (not simultaneously) on the periphery of the floral apical meristem; Usually, the adaxial whorl stamens initiate first, followed by the second stamens, and then the outermost stamens. The sequence of the stamen initiation in the polystemonous androecium is somewhat irregular but is whorled (three to four whorl) and centrifugal overall. The pistil is initiated after initiation of the first or second whorl stamen. Significantly, early stamen development in the male flower is resembles that of female flower, nevertheless stamens are turn into staminode during the later development period of the female flower; likewise, pistil also develop in the early male flower, but pistil are turn eventually into pistillode in the male flower. These observation result will be provide further information into the circumscription between female and male flowers.

This research was supported by Natural Science Foundation of Shanxi (2010011039–1)

Phylogenetic relationships in *Anaphalis* DC. (Asteraceae),

inferred from chloroplast genomes

***Junyu Gu**, Zhen Wei, Xuemin Xu, Shixin Zhu*
Zhengzhou University

Anaphalis DC. belongs to the tribe Gnaphalinae, family Asteraceae. The circumscription of the *Anaphalis* is ambiguous due to its unstable and variable characters. Therefore, it is one of the most problematic groups in Asteraceae. DNA sequence analysis is a powerful tool to detect the variation of genetic material, and has been proven to be robust in revealing the evolution and phylogenetic relationships of plants. As sequencing technologies developing, chloroplast genomes have been used to construct phylogenetics on species, genus, tribe and family levels. In this study, we sequenced chloroplast genome sequences of thirty *Anaphalis* species using Illumina Hiseq-PE150 platform. The cp genomes were then annotated and coding/non-coding DNA and RNA sequences were extracted respectively. The phylogenetic relationships in *Anaphalis* were constructed and compared based on different datasets.

A103

Ferns' homologs of leaf polarity gene *ARF4* in *Arabidopsis*

Gui-Sheng Li
Jishou University

Because the evidence at the aspect of gene function on the hypothesis of multiple origin of leaves is scarce, this project studied the evolution of leaf polarity gene *ARF4*. Firstly, this project aiming at the development of fern leaves conducted transcriptome sequencing to two samples of *Ceratopteris pteridoides* and each one sample of *Cyrtomium guizhouense* and *Parathelypteris nipponica*, producing 11.6,12.3,13.3 and 13.3 Gb clean data respectively, and with the combination of RT-PCR obtained the complete coding region of *ARF4* from these three species. It is possible that the three clades of the *ARF* family, *ARF5*/*6*, *ARF10* and *ARF2*/*4* are involved in leaf development in ferns. The *ARF2* and the *ARF4* sub-clade have diverged in ferns, with the former being of multiple copy while the latter single copy. *ARF4* has undergone a gene duplication in the common ancestor of seed plants and the common ancestor of angiosperms. Fern *ARF4* may possess a single tasiR-ARF binding site, while for gymnosperm *ARF4* some have two but some have only one such site, meanwhile angiosperm *ARF4* always have two such sites. It is similar to seed plants that ferns contain two types of *TAS3* genes which can produce tasiR-ARF. Small RNA sequencing of two samples of *Ceratopteris pteridoides* found 284 known miRNA and 173 brandnew miRNA, especially mining out miR390 responsible for *TAS3* processing and small RNA matching tasiR-ARF. In *Ceratopteris pteridoides ARF2* may have been sliced by tasiR-ARF, however whether *ARF4* is cut by tasiR-ARF remained unclear. *ARF4* is expressed in sporangia which are located at the back of leaves. Therefore, the sequence and expression pattern of fern *ARF4* is inclined to the opinion of independent origin of lycophyte microphylls, fern leaves and leaves of seed plants respectively.

Taxonomic studies on species of *Macromitrium* (Orthotrichaceae, Musci) with irregular lamina stratose

*Dandan Li[1], Si He[2], **Shuiliang Guo**[1], Tong Cao[1]*
1. Shanghai Normal University
2. Missouri Botanical Garden

Eight species with irregular lamina stratose in the genus *Macromitrium* (Orthotrichaceae) are morphologically illustrated. Among them, *M. diaphanum* Müll. Hal., *M. nepalense* (Hook. & Grev.) Schwägr., *M. serpens* (Hook. & Grev.) Schwägr. and *M. tongense* Sull. have the character of irregular 1-3 (4)-stratose proliferation with pluripapillose cells over both leaf upper surfaces. The leaf upper parts of *M. st.-johnii* E.B. Bartram and *M. amaniense* P. de la Varde are also special, similar to those of *M. longipes* (Hook. & Grev.) Schwägr. and *M. longirostre* (Hook. & Grev.) Schwägr., partially and variably bistratose, but occasionally arranged jaggedly. Their morphological characteristics are further revealed graphically by compiling figures of digitalized transverse sections of branch leaves. Based on the overall similarities of their gametophytic features, *M. tongense* is reduced to synonymy of *M. serpense*. A key is given to separate the species of the genus *Macromitrium* with irregular lamina stratose stratose.

T2

A105

New synonyms and a quantitative study of the patterns of morphological variation within *Macromitrium microstomum* complex (Bryophyta, Orthotrichaceae)

*Jing Yu[1], Si He[2], **Shuiliang Guo**[1], Tong Cao[1]*
1. Shanghai Normal University
2. Missouri Botanical Garden

Macromitrium microstomum (Hook.& Grev.)Schwägr. is the most widely distributed species of the genus in the world and exhibits a great deal of morphological variations as evident by the inclusion of 28 synonyms. A quantitative study of 98 relevant specimens of *M. microstomum*, including 17 types from its synonyms, was carried out to test and understand the patterns of morphological variation within the species. Data of 63 morphological traits were used to construct a dendroogram. A two-dimensional scatter plot and the variation patterns were evaluated by Cluster Analysis and Detrended Correspondence Analysis methods. The morphological variations were further revealed graphically by compiling figures of digitalized branch leaves and perichaetila leaves. Our quantitative analyses show that variation coefficients differ enormously ranging from 0.187 to 0.647among morphological traits, especially from the branch leaves in terms of leaf length, length/width ratios at median and upper parts as well as the angles of leaf apex. The average variation coefficient of the morphological indices is larger in perichaetial leaves than in branch leaves. Other variations from sporophytic traits, such as the width at capsule mouth and seta length of *M. microstomum* were also analysed. Our study shows that variations, particularly in morphological traits obtained from leaf angles and leaf length do exist in the specimens from different geographical regions, although the overall morphological variations are continuous among 98 specimens. *Microstomum* *filicaule* Müll. Hal., *M. pacificum* var. *brevisetum* Thér., and *M. pacificum* var. *longisetum* Thér., and *Macromitrium subnitidum* Müll. Hal are four new synonyms of *M. microstomum*.

De novo genome assembly of the mahogany mangrove *Xylocarpus granatum*

Zixiao Guo, *Zhang Zhang, Suhua Shi*
State Key Laboratory of Biocontrol, School of Life Sciences, Sun Yat-sen University

Plants of Meliaceae family are well known for their high-quality timber as "mahogany" in furniture trade. Being the only mangrove genus in mahogany family, *Xylocarpus* is further interested for its ecological adaptation into intertidal zones as well as medicinal usage of natural products isolated from all parts of the plants such as various limonoids. Hence, we first sequenced and assembled a draft genome of *Xylocarpus granatum,* which is the most widely distributed species in the genus. A total of 96.63 short reads are generated on Hiseq 2000 platform with inserts from 0.3 to 8 Kb to *de novo* assemble the genome. The assembled genome contains 44,231 scaffolds and accumulates to 293.91 Mb, covering 85.22% of the genome which was estimated as 344.87 Mb by K-mer estimation. The longest, N50 and N90 scaffolds are 6.54,2.50 and 0.063 Mb respectively. The assembly is of high quality reflecting by 98.08% of the transcriptome sequences generated from leaf, flower and root being covered, 93.55% of the 248 ultra-conserved CEGs presenting in the assembly. We estimated that 42% of the genome consists of repetitive sequences, 88% of which (or 37% of the genome) are Long Terminal Repeats (LTR). In total, 30455 protein coding genes are predicted, among which 28492 genes could be matched to homolog in NR, SWISSPROT; 22,311 could be assigned at least one Gene Ontology term and 8659 could assigned at least one KEGG ortholog term. The genome experienced at least one Whole Genome Duplication (WGD) event, indicating by that 614 collinear blocks covering 22,682 genes or 68.49% of the genome were identified. The draft mahogany genome will provide valuable resource for investigating novel genes involved in bioactive compounds biosynthesis in this plant as well as its evolutionary mechanism of transition from terrestrial plants to mangroves.

Evolutionary analysis of the *LAFL* genes involved in the land plant seed maturation program

Jing-Dan Han, *Guang-Yuan Rao*
Peking University

Seeds are one of the most significant innovations in the land plant lineage, critical to the diversification and adaptation of plants to terrestrial environments. From perspective of seed evo-devo, the most crucial developmental stage in this innovation is seed maturation, which includes accumulation of storage reserves, acquisition of desiccation tolerance, and induction of dormancy. Based on previous studies of seed development in the model plant *Arabidopsis thaliana*, seed maturation is mainly controlled by the LAFL regulatory network, which includes *LEAFY COTYLEDON1* (*LEC1*) and *LEC1-LIKE* (*L1L*) of the *NF-YB* gene family, and *ABSCISIC ACID INSENSITIVE3* (*ABI3*), *FUSCA3* (*FUS3*), and *LEC2* (*LEAFY COTYLEDON2*) of the B3-*AFL* gene family. In the present study, molecular evolution of these *LAFL* genes was analyzed, using representative species from across the major plant lineages. Additionally, to elucidate the molecular mechanisms of the seed maturation program, co-expression pattern analyses of *LAFL* genes were conducted across vascular plants. The results show that the origin of *AFL* gene family dates back to a common ancestor of bryophytes and vascular plants, while *LEC1*-type genes are only found in vascular plants. *LAFL* genes of vascular plants likely specify their co-expression in two different developmental phrases, spore and seed maturation, respectively, and expression patterns vary slightly across the major vascular plants lineages. All the information presented in this study will provide insights into the origin and diversification of seed plants.

Taxonomic notes on *Eritrichium* (Boraginaceae: Cynoglosseae) in the Pan-Himalaya

Jia-Chen Hao, *Quan-Ru Liu*
College of Life Sciences, Beijing Normal University

In order to compile the *Flora of Pan-Himalayas* (*Eritrichium*), we have consulted many reports regarding *Eritrichium*, checked all relevant specimens and verified 46 scientific names which belong to 26 species, 1 subspecies and 5 varieties. Based on above works, we carried out comprehensive field investigations, population observations, combined with macro- and micro-morphology studies of nutlets. As a result, we found three taxa need to be revised: initially, *E. heterocarpum* Y. S. Lian et J. Q. Wang is conspecific with *E. echinocaryum* (I. M. Johnst.) Y. S. Lian et J. Q. Wang. There are no differences in external morphology between these two taxa. And we found that some individuals produced heteromorphic nutlets just like *E. heterocarpum* and others developed homomorphic nutlets like *E. echinocaryum* in same populations. Also the distribution areas of *E. heterocarpum* overlap with *E. echinocaryum*'s. Furthermore, *E. longifolium* Decne. is shown to be significantly different from *E. aktonense* Y. S. Lian & J. Q. Wang, but to be conspecific with *E. petiolare* var. *villosum* W. T. Wang. Additionally, *E. lasiocarpum* W. T. Wang is identical with *E. minimum* (Brand) H. Hara and *E. lasiocarpum* is treated as a synonym of the latter. Finally, it is concluded that there are 23 species, 1 subspecies and 5 varieties in total of the genus *Eritrichium* in the Pan-Himalaya region.

Some new recorded plants from Hebei

Tiran Huang
Beijing University of Agriculture

Hongsongwa Nature Reserve (N42°10'~42°20', E117°18'~117°35') is located in the northern part of Weichang manzu Mongolian autonomous county, Hebei province, and seated in the eastern part of the Daxing'anling Mountains and the eastern section of the Yanshan Mountains. It is a plateau platform, which is located in the southern edge of the Mongolian plateau, and its main body is the mountains. The average elevation is 1750m, which changes from 1400 to 2067m. The vegetation types is tessellated meadow which is the typical lot of the Saihanba forest edge landscape. From the division of flora, The Nature Reserve is the transition area from North China flora to the Mongolian flora[1], and there are some components of the Northeast flora. In recent years, in the process of the investigation of completing the plant background resources and the effective management of biodiversity in the Nature Reserve, we carried out a detailed field investigation on the Nature Reserve and its surrounding areas, collected a large number of specimens, after the specimen sorting, identification and literature research, eight species of plants were identified, which had not been recorded in the Flora of Hebei. The specimens cited in this text are collected in the Plant Specimen Room of College of Biological Sciences China Agricultal University: *Galatella dahurica* DC. In Prodr. 5: 256. 1836; FOC Vol. 20-21: 561,562. Heibei: Hongsongwa, Meadows, grasslands on slopes. Polyploid speciation and genome evolution of *Panax* (Araliaceae)

Peng Jiang[1], *Fengxue Shi*[1], *Yaling Li*[1], *Mingrui Li*[1], *Bao Liu*[1], *Linfeng Li*[2]

1. Northeast Normal University
2. South China Botanical Garden, Chinese Academy of Sciences

Panax L. (Araliaceae) is a medicinally important genus in the East Asia and almost every species within the genus has cultural significance for traditional Chinese medicine. The taxonomy of *Panax* has been controversial due to the circumscription of *P. pseudoginseng* and *P. japonicus*. Recent studies based on species geographic distribution, chromosome number and phylogenetic position suggested that the genus *Panax* includes three tetraploid, four diploid species and one species complex. Further biogeographic and phylogenetic analyses revealed two independent origins of the East Asia and North America disjunct distribution of this genus and multiple rounds of whole genome duplications (WGDs) might have occurred during the evolutionary process. In our recent studies, we employed multiple chloroplast and nuclear markers to investigate the evolution and diversification of *Panax*. Our phylogenetic analyses confirmed previous observations of the independent origins of disjunct distribution and both ancient and recent WGDs have occurred within *Panax*. The estimations of divergence time implied that the ancient WGD might have occurred before the establishment of *Panax*. Thereafter, at least two independent recent WGD events have occurred within *Panax*, one of which has led to the formation of three geographically isolated tetraploid species *P. ginseng*, *P. japonicus* and *P. quinquefolius*. Population genetic analyses showed that the diploid species *P. notoginseng* harbored significantly lower nucleotide diversity than those of the two tetraploid species *P. ginseng* and *P. quinquefolius* and the three species showed distinct nucleotide variation patterns at exon regions. Our findings based on the phylogenetic and population genetic analyses, coupled with the species distribution patterns of *Panax*, suggested that the two rounds of WGD along with the geographic and ecological isolations might have together contributed to the evolution and diversification of this genus.

Chasing ghosts: Allopolyploid origin of *Oxyria sinensis* (Polygonaceae) from its only diploid congener and an unknown ancestor

Jianquan Liu

Sichuan University

Reconstructing the origin of a polyploid species is particularly challenging when an ancestor has become extinct. Under such circumstances the extinct donor of a genome found in the polyploid may be treated as a ‘ghost’ species in that its prior existence is recognised through the presence of its genome in the polyploid. In this study, we aimed to determine the polyploid origin of *Oxyria sinensis* (2n =40) for which only one congeneric species is known, i.e. diploid *O. digyna* (2n=14). Transcriptome, genomic *in situ* hybridization (GISH) population genetics analyses and ecological niche modeling, were conducted for this purpose. Results indicate that following divergence from *O. digyna* (2n=14), involving genome duplication around 12 million years ago (Ma), a second genome duplication occurred approximately 6 Ma to give rise to *O. sinensis*. *Oxyria sinensis* was shown to contain homologous gene sequences divergent from those present in *O. digyna* as well as a set that clustered with those in *O. digyna*. In addition, GISH revealed that *O. sinensis* comprised 14 chromosomes from *O. digyna* and 26 chromosomes from an unknown ancestor. Coalescent simulations indicated that *O. sinensis* expanded its distribution approximately 6-7 Ma, possibly following the second polyploidization event, whereas *O. digyna* expanded its range much later. It was also indicated that the distributions of both species contracted and re-expanded during the Pleistocene climatic oscillations. The ecological niche modeling similarly suggested that both species experienced changes of the distributional ranges in response to the recent Quaternary climatic changes. The extinction of the unknown 'ghost' species implicated in the origin of *O. sinensis* could have resulted from superior adaptation of *O. sinensis* to repeated climatic changes in the region where it now occurs.

Morphological and karyological changes in multiple lineages of *Artemisia* L. (Asteraceae) from Qinghai-Tibetan Plateau

Bohan Jiao[1,2], *Tiangang Gao*[1], *Guojin Zhang*[1,2], *Bao Nie*[1,2], *Li Song*[1,2], *Hong Yan*[1,2], *Jiye Zheng*[1,2], *Guohao Niu*[1,2]
1. Institute of Botany, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Early studies noticed some trends of morphological and karyological changes in flowering plants when they moved to high mountains. However, we know little about the trends in the "third pole"—Qinghai-Tibetan Plateau. Here we surveyed morphological and karyological differences between closely related but independent evolved lineages of *Artemisia*. We first reconstructed the phylogenetic relationship of 297 species of Artemisia. Based on the phylogenetic result and geographical distribution of *Artemisia*, we defined the Qinghai-Tibetan Plateau lineages and their sister groups. We compared the morphological traits, such as maximum height, cauline leave blade size and capitula diameters and tested whether traits were significantly different between Qinghai-Tibetan Plateau lineages and their sister groups. At the same time, we compared percentage of polyploidy between Qinghai-Tibetan Plateau taxa and other taxa. Our results indicated: (1) *Artemisia* has independently adapted to Qinghai-Tibetan Plateau more than 10 times; (2)Plant height and blade size in Qinghai-Tibetan Plateau lineages were definitely reduced; (3)Capitula diameters in Qinghai-Tibetan Plateau lineages was definitely increased; (4)Percentage of polyploidy in Qinghai-Tibetan Plateau taxa was notably lower than other taxa. Our result is contrary to early conclusion that polyploidy increases with environmental severity. But the effect of polyploidy can be replaced by enlarged head diameters. Both of them can create high heterozygosity in the offspring. Our result provided new insights for understanding the responses and adaptations of plants when they moved to high mountains.

Morphobiological features of the nomenclatural type of *Allium nigrum* L., nom. cons.

Lyudmila Krassovskaya, ***Igor Levichev***
Komarov Botanical Institute of the Russian Academy of Sciences

The absence of an authentic sample of *Allium nigrum* L. in Carl Linnaeus' herbarium and partial compliance of characteristics of this taxon to *A. magicum* L. has forced to conserve the first binomen with a typical sample of the second. Conservation has formally excluded application of the name *A. magicum*. The fusion of two linnaeons resulted in nomenclatural doubts concerning a dozen of other taxa with glossy, black ovaries. We observed that *A. magicum* always reproduces a uniquely original set of properties and signs: absence of black ovaries, compulsory formation of vegetative bulbils at leaf tips, active deepening of the cotyledon basis into the soil, and other constant ontogenetic features. Ovaries and capsules of this taxon are always green with a scabrous surface that contrasts to the black ovaries in other related species. The formation of a vegetative bulbil on the tip of the innermost leaf lamina is an unique biological feature of *A. magicum* specified by Linnaeus after many predecessors and images in the studies of L'Obel, Gerard, Clusius, Sweert, *etc*. This bulbil is regularly formed starting from the second year of life of a seedling, and from the first year in vegetative reproduction. At the start of ontogenesis (about 10 years long), the gemmiferous leaf is short and the bulbil is below the soil surface. Every year this leaf becomes longer. The bulbil emerges over the soil surface only in the mature reproductive age. In older plants, this leaf reaches 20-40 cm length, and every year bifurcation of its lamina tip is extended, reminiscent of a swallow tail. The width of other leaves increases to 10-11 cm. During ontogenesis, the phyllome in this taxon starts with the unifacial type of the cotyledon and bulbous scales. Later leaves are flat, but own quasibifacial nature: two rows of vascular bundles are ring-like positioned. Tepals are bifacial. The seed germination of *A. magicum* demonstrates a phenomenal functionality: the root rudiment and the hypocotyl deepen to 10-20 cm where the first bulb is also formed. There is a paradoxical situation – the cotyledon actively grows above the hypocotyl, actually it grows upwards but pushes the root node downwards. The short (less than 1 mm) root primordium starts extending only after the formation of a bulb on the 4th metamer position. For this reason, the bulb is protected by the cotyledon sheath and rudiments of the 2 first true leaves. Along with the bulb, under the soil surface, the diameter of the cotyledon increases and marks the starting point of its digeotropic growth (see e-poster). The specified unique traits do not correspond to characteristics of *A. nigrum* sensu Linnaei. Therefore, *A. magicum* cannot serve as type of this name. It is necessary to select the epitype among the *A. nigrum* forms which are still cultivated in botanical gardens of European countries.

A114

Phylogeny and biogeography of the Neotropical fern genus *Campyloneurum* (Polypodiaceae)

Paulo Labiak[1], *Robbin Moran*[2]
1. Universidade Federal do Parana
2. The New York Botanical Garden

Campyloneurum belongs to the Polypodiaceae and has about 60 species, all restricted to the Neotropics. It is characterized mainly by its simple and entire leaves (three species are 1-pinnate), prominent lateral veins that run from the midrib to the margin that are cross-connected by finer veins to create a series of areoles. Within each areole there are 1–5 free veinlets, and the sori are born at the apices of these veinlets. Because of its simple morphology, *Campyloneurum* is one of the most difficult genera taxonomically. Several species complexes need study. Previous phylogenetic studies have suggested that *Campyloneurum* is closely related to *Niphidium* and *Microgramma*, but a comprehensive phylogeny for the genus is still lacking. We investigated the phylogenetic relationships of *Campyloneurum* with other Polypodiaceae and of the species within the genus. Phylogenetic relationships were recovered under Maximum Likelihood and Bayesian methods, using a dataset that includes about 85% of the known species, and are based on four plastid markers (*rbcL, rps4-trnS, trnG-trnR, trnL-trnF*). *Campyloneurum* was recovered as monophyletic, and more closely related to *Niphidium*. Our results suggest that convergence frequently occurs in *Campyloneurum*, both in habitat specialization and morphology, and several characters that have been used to delimit species need to be re-evaluated. However, some morphological characters can be used to diagnose some clades, such as lamina division, and rhizome pruinosity. The molecular phylogeny also suggests that several species currently recognized are paraphyletic, and many new species have yet to be described. In terms of geography, the Andes are the most important area of phylogenetic diversity for the genus. Other important areas are the mountains of Central America and the Atlantic Rain Forest of Brazil, where some endemic clades can be found.

A115

Evolutionary modes and trends during origination of angiosperms

Igor Levichev
Komarov Botanical Institute of the Russian Academy of Sciences

The author of telome theory Walter Zimmermann specified six elementary processes that formed cormophytes: *overtopping, planation, coalescence to leaf, anastomoses of axis, reduction, incurvation*. The presence of telomes at vascular plants ancestors coming on the land determined the fundamental evolutionary mode - metamerism. Dichotomous branching caused formation of telomes, thus turning the original telomes into mesomes. In fact, the body of ancestral vascular plants consisted of mesomes and sterile phylloids that carried out photosynthesis. Roots were missing. Individual stopped pairwise branching, and historically later individuals became a single sporangium bearing telomes. Solitary terminal and lateral formations of the anisotomic (monopodial) axis resulted from indisputable predominance of dichopodial development in unsupporting air environment. The single, unitary organism of the metameric-colonial body was united by the bipolar association of vascular bundles. The telome was originally capable of branching on both ends: ageotropic and geotropic. In later evolutionary phases, one of the geotropic bifurcations became the root, the second one – into the reserve sympodial branch. On land it was not telome that evolved but its derivate, the bipolar mesome. New divisions, classes, *etc.* arose on earth by quantitatively and qualitatively different mesome associations. For example, the angiosperms arose by union of monopodium and sympodium into a single metamer, which was accompanied by the debut of the true (dimeric) leaf of sporangial nature. This concept is detailed below (see e-poster). A-modus. Metamerism; Aa-trend. Modularity. Ab. Multilayer shoot. Ac. Specialization of vegetative and reproductive mesomes; B. Bipolarity; Ba. Ageotropic phyllome. Bb. Ageotropic continuation of axis (“monopodium”). Bc. Geotropic (root) branching and stele (*anastomoses of axix*). Bd. Side (geotropic) bud and reserve sympodium; C. Rotation (right, left) or 7-dimensional capture of habitat (above and below the soil surface + lifespan); Ca. Vertical balance of soma. CB. Orientation of branches and phylloms, phyllotaxis; D. Growth; Da. From isodichopodial to dichopodial, (*overtopping*). Dd. From herbs of surf line to wood giants of dry land. DC. Intercalary growth and grandization. DD. Cyclicism, *reduction*, (long-livers, annuals); E. Association; Ea. Convergence of gematophyte and sporophyte, vegetative and reproductive propagation. Eb. *Planation*, lateral webbing of vaia (*coalescence to leaf*). Ec Supraposition of metamers (ageotropic and geotropic). Ed. Juxtaposition. Ee. Monosympodia (dimery of axes and phyllome). Ef. Gorgonoid, podium; F. Protection of bud and ovule; Fa. Phyllome and sheath. Fb. Phyllome morphogenesis of sporangium, strobilus, cones, flower. Fc. Integuments, *incurvation*, obturators; G. Heredity; Ga. Symbiogenesis and unification of genome. Gb. Hybridization, ploidy, recombination, gene transfer, *etc.*; H. Phytospreading; Ha. Migration. Hb. Selection. Hc. Symbiosis with animals and man (pollination, dispersion, selection); I. Neoteny (main biogenetic law); Ia. Recapitulation (neotenic divergence). Ib. Oligomerization, namism, herbaceous habit. It is particularly indicative that any degree of evolutionary rollback at neotenic recapitulations never results in alien formations like “horns”, “hooves”, root instead of phyllome, *etc.*, but always reproduces embryological ancestral form, up to “telome” with mandatory increase of the protection degree of each plant body element during embryogenesis and histogenesis.

A synopsis of the genus *Premna* L. (Lamiaceae) in China

Bo Li
Jiangxi Agricultural University

The genus *Premna* L. belongs to the family Lamiaceae with ca. 200 species worldwide and is distributed chiefly in Old World tropics and subtropics. *Premna* ranks among the most taxonomically difficult and complicated genera of Lamiaceae and is considered one of the fifth largest genera with 46 species in the mint family of the Flora of China. In this paper, a taxonomic revision of the genus in China is presented. Totally 35 species and four varieties are recognized. Keys, descriptions, notes on ecology, distribution, local uses, vernacular names and conservation status, and some illustrations are also provided. Three names are lectotypified in this paper, five new names are adopted and 13 names are placed into synonymy for the first time. Two new species from Yunnan Province were described and illustrated.

A117

A numerical taxonomy of *Epimedium* L.

Chao Li[1], *Mingli Zhang*[2]
1. North China University of Science and Technology
2. Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences

Based on 30 qualitative and 15 quantitative characters of 55 species of *Epimedium*, a numerical taxonomy is presented by using the cluster analysis and principal components analysis. Results of cluster analysis shown that the genus can be divided into macro-flower taxa and micro-flower taxa, treatment of Section *Macroceras*, Section *Polyphyllon* and Subgenus *Rhizophyllum* is justified which is established by Stearn, taxonomic status of Sect. *Epimedium* is doubted. In principal components analysis, cumulative ratio of the first three principal components seems lower only 51.86%, this is probably related to the diversity variation and taxonomic complication of *Epimedium* evolution. however, result of principal components analysis also indicates the generic division of macro-flower and micro-flower taxa. These important taxonomic characters in *Epimedium* resulted from principal component analysis, such as ratio of petal length to inner sepal length, spur, whorls of sepal, are valuable for taxonomy of this genus.

Global versus Chinese perspectives on the phylogeny of the N-fixing clade

Hong-Lei Li[1,2,3], *Wei Wang*[2], *Shou-Zhou Zhang*[1], *Hong Wu*[3], *Zhi-Duan Chen*[2], *An-Ming Lu*[2]
1. Fairy Lake Botanical Garden, Shenzhen & Chinese Academy of Sciences
2. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences
3. College of Life Sciences, South China Agricultural University, Guangzhou

There has been increasing interest in integrating a regional tree of life with community assembly rules in the ecological research. This raises questions regarding the impacts of taxon sampling strategies at the regional versus global scales on the topology. To address this concern, we constructed two trees for the nitrogen-fixing clade: (i) a genus-level global tree including 1023 genera; and (ii) a regional tree comprising 303 genera, with taxon sampling limited to China. We used the supermatrix approach and performed maximum likelihood analyses on combined matK, rbcL, and trnL-F plastid sequences. We found that the topology of the global and the regional tree of the N-fixing clade were generally congruent. However, whereas relationships among the four orders obtained with the global tree agreed with the accepted topology obtained in focused analyses with more genes, the regional topology obtained different relationships, albeit weakly supported. At a finer scale, the phylogenetic position of the family Myricaceae was found to be sensitive to sampling density. We expect that internal support throughout the phylogeny could be improved with denser taxon sampling. The taxon sampling approach (global vs. regional) did not have a major impact on fine-level branching patterns of the N-fixing clade. Thus, a well-resolved phylogeny with relatively dense taxon sampling strategy at the regional scale appears, in this case, to be a good representation of the overall phylogenetic pattern and could be used in ecological research. Otherwise, the regional tree should be adjusted according to the correspondingly reliable global tree.

Molecular phylogenetics and historical biogeography of *Sorbus* sensu stricto (Rosaceae)

Meng Li[1,2,3], *Ohi-Toma Tetsuo*[4], *Yun-Dong Gao*[1], *Bo Xu*[1], *Zhang-Ming Zhu*[1], *Wen-Bin Ju*[1], *Xin-Fen Gao*[1]
1. Chengdu Institute of Biology, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences
3. Arnold Arboretum of Harvard University
4. Botanical Gardens, Graduate School of Science, The University of Tokyo

Explaining how plants from eastern Asia migrated to other Northern Hemisphere regions is still challenging. Here, genus *Sorbus* sensu stricto (including *c*. 88 species) is considered as a good example to illuminate this scenario due to wide occurrence in the temperate zone and diversity in the Himalayas and H-D Mountains. Based on four nuclear markers (*LEAFY*-2, *GBSSI*-1, *SBEI* and *WD*) and one chloroplast marker (*rps16-trnK*), we reconstructed the phylogenetics relationship of *Sorbus* using 54 taxa (60% of the genus) representing all subgenera, sections or series and geographical areas in the previous classifications, and estimated divergence time and historical biogeography of the genus. Phylogenetic analyses supported that the subgenera *Sorbus* and *Albo-carmesinae* defined by traditional morphological characteristics are suitable, and associated with the two different kinds (orange-red & crimson-white) of fruit color. But, suggested that the genus *Sorbus* comprises five well-defined clades that are not consistent with the traditional section or series. Molecular dating and biogeographic reconstruction showed that the age of the most recent common ancestor was estimated at 41 mya (95% HPD: 35–49 mya) in the eastern Asia. Four dispersal events are assumed to explain the wide distribution of *Sorbus* in the temperate zone and diversification in the edges of Qinghai-Tibet Plateau (QTP). Some species dispersed to eastern Asia, Tianshan Mountain, North America and Europe in Oligocene and Miocene. We found that polyploidization occurred mainly in the subgenus *Albo-carmesinae*, in the area of Tianshan Mountains, Himalayas and H-D Mountains. Lastly, the striking species diversity in Himalayas and H-D Mountains, when contrasted to other regions may be caused by polyploidization and hybridization in response to the multi-stage uplifting and the subsequent increases in geological, ecological and climatological diversity.

A120

An east–west phylogeographic break in the Qinghai-Tibet Plateau (QTP) across the 500 mm isohyet, revealed by the genetic structures of six *Allium* species (Amaryllidaceae)

Minjie Li
Sichuan University

The Qinghai-Tibet Plateau (QTP) has been assumed to be fractionized into the east monsoonal and the west continental climatic zones along the 500 mm isohyet marking the boundary between humid–semihumid and arid–semiarid in the present time. And simultaneously it is hypothesized that the Hengduan Mountains Region (HMR) uplift around 4–3 Ma and Pleistocene climatic oscillations could have contributed to the environmental changes in the QTP. However, these biogeographic hypotheses have rarely been tested using a phylogeographic approach, let alone the effect of the actual equilibrium line altitudes (ELAs) to the local survival from the Quaternary glacial crisis. Three chloroplast DNA regions, one nuclear ITS sequence and 9 nuclear microsatellite loci, were screened for genetic variation for 71 populations represented by 577 individuals across the distributional ranges for *Allium* subgenus *Cyathophora* and *A. fasciculatum*, supplemented with the principal component ordination (PCA) of bioclimatic variables, the ecological niche model (ENM) and the seed weight. Our genetic data consistently identified the east–west break through the distributional ranges of *Cyathophora* and *A. fasciculatum* along the 500 mm isohyet, which is also strongly supported by the different environmental space. The causative factor for this divide was suggested to be the climatic conditions differentiation due to the development of South Asian monsoon in the HMR and the strengthening of aridification in the west QTP, until to the boundary between humid–semihumid and arid–semiarid are clearly existent marked by the 500 mm isohyet, but other processes, particularly divergent selection for the morphological adaptation within *Cyathophora*, may also play a role in maintenance and deepening this split, while the postglacial expansion from east to west within *A. fasciculatum*, blurred this split. Moreover, the montane isolation resulted from the uplift QTP could be responsible for the divergence in the ancestral areas during Pliocene-Pleistocene, and the Pleistocene climatic fluctuations for the intraspecific isolation by contraction-expansion patterns. Additionally, the Pleistocene climatic fluctuations could have created new open micro-habitat for the self-sustaining allotetraploid species occurring at the current contact zone of *A. farreri* and *A. cyathophorum* during the postglacial. The postglacial expansion of this stable hybrid zone could have made introgression to *A. cyathophorum*. As thus, the range displacement due to the moving hybrid zone could have promoted the divergence of *A. cyathophorum*. The genetic structures revealed that the glacial refugia in the QTP mostly located in the montane regions with lower ELAs. These findings highlight the importance of orogeny and climatic changes in the QTP in shaping species diversification during the Pliocene-Pleistocene.

B-class MADS-box genes and gibberellin in response to variations in photoperiod are associated with chasmogamous and cleistogamous flower development in *Viola philippica*

Kun Sun, *Qiaoxia Li*
Northwest Normal University

Some plants develop a breeding system that produces both chasmogamous (CH) and cleistogamous (CL) flowers. However, its underlying molecular mechanism remains elusive. *Viola philippica* develops CH flowers with short daylight, whereas an extended photoperiod induces the formation of intermediate CL and CL flowers. In response to long daylight, the respective number and size of petals and stamens was lower and smaller than those of normally developed CH flowers, and the use of ≥14h light induced complete CL flowers that had no petals but developed two reduced fertile stamens. The floral ABC model indicated that B-class MADS-box genes largely influenced the development of the affected two-whorl floral organs. Moreover, gibberellins also affected the development of stamens and petals, and regulated the expression of B-class MADS-box genes. Therefore, we focused on characterizing the B-class MADS-box genes and *GA3oxidase* in *V. philippica* to understand this particular developmental transition. Three B-class MADS-box genes were isolated, and respectively designated as *VpTM6-1*, *VpTM6-2*, *VpPI*. In line with no distinguishable differences during early flower development and no observed floral homeosis, these genes shared a relatively similar expression pattern during floral organogenesis of CH, CL, and inCL flowers, indicating that these genes might play a conserved role in establishing floral organ identity. However, *VpTM6-1*, *VpTM6-2*, and *VpPI* were differentially expressed in the later flower development stage (particularly in petals and stamens) and the highest level of expression was observed in CH flowers; significantly low levels were detected in intermediate CL flowers, and the lowest level in CL flowers. The observed variations in the levels of expression after floral induction and organogenesis apparently occurred in response to variations in photoperiod. We assumed that the differential expression of these B-class MADS-box genes might be influenced by the gibberellin content in flowers. Therefore, *GA3oxidase* was isolated, and designated as *VpGA3ox*. VpGA3ox was the key enzyme during the synthesis process of active GAs in the last step. With the extension of photoperiod, the expression of *VpGA30ox* in flower buds was decreased, and the highest level of *VpGA30ox* expression was observed in CH flowers, significantly low level was detected in intermediate CL flowers, and the lowest level in CL flowers. So the expression of *VpGA3ox* was also in response to variations of photoperiod, and the level of expression was accorded with the three B-class MADS-box genes in flowers. Therefore, inhibition of the development of petals and stamens might be due to the downregulation of B-class MADS-box gene expression dosage by long daylight or by lower content of gibberellin, thereby inducing the generation of CL flowers. Our work contributes to the understanding of the formation of dimorphic flowers in plants during adaptive evolution.

Four new synonyms of *Jackiella javanica* Schiffn. (Jackiellaceae, Hepaticae)

Wei Li
Key Laboratory of Forest Ecology and Management, Institute of Applied Ecology, Chinese Academy of Sciences

Jackiellaceae R.M. Schust. with ten species (including varieties) worldwide, is a monogeneric family. The monogeneric status of *Jackiella* is supported by a molecular study based on three loci by Hendry *et al.,* (2007). When I checked the type specimens located in herbarium of Edinburgh Royal Botanical Garden (E), and plants distributed in China, I found *Jackiella angustifolia* Herzog, *Jackiella javanica* var. *cavifolia* Schiffn., *Jackiella sinensis* (W.E. Nicholson) Grolle, and *Jackiella renifolia* Schiffn. as four new synonyms of *Jackiella javanica* Schiffn. I thank the National Natural Science Foundation of China (No. 31370003, 31000100) for supporting this project. Thanks are also given to the herbarium of Edinburgh Royal Botanical Garden (E) for loan of type specimens.

The Miocene biota of Zeku County, Qinghai Province and its taphonomic environment

Xiangchuan Li[1,2], *Liang Xiao*[1], *Yunzhi Yao*[3], *Dong Ren*[3], *Wenlong He*[4], *Zhengchuang Hui*[5]
1. Chang'an University
2. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences,
3. Capital Normal University
4. Xian University of Science and Technology
5. Lanzhou University

Palaeobotanical studies on the Cenozoic fossil floras in eastern China have been exhaustively reported in the past dozen years. But contrarily, the similar achievements on the coeval floras from northwestern China can be hardly found. Recently, we collected abundant fossils from the Miocene of Zeku, Qinghai. The fossiliferous horizons here are confined to the Early-Middle Miocene based on the magnetostratigraphic and palynological data (Li *et al.,* 2016). This palaeobiota yields numerous exquisitely-preserved animal and plant fossils, including insects, spiders, fruits, seeds, woods or stems, pollen grains, leaves and bird feathers (Li *et al.,* 2016). First, concerning the plant macrofossils, Li *et al.,* (2016) established a fossil species *Koelreuteria quasipaniculata* based on several exquisitely preserved fossil membranous capsules. This is a characteristic anemochorous tree. Furthermore, most co-occurring plant fossils are numerous winged fruits or seeds which belong to *Acer*, *Ulmus*, *Fraxinus* and Pinaceae *etc.* They are also typical of wind dispersal and predominately show temperate affinities. Whereas, there are many fossil legumes discovered here and recognized as *Podocarpium podocarpum* (Li *et al.,* 2013) and *Cercis*. It is amazing that the anemochorous arboreal species exhibits a high abundance relative to the overall paleofloral composition. The large diversity of anemochorously dispersed tree plants here probably indicates an actual original characteristic of the vegetation rather than taphonomic bias. It is well known that oil shale can only be deposited in the swamp or deep lacustrine environment. Whereas, the fossil stems are always discovered in the shallow lake area because the decreasing water power towards the deep lake area can hardly carry bigger items forwards, and insects usually live on the grass near the shallow water. Therefore, the co-occurrence of fossil stems, insects or spiders with fine hairs and bird feathers support the conclusion that their taphonomic condition of the fossiliferous horizons should be the swamp not deep lacustrine facies. The predominance of winged fruits and seeds suggests that wind may gradually become an essential factor for plant dispersal and fossil burial, probably an ecological response to the Tibetan Plateau uplift and potential regional environmental change. Secondarily, concerning the fossil insects, Li *et al.,* (2017) described a cicada species *Cixius discretus*, which is the first record of Cixiidae from the Miocene of the Tibetan Plateau. The diet of extant *Cixius* adults consist entirely of various shrubs and trees, which demonstrates the view point that the temperate forest occurred here in the past. According to the preliminary identification results, the fossil insect taxa also include *Mycetophila*, *Dryomyza*, *Dasysyrphus*, Tipulidae, Notonectidae, Ichneumon, Corixidae and Odonata *etc*. Among them, Corixidae dwell in slow rivers and bodies of still water, e.g. ponds, and most of them feed on aquatic plants and algae. Odonata juveniles inhabit in various bodies of shallow water for over two years and then clime up out of the water along the aquatic weeds and become the adults. Therefore, they all support the view point that the fossil biota was buried in a swamp not in the central area of a large lake.

A124
Diversification of *Aristolochia* subgenus *Siphisia* (Aristolochiaceae) in East and South Asia

Xiao-Qin Li[1], *Shuai Liao*[1], *Yun-Juan Zuo*[1], *Xin-Xin Zhu*[2], ***Jin-Shuang Ma***[1]
1. Shanghai Chenshan Plant Science Research Center, Chinese Academy of Sciences
2. College of Life Sciences, Xinyang Normal University

Aristolochia subgenus *Siphisia* (Raf.) Duch comprises about 70 species, 50 of which occur in East and South Asia, while the remaining 20 species are restricted to Central and North America. Taxonomic treatments of the subgenus *Siphisia* are controversial, especially for those distributed in the region of East and South Asia. Furthermore, some new species were discovered from Asia recent years. A robust phylogeny with extensive and intensive sampling should be urgently needed to clarify the phylogenetic relationships among species and it will also provide assistance with the taxonomy of this genus. We constructed phylogenic trees of about 120 accessions based on maximum likelihood, maximum parsimony and Bayesian phylogenetic analyses using five chloroplast regions (*rps16-trnK, petB-petD, trnH-psbA, atpB-rbcL* and *rpl16* region) and the nuclear gene *phyA*. Divergence time was estimated with relaxed molecular clock approach using two fossil calibrations. Reconstruction of the ancestral distribution areas within *Siphisia* are based on nuclear *phyA* tree from the Beast implemented in the software RASP. The combined trees resolved the relationships of major clades of *Aristolochia* and reflected distinguished geographic patterns. Strong genetic differentiation was also detected between the Sino-Himalaya and Sino-Japan regions. While the topologies of nrDNA and plastid phylogenies are not significantly congruent, suggesting reticulate evolution or insufficiency of informative sites. The genetic structure of populations within *Siphisia* reflected the interactions of various evolutionary processes in the long-term evolutionary history. Based on the analysis of molecular dating and ancestral area reconstructions, favored a major diversification of the Sino-Himalaya within *Siphisia* occurred around the time during the Miocene to Pliocene/Pleistocene and involved vicariance and dispersal events. Paleoclimatic oscillations may be contributed to differential rates diversification and successive vicariance events. Divergence within the subgenus might be closely related with habitat fragmentation, gene duplication/polyploidization, specialization of pollinator and characteristics of floral organ.

Superiortrapa weichangensis gen. et sp. nov. (Lythraceae s.l.)

from the Miocene of North China

Ya Li[1,2], *Xiao-Qing Liang*[3], *Yong-Dong Wang*[1], *Cheng-Sen Li*[2]
1. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
2. Institute of Botany, Chinese Academy of Sciences
3. Yuxi Normal University

Superiortrapa weichangensis gen. et sp. nov. (Lythraceae s.l.) is described on the basis of receptacle, calyx and fruit remains, collected from the early Miocene of Weichang County, Hebei Province, North China. *Superiortrapa* has actinomorphic, 4-merous, hypogynous flower, four decussate antennae-shaped sepals with recurved barbs, four inter-sepal appendages (or epicalyx segments), and a superior ovary. Fruits are fusiform with persistent sepals and approximately eight slender ribs on the fruit body. Detailed morphological analyses and comparison of the genus with related fossil and extant genera allowed the placement into the subfamily Trapoideae of the Lythraceae s.l. based on a suite of characters. *Superiortrapa* can be distinguished from all the other genera of the family Lythraceae s.l. by having hypogynous flower rather than perigynous flowers in Lythraceae s.str., or hemi-epigynous to epigynous flowers in *Duabanga*, *Punica*, *Sonneratia* and *Trapa*. It might represent an extinct linage, probably secondarily derived from the extinct genus *Hemitrapa* of Trapoideae, Lythraceae s.l.

DNA barcoding evaluation and its taxonomic implications in the recently evolved genus *Oberonia* Lindl. (Orchidaceae) in China

Yuling Li[1,2], *Yi Tong*[1], *Fuwu Xing*[1]
1. Key Laboratory of Plant Resources Conservation and Sustainable Utilization, South China Botanical Garden, Chinese Academy of Sciences
2. University of the Chinese Academy of Sciences

The orchid genus *Oberonia* Lindl., is a taxonomically complex genus characterized by recent species radiations and many closely related species. All *Oberonia* species are under conservation as listed in the CITES and the IUCN Red List Categories and Criteria. Given its difficulties in taxonomy and conservation status, *Oberonia* is an excellent model for developing DNA barcodes. Three analytical methods and five DNA barcoding regions (*rbcL*, *matK*, *trnH-psbA*, ITS and ITS2) were evaluated on 127 individuals representing 40 species and 1 variety of *Oberonia* from China. All the three plastid candidates tested (*rbcL*, *matK* and *trnH-psbA*) have a lower discriminatory power than the nuclear regions (ITS and ITS2), and ITS had the highest resolution rate (82.14%). Two to four combinations of these gene sets were not better than the ITS alone, but when considering modes of inheritance, *rbcL*+ITS and *matK*+ITS were the best barcodes for identifying *Oberonia* species. Furthermore, the present barcoding system has many new insights in the current *Oberonia* taxonomy, such as correcting species identification, resolving taxonomic uncertainties, and the underlying presence of new or cryptic species in a genus with a complex speciation history.

Organogenesis of reproductive organs in *Loranthus* Jacquin (Loranthaceae): The origin and identity of the bract and the calyculus

Ruozhu Lin[1], *Bei Cui*[2], *Wenxia Zhao*[1]
1. Research Institute of Forest Ecology, Environment and Protection, Chinese Academy of Forestry
2. Research Institute of Forestry, Chinese Academy of Forestry

The parasitic family Loranthaceae are characterized by monochlamydeous bisexual flowers, which are usually subtended by an outermost bract (some with several bracteoles) and a circular rim, denominated calyculus, positioned outside the perianth (petals). Various hypotheses have been proposed to explain the origin of the calyculus: an outgrowth of the axis without relation to the perianth, equivalent to an epicalyx, a bracteolar (prophyllar) origin, or a reduced calyx. To find out the origin and identity of the calyculus, we investigated the flowers of *Loranthus tanakae* Franchet & Savatier using scanning electron microscopy. The results show that the pedicel is extremely short at the beginning and slightly elongate thereafter to become concave at the base of the mature flower where a “bract” is thought to be located on. The calyculus is initiated as a semicircular primordium outside the flower primordium on the abaxial side. It then develops towards the axis and both sides are adnate to each other on the adaxial side to form a circular structure, encircling the young flower. The calyculus keep growing upwards and eventually adnate to the receptacle to become a cylinder. Inside of the calyculus, the hemisphere of flower primordium cleaves into five or six (occasional four) undifferentiated perianth from its centre, before or after the calyculus closed. Isomerous stamens are opposite to petals. The ovary is inferior and adnate to the cylinder of receptacle and calyculus at maturity. Evidence based on our observations suggests that the concave structure previously known as a “bract” is only a part of the pedicel rather than a real organ. There is no “bract” primordium is initiated outside the calyculus. Our results support the bracteolar origin of the calyculus, and further consider it equivalent to a bract for two reasons. First, the calyculus is initiated as a single primordium which shows the same morphology and the same position as a bract does. Secondly, the developmental processes of the calyculus is relatively independent of other floral organs: there is no quantitative, spatial and temporal relations between the calyculus and the petals, which means the calyculus is not likely a reduced calyx. This study led up to the conclusion that *Loranthus* has one circular bract, namely calyculus, and three whorls of floral organs: petals, stamens, and carpels.

Taxonomic studies on *Rungia* (Acanthaceae) in China

Zheli Lin[1,2], *Yunfei Deng*[1]
1. Key Laboratory of Plant Resources Conservation & Sustainable Utilization, South China Botanical Garden, Chinese Academy of Sciences, 510650 Guangzhou, People’s Republic of China
2. University of Chinese Academy of Sciences, 100049 Beijing, People’s Republic

Rungia Nees (Acanthaceae: Justicieae) is a genus of about 50 species distributed in tropical and subtropical regions of the Old World, and sixteen species with twelve endemic species are recognized in recently published volume 19 of *Flora of China.* It is generally accepted to be closely related to *Justicia* Linn. nowadays, but differs in the rising placenta in ripe capsule and generally with one sterile bract and one fertile bract at each node of the spike. Some researchers suggested to merge *Rungia* with *Justicia*, however, as the genus *Justicia* itself is paraphyletic and the morphological studies indicated some differences between two genera, we prefer to treat *Rungia* as an independent genus for the present before there is sufficient evidence to demonstrate that *Rungia* should be merged into *Justicia*. This study was based on examinations on literatures and specimens, field investigations, pollen morphology, seed morphology and cytological analyses, the main results are as follows. 1. Pollen morphology of sixteen species were observed, the result indicated that the pollen morphology of *Rungia* is of great diversity and can be divided into 7 types; seed morphology of thirteen species were observed and can be divided into 4 types; chromosome number and karyotype of fifteen species were analysed, the basic chromosome number are: x=10,11,13,14 and 25. The results mostly match the macromorphology and are significant in taxonomic studies of *Rungia*. 2. According to the macromorphology and the results above, we revised the *Rungia* species in China. Sixteen species of *Rungia* in China were recognized. Six names were reduced to the synonymy. *R. monetaria* turned out to be not ocuured in China, four species, *R. angustifolia*, *R. burmanica*, *R. eberhardtii* and *R. khasiana*, are newly recorded from China and three new species are discovered, viz. *R. flava* Z. L. Lin & Y. F. Deng, *R. sinothailandica* Z. L. Lin & Y. F. Deng and *R. glabra* Y. H. Tan, Z. L. Lin & Y. F. Deng.

Three new species of *Ulnaria* (Bacillariophyta) from the Wuling Mountains Area, China

Bing Liu, *Qi-Jian Tian, Gong-Xi Chen, Jing Li*
Key Laboratory of Plant Resources Conservation and Utilization, College of Hunan Province; College of Biology and Environmental Science, Jishou University

Three new species of *Ulnaria* from the Wuling Mountains Area, China, have been studied by light and scanning electron microscopy. All possess at least six closed girdle bands. The pattern of valve striation is not uniform as some do not have a corresponding opposite structure. The cells of *Ulnaria sinensis sp. nov*. are linked and form colonies with frustules connected by interlocking linking spines. *U. sinensis* has very long valves (296–512 μm) and uniseriate striae. Both *Ulnaria ulnabiseriata sp. nov*. and *Ulnaria gaowangjiensis sp. nov*. have biseriate striae. *U. ulnabiseriata* differs from *U. gaowangjiensis* in LM by its more lanceolate valve shape as the valves of *U. ulnabiseriata* taper towards the pole from one third of the length of the valve, whist *U. gaowangjiensis* tapers towards the pole from two thirds of the length of the valve, and by its larger valve length (105–229 μm vs 61–108 μm). The three new species are all epilithic and live in freshwater habitats in or near nature reserves.

A130

Diversification and historical biogeography of the parasitic family Loranthaceae: Synchronous with the radiation of tropical forests and songbirds

Bing Liu, *Zhiduan Chen*
Institute of Botany, Chinese Academy of Sciences

The mistletoe family Loranthaceae originated in Australasia in Mid Cretaceous, and then spread to South America via Antarctic but was absent in Africa. Some genera of Elytrantheae and Lorantheae dispersed from Australasia to Asia and back to Australasia for several times via the island chains in Southeast Asia since the Late Eocene. The lineages distributed in Africa and Europe are young members migrated from Asia after Late Eocene. Loranthaceae rapidly diversified along with the formation of tropical forests in most of the tropical and subtropical regions during Early Eocene, and simultaneously converted the trophic mode to aerial parasitic and made a special adaptation to bird-dispersal. Trees in tropical forests as hosts and songbirds as dispersers are both significant factors during the diversification and historical biogeography of Loranthaceae.

Transcriptomic analysis of heteromorphic stamens in *Cassia biscapsularis* L.

Zhong-Lai Luo[1]*, Jin Hu*[2]*, Zhong-Tao Zhao*[1]*, Dian-Xiang Zhang*[1]
1. South China Botanical Garden, the Chinese Academy of Sciences
2. Shenzhen Park Service

Hermaphroditic flowers have evolved primarily under the selection on male function. Evolutionary modification often leads to stamen differentiation within flowers, or “heteranthery”, a phenomenon intrigued scientists since the 18th century until recently. However, the genetic basis and molecular regulation mechanism has barely been touched. Here we conducted comparative transcriptome profiling in *Cassia biscapsularis* L., a heterantherous species with representative patterns of stamen differentiation. Numerous differentially expressed genes (DEGs) were detected between the staminodes (the degenerated stamens) and fertile stamens, while much fewer genes differentially expressed among the three sets of fertile stamens. GO term enrichment and KEGG pathway analysis characterized functional properties of DEGs in different stamen types. Transcripts showing close correlation between expression pattern and stamen types were identified. Transcription factors from the bHLH family were suggested to have taken crucial part in the formation of staminodes. This first global transcriptomic analysis focusing on stamen differentiation opens the door toward a more comprehensive understanding on the molecular regulation of floral organ evolution. Especially, the generated unigene resource would be valuable for developing male sterile lines in agronomy.

A132

Reproductive isolation between sympatric sister species,

Mussaenda kwangtungensis and *M. pubescens* var. *alba*

Zhong-Lai Luo[1], *Ting-Ting Duan*[1], *Shuai Yuan*[1], *Shi Chen*[2], *Xiufeng Bai*[3], *Dian-Xiang Zhang*[1]
1. South China Botanical Garden, the Chinese Academy of Sciences
2. Beneficial Insects Institute, Fujian Agriculture and Forestry University
3. Department of Cell Biology, the Third Military Medical University

Reproductive isolation defines the biological species concept and plays a key role in the formation and maintenance of species. The relative contributions of different isolating stages have been suggested to be closely associated with phylogenetic relatedness. Few studies have focused on the relative contributions of pre- versus postzygotic mechanisms, and even fewer have been conducted under strict phylogenetic frameworks. Pre- and post-zygotic reproductive isolation stages have been investigated in the sister species *Mussaenda kwangtungensis* and *M. pubescens* var. *alba*. The two species have partly overlapping distribution ranges and flowering times, while the principal pollinators differed strikingly for them, demonstrating strong pre-zygotic isolations. Natural hybrids were detected by simple sequence repeat markers and their maternal parents were identified based on chloroplast gene sequences.Five out of 81 individuals were suggested to be hybrids that fall into the categories F2, BC1, and BC2 by the NewHybrids analysis. Interspecific crossings resulted in significantly reduced fruit set and seed germination rates. Phylogenetic analysis revealed short Kimura-2-parameter distance between *M. kwangtungensis* and *M. pubescens* var. *alba*. These findings strongly supported the hypothesis that for species with a closer phylogenetic relationship, prezygotic isolation plays an important part in limiting gene exchange in sympatric areas.

T2

A133

Phylogenetics, reticulate evolution and taxonomic evaluation of *Miscanthus* and related genera (Andropogoneae, Poaceae)

Hong-Zheng Ma[1], *Wen-Li Chen*[2], *Zhe Cai*[2], *Si-Lan Dai*[3], ***Song Ge***[2]
1. College of Horticulture and Landscape, Tianjin Agricultural University
2. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences
3. College of Landscape Architecture, Beijing Forestry University

Miscanthus species, disjunctly distributed in Asia and Africa, are important germplasm resource for bioenergy crops with excellent tolerance to biotic and abiotic stresses. Despite many studies, taxonomic delimitation and evolutionary history of this genus remain dispute. We herein collected 59 samples representing 15 species of *Miscanthus* and 18 species from its related genera through their entire distribution area. Based on sequences of 14 plastid fragments and 4 nuclear gene (*ITS*, *FLO/LFY*-like and *Ahd1* gene), we reconstructed the phylogeny of the genus and its relatives. Although discordance between nuclear and chloroplast phylogenies exists, the inferred species tree confirmed three main clades: first one including Eastern and Southeastern Asian *Miscanthus* species (ESA clade), the second consisting of species in subgen. *Rubimons* (*Rubimons* clade) and the last representing '*Saccharum* complex' members (complex clade). The results support the speculation that *Miscanthus s.l.* and related genera experienced extensive reticulate evolution. Biogeography analysis indicated that *Miscanthus* and its related genera originated in Southeast China and diverged within recent three million years (My), and all species in ESA clade occurred in the last one My when the fluctuation of sea level gradually slowed down. Moreover, the current geographic distribution of *Miscanthus* species in Himalaya, Africa and America is the consequence of both the vicariance and the multiple long-distance dispersals. On these bases, we suggest that ESA clade consisting of two sections should be delimited as *Miscanthus* and support the treatment of independent genera for *Rubimons* and *Diandranthus*.

A134

Study on taxonomy and flora of mosses in Altun Mountains National Nature Reserve, Xinjiang, China

Sulayman Mamtimin, *Shuayib Yusup, Winira Ilghar, Sabiram Esrayi, Rabiye Gupur*
College of Life Science and Technology, Xinjiang University

The Altun Mountains National Nature Reserve is located in Qakilik County, Xinjiang Uygur Autonomous Region, northwestern China. The reserve covers 46,800 square kilometers and has an average altitude of 4,500 meters. The reserve was regarded as one of the rare gene banks of plateau species by International Union for Conservation of Nature (IUCN) and World Wildlife Fund (WWF). Branching off from the Kunlun Mountains, the mountain range runs for more than 650 kilometers from southwest to northeast to form the boundary between the Tarim Basin to the north and the minor basin of Lake Ayakekumu and the Qaidam Basin areas of interior drainage to the south (https://global.britannica.com/place/Altun-Mountains). Unique geographic position and natural conditions of the Altun Mountains cause bryophyte of the area can bear bitter cold on highland. Bryophyte is one of the important components of montane vegetation in this area. Considering the bryophyte flora of the Altun Mountains remains poorly studied, recently, we carried out field expedition and specimen collection. Basing on the systematic field investigation of 22 sampling sides, identification of specimens and data analysis, the taxonomy and flora of mosses in Altun Mountains National Nature Reserve have been conducted, which can provide basic data and scientific evidence for mosses flora of Xinjiang and plant conservation and sustainable utilization of Altun Mountains National Reserve. The main results are as follows:1. One hundred and thirteen species belonging to 38 genera and 12 families have been identified. Among those species, *Grimmia orbicularis* Bruch ex Wilson and *Didymodon validus* Limpr. are newly recorded in China, and 14 species are new to Xinjiang: *Brachymenium pendulum* Meut., *Bryoerythrophyllum neimonggolicum* X. -L. Bai & C. Feng, *Bryum clavatum* (Schimp.) Mull. Hal., *B. leptocaulon* Cardot, *B. pachytheca* Mull. Hal., *B. riparium* I. Hagen, *Didymodon mongolicus* D. P. Zhao & T . R. Zhang, *D. acutus* (Brid.) Saito, *D. gaochenii* B. C. Tan & Y. Jia, *Grimmia crassiuscula* H. C. Greven & C. Feng, *Gymnostomum rividulum* Brid., *Stegonia latifolia* var. *pilifera* (Dicks.) Broth., *Tortella alpicola* Dix., and *Tortulalanceola* R. H. Zander (=*Pottia lanceolata*). 2. Pottiaceae Schimp., Bryaceae Schwāgr., Amblystegiaceae G. Roth, Encalyptaceae Schimp. and Ditrichaceae Limpr. are five dominant families (≥ 5 species), totally including 29 genera and 97 species (account for 85.84% of the total number of species). *Bryum* Dill., *Didymodon* Hedw., *Tortula* Hedw., *Encalypta* Hedw., *Bryoerythrophyllum* P.C.Chen, *Syntrichia* Brid., and *Grimmia* Hedw. are seven dominant genera (≥ 4 species), totally including 60 species (account for 51.72% of the total number of species). 3. Mosses flora in Altun Mountains includes 9 types of floristic elements. Among those elements, North temperate element (account for 61.05%) plays a dominant role, followed by East Asia element (8.42%), Old World Temperate element (6.32%), Endemic to China element (6.32%), Temperate Asia element (6.32%), East Asia and North America disjuncted element (4.21%), Pantropic element (4.21%) and tropical Asia element (3.16%).

Pollen morphology of *Eritrichium* (Boraginaceae) in Pan-Himalayas and its taxonomic significance

Paras Mazari, *Jiachen Hao, Quanru Liu*

College of Life Sciences, Beijing Normal university, China

The genus *Eritrichium* comprises about 50 species, mainly distributed in Central Asia and Pan-Himalaya, with a few species in Europe and North America.There are about 43 species in China and Pan-Himalaya. The Infrageneric classification of *Eritrichium* has long been controversial and pollen morphology of *Eritrichium* species in the Pan-Himalayan region is still largely unknown. Furthermore, Boraginaceae is a eurapalynous family and its complexity is rare in angiosperms especially in regard of pollen apertures. The aim of our study is to analyze the pollen morphology of *Eritrichium* and to evaluate its taxonomic significance. In the present work pollen morphology of 38 samples representing 33 species of *Eritrichium* were examined by using scanning electron microscope. The result showed great diversity in shape and aperture characters of the pollen grains of the *Eritrichium*. The common type of the pollen grains were cocoon-shaped, 6-heterocolpate and smooth surfaced with minute pores. Within species the shape, number and position of apertures were also significantly different. In some species like *E. sessilifructum* pollen grains were oblong and without constriction in the equator part. Pollen grains of *E. thymifolium* subsp. *latialatum* had only one aperture located in the center of the pollen grains while in other species like *E. longipes* single aperture was located on one terminal pole. However *E. hemisphaericum* had two apertures located on each pole of the pollen grain.The pollen morphology is helpful for identification of species, although pollen characters alone are insufficient to reconstruct the taxonomic relationships within *Eritrichium* but palynological data can provide some useful information for correct identification and the species-level revisions. Furthermore, Cluster analysis (CA) and Principal component analysis (PCA) were conducted based on four quantitative and three qualitative pollen characters, including pollen shapes, relative size of polar/equatorial, number and location of apertures characters.

Embryonic development pattern of Leptosporangiatae: A case study of *Dryopteris goeringiana*

Gaowa Morigen, Xin Wang, Huining Jia, Longyun Tan, ***Baodong Liu****

Harbin Normal University, Key Laboratory of Plant biology, College of Heilongjiang Province, Harbin

Relative to other plants, the embryonic development of the Leptosporangiatae was extremely weak. As early as 1992, the embryonic development process of families from angiosperms had been compared in detail. While the latest report in 2014 only showed 8 diagrams of *Bolbitis angustipinna*. *Dryopteris goeringiana* was chosen as material. The artificial cultivation of gametophyte generation was taken in simulation natural conditions. With paraffin method, the whole process of embryo development was recorded. The results showed that the primitive cell of organ formed in the 16-cell embryo period. Meanwhile, the formation of the first leaf primitive cell was earlier than the first root primitive cell. In the hippocampal embryo period, the first leaf primordium and the first root primordium broke through cap-shaped parts, and then formed obvious vascular bundles of the first leaf and the first root respectively. Stem was a complex which was composed of residue of roots and petioles. Free nuclei existed during embryonic development. Firstly, this paper made 8 diagram enriched 13 points line graph, including the process from zygote formation to the first leaf and the first root maturity, the division mode of early embryonic cells, the characteristic of the cell nuclei and nucleoli, organogenesis order and their mutual relations. Secondly, the formation of roots and leaves was concluded from three aspects, which was the primitive cell, the tissue and the organ. It was the first time to summarize the embryonic development mode of leptosporangiatae in detail which supported Nayar's Phyllorhize Theory. This paper couldn't agree with the theory that the vegetative organ of seed plants evolved from the Leptosporangiatae, but advocated the stems from Leptosporangiatae and seed plants were different in essence, but with a common ancestor, were two groups of the parallel development.

Plant radiations in hotspots of biodiversity surrounding the Qinghai-Tibet Plateau: An integrative approach

Alexandra Muellner-Riehl[1], *Jana Ebersbach*[1], *Hang Sun*[2], *Adrien Favre*[1]

1. Leipzig University

2. Kunming Institute of Botany

Many studies invoke orogenesis as the main driving force for the radiation of plants in mountains. The role of climate oscillations and key opportunities as well as key innovations as contributors to the establishment of high levels of biodiversity around the Qinghai-Tibet Plateau (QTP) is often neglected. To understand the contribution of orogenesis to plant radiations and the importance of the QTP for the diversification of temperate plants, we investigated the evolutionary history of two taxa with high species numbers in the QTP region, Gentianinae and *Saxifraga* using an integrative approach. We combined extensive field work campaigns and herbaria sampling to obtain well-resolved phylogenies covering our target groups and extensive outgroups. As a key element to our study, we performed divergence time estimation in BEAST using uncorrelated log-normal molecular clock models and multiple, carefully chosen fossil calibration points. In order to understand the role of the QTP region as a cradle for northern temperate plants, we used the resulting dated phylogenies for ancestral range estimation using BioGeoBEARS. Contrary to the "out of Tibet" hypothesis, not all lineages that radiated in the QTP region had originated there, and immigration contributed to the high species richness of this region. Next, we performed diversification rate analyses in BAMM and BayesRate to investigate the temporal association between the uplift of the QTP itself and the adjacent mountain ranges and species-rich radiations in both Gentininae and *Saxifraga*. Similar to several other studies, we found a significant delay between the start of orogenesis and radiations. In addition, we investigated the role of key innovations with BiSSE during diversification and found several traits that were of importance. The evolution of berry-like fruits (as a means of efficient dispersal) were associated with higher speciation rates in *Tripterospermum* (subtropical Gentianinae) while the evolution of the cushion life form (as an adaptation to alpine conditions) played an important role during the diversification process in *Saxifraga*. Finally, we used species distribution models (Maxent) and stochastic character mapping to shed light on the niche evolution of mountain plants and found that niche divergence, as exemplified by larger niche breadth and shifts to below-treeline habitats, dominated in species rich clades. We conclude that the underlying causes for plant radiations in mountains are likely to be multi-faceted. Rather than geomorphological processes themselves, it emerges that the interaction of lineage-specific traits and complex geological settings and/or climatic modifications providing key opportunities are drivers of mountain biodiversity.

A138

No evidence of S-RNase-based gametophytic self-incompatibility in Orchidaceae, similar to that known for Rosaceae, Solanaceae, and Plantaginaceae

Shan-Ce Niu
Institute Of Botany, Chinese Academy Of Sciences

Self-incompatibility (SI) is found in approximately 40% of flowering plant species and in at least 100 families. Although orchids belong to the largest angiosperm family, only 10% of the orchid species present SI, which might be gametophytic self-incompatibility (GSI), while a majority (72%) of the *Dendrobium* species, one of the largest Orchidaceae genera, show SI. Molecular characterization of S-determinants of GSI is well advanced in Solanaceae, Rosaceae, and Plantaginaceae, which are S-ribonuclease (S-RNase) lineages. In the present study, two SI species (*Dendrobium longicornu* and *D. chrysanthum*) were identified using fluorescence microscopy. The S-RNase and SSK1-like genes present in their transcriptomes and in the genomes of *Phalaenopsis equestris*, *D. catenatum*, *Vanilla shenzhenica*, and *Apostasia shenzhenica* were identified. Sequence, phylogenetic, and tissue-specific expression analyses revealed that none of the genes identified was an S-determinant, suggesting Orchidaceae might have novel SI mechanism. The results also suggested that RNase-based GSI might have evolved after the split of monocots and dicots but before the split of Asteridae and Rosidae. However, studies on gene identification, differential expression, and segregation analyses in controlled crosses are needed to further evaluate the genes showing high expression levels in GSI tissues.

Postglacial contraction of a cold-adapted herb, *Triplostegia* (Caprifoliaceae): Insights into Hengduan Mountain-Taiwan disjunctions

Yanting Niu[1,2], *Jianfei Ye*[1,2, 3], *Limin Lu*[1], *Tuo Yang*[1], *Xiaoxin Wei*[1], *Jianhua Li*[4], *Zhiduan Chen*[1]
1. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences,
2. Graduate University of Chinese Academy of Sciences
3. Beijing Botanical Garden, Institute of Botany, Chinese Academy of Sciences
4. Biology Department, Hope College, Holland

Current disjunction patterns can be caused by long-distance dispersal or distribution contraction due to climate fluctuations. We herein investigate the evolutionary history of *Triplostegia*, an ecologically sensitive herb, to gain insights into the formation of its disjunction distribution between the Hengduan Mountain region (HM) and Taiwan. Five chloroplast DNA regions (*psb*K–*psb*I, *rpl*20–*rps*12, *trn*H–*psb*A, *trn*L–F and *trn*S–*trn*G) and the ribosomal nuclear internal transcribed spacer (ITS) for 397 individuals from 48 populations were used to investigate the genetic diversity and structure of *Triplostegia*. Divergence time estimates, ancestral area reconstruction and ecological niche modeling (ENM) were conducted to examine the demographic history of the *Triplostegia* populations. Both the chloroplast and ITS data supported three major lineages within *Triplostegia* corresponding to their distribution in Southwest China (SW), Central China (CC) and Taiwan (TW). Great genetic differentiations among populations from SW, CC and TW were detected. *Triplostegia* was estimated to have originated in SW at *c*. 6.79 million years ago (Ma), migrated to CC at *c*. 4.03 Ma, and finally arrived TW at *c*. 2.15 Ma. The ENM suggested distribution expansion during the Last Glacial Maximum (LGM) whereas range retraction during the Last Inter Glacial (LIG) in *Triplostegia*. *Triplostegia* shares similar adaptive patterns as other cold-adapted species. The disjunct distribution of *Triplostegia* between HM and Taiwan is most likely the consequence of range contraction since the LGM. The predicted distribution of *Triplostegia* in 2070 shows a shrinking and northward scenario. With continuing global warming and human-induced deforestation, extinction risk may increase for cold-adapted species and appropriate strategies should be made for the conservation of ecosystem.

Preliminary study on abnormal morphological characters of *Cycas revoluta*

Aifang Pan

Fuzhou Botanical Garden

Two kinds of morphological anomalies in *Cycas revoluta* were observed in Fuzhou, Fujian Province. The first was that a sucking bud seedling had grown 5 pieces of abnormal leaflets, one piece with a bifurcated midrib was longer than normal leaflets, and another had a double-pieced base. And the second was that a male cone had a rosette tip, as if there were a female cone on its top. These kinds of anomaly would provide some new basic data for cycad systematics and evolution.

A144

Demographic and spatial determinants of plant hybrization and consequences for speciation

Remy Petit, *Etienne Klein*
INRA

Hybridization is a key evolutionary process with major consequences for speciation. Its study in a spatial context is a new research line with considerable potential. It offers a way to evaluate in situ the strength of sexual barriers. In turn, the strength of sexual barriers, in conjunction with pollen dispersal and abundance, determine the degree of intermixing that result in hybridization rates sufficiently low for species to coexist. We explore this idea experimentally in oaks in a long-term mixed species plot as well as analytically and through simulations. To obtain baseline predictions on hybridization rate between two species differing in abundance and to evaluate the effect of pollen limitation, we first used a mean-field model. We then explored a spatially explicit individual-based mating model relying on pollen dispersal kernels to predict hybridization rates in a mixed-species stand, under different scenarios for (i) the strength of sexual barriers; (ii) the spatial distribution of individuals within the site; (iii) the variation in individual fecundity; and (iv) the magnitude, shape and asymmetry of pollen dispersal kernels. Pollen limitation was shown to have the potential to greatly increase hybridization rates. Similarly, fine-scale variation in species composition can result in elevated hybridization rates compared to mean-field predictions, especially with strong sexual barriers. However, species clustering in combination with reduced pollen dispersal has the opposite effect, protecting from hybridization. Our simulation results show that variation of the pollen pool composition at the scale of individuals or stigmas due to spatial configurations or pollen limitation can substantially modify hybridization rates. We explain this by the disproportionate effect of some pollen environments on average hybridization rates. This suggests thoroughly evaluating individual behaviour in terms of hybridization, especially for rare or patchy species. The analyses also support the idea that asymmetric barriers could evolve in response to asymmetric contact between species, for instance during succession, as proposed in oaks.

Studies on the micromorphology of *Cynanchum* (Asclepiadaceae) in China

Xinsheng Qin
South China Agricultural University

The microphology of leaf epidermis of 42 species, 1 subspecies and 1 variety in *Cynanchum* in China were examined under environmental scanning electron microsope (ESEM). The results showed that it had high diversity in the micromorphology of leaf epidermis in *Cynanchum*. A few species are distinctively different from others in their size of stomata and ornamentation of cuticular membrane. The similar features of the leaf epidermis in *Cynanchum* mainly displayed in the shapes of leaf epidermal cells were usually polygonal or irregular. All the abaxial epidermis had stomata, except *C. stenophyllum*, and most of the shapes of the stomata were not sunken. Many species of *Cynanchum* had glabrous leaves and thick cuticular membrane on leaves. A few species are distinctively different from others in their size of stomata and ornamentation of cuticular membrane. It is supported that *C. muliense* and *C. steppicolum* were treated as synonyms of *C. forrestii* in *Flora of China* (Vol.16), and it is not supported that *C. alatum* was treated as a misidentification of *C. callialatum, C. cathayense* as a synonym of *C. acutum* subsp. *sibiricum*, and *C. komarovii* as a synonym of *C. mongolicum*. The feature of the pollinarium morphology of 29 species and 1 subspecies of *Cynanchum* in China were observed under light microscope (LM). Three types of pollinia (spheroidal, prolate and perprolate) and six types of retinaculum (oblong, near roundness, square, near square, regular triangle and near triangle) were observed. This had important significance for the classification of *Cynanchum otophyllum* and supported the treatment of *Cynanchum* Sect. *Vincetoxicum* in *Flora of China* (Vol.63). The caudicle of *C.alatum* was the least developed, while *C. decipiens* was most developed. The feature of the pollinarium morphology of *C. atratum* and *C. officinale*, *C.corymbosum* and *C. verticillatum* were similar. It was considered that *C. alatum* was the false identification of *C. callialatum* in *Flora of China* (Vol.16), but the results showed their pollinarium morphology were different.As the pollinarium in *Cynanchum* was sagging while horizontal in *Tylophora*, it support that *Tylophora* should be a unique group. Seed morphology characters of 9 species of *Cynanchum* were observed under ESEM. The results showed that the seeds of *Cynanchum* had some differences in shape, size and epidermal ornamentation among species. Seeds of *Cynanchum* Sect.*Vincetoxicum* were relative consistency in appearance, size and epidermal ornamentation. Seed ornamentation characteristics in *Cynanchum* Sect. *Endotropis* were significantly different. The seed surface of *Cynanchum auriculatum* presents immersed rumination, irregular mesh and that of *Cynanchum giraldii* immersed reticulation with more regular mesh. These results supported the treatment of *Cynanchum* Sect. *Vincetoxicum* in *Flora Reipublicae Popularis Sinicae* (Vol.63).

Genus *Scutellaria* L. (Lamiaceae) in Azerbaijan

Rashad Salimov[1], *Parvana Garakhani*[2], *Hajiaga Safarov*[3]
1. Institute of Botany of Azerbaijan National Academy of Sciences
2. Institute of Botany of Azerbaijan National Academy of Sciences
3. Hirkan National Park, Azerbaijan

Azerbaijan demonstrates an extremely diverse native flora, consisting of about 4,500 species of vascular plants of which around 950 are Caucasian and 200 national endemics. Azerbaijan flora represents 64% of the total species known for the Caucasus region, one of the biodiversity and endemism Hotspots of the world, certifies its unique feature and justifies the existence of global importance of its conservation. *Scuttelaria L.* (Lamiaceae) has a specific place within the Azerbaijan flora according to its composition of rare and endemic species (Solomon *et al.,* 2013). *Scuttelaria L.* is a large and taxonomically complex genus comprising 350 to 400 species distributed all continents except Antarctica. The main reason for the complexity of taxonomy of the genus is the ambiguous treatment of species due to their high polymorphism. *Scutellaria* L. is insufficiently studied in the flora of Azerbaijan (Flora Azerbaijan, 1957). When *Scutellaria* L. was compared with the number of the taxa and endemism ratio in the adjacent countries' flora; it is represented by 3 sections of 15 species determined in Azerbaijan flora. Five species (33.3%) of them are Azerbaijan and six (40%) are Caucasian endemics (Solomon & *et al.,* 2014). And In the Flora Iranica (Rechinger, 1982) there are 40 species belonging to the genus, and the number of endemic taxa is 39 (72%). Thirteen species (41%) of the genus represented by 34 taxa in Turkey are endemic (Edmondson, 1982). A total of 7 taxa were included in the Armenian flora (Flora Armenia, 1987). In Georgian flora (Flora Georgia, 1987), only 2 species (15.5%) of 13 species are national endemic. The rarity status of all endemic species of *Scutellaria* L. were assessed for the Red List of the Caucasus (V. Ali-zade et al, 2013. *In*: Solomon *et al.,*), two of them were listed in the 2nd edition of the Red Book Azerbaijan (2013): *Scutllaria grossheimiana* Juz.-NT and *S. prilipkoana* Grossh.- VU D2. Distribution and ecology of the species, and causes of extinction of their populations are considered. The phylogenic study using both morphological and molecular data for treatments *Scuttelaria L.* (Lamiaceae) in Azerbaijan flora are planned.

A147

Phylogeographic Study of *Chrysanthemum lavandulifolium* complex

*Yina Xu, **Chuze Shen,** Guangyuan Rao*
School of Life Sciences, Peking University

Chrysanthemum lavandulifolium complex consists of several closely related species, i.e., *C. lavandulifolium, C. potentilloides, C. dichrum* and some types of *C. indicum*. This species complex distributes in East Asia, but its diversity center locates in the Taihang-Lvliang Region of China, where *C. potentilloides* and *C. dichrum* are endemic. For a better understanding of evolutionary trajectory of this complex, especially of endemic *C. potentilloides* and *C. dichrum*, a total of 658 individuals was sampled in this study from 28 populations in the Taihang-Lvliang Region. Leaf morphological analysis was conducted by the data extracted by landmark and LAMINA, and ploidy level was identified for every studied individual by flow cytometry or chromosome counting. Population genetic structure and relationships were inferred from phylogeographic and phylogenetic analyses of three chloroplast DNA fragments and nine nuclear DNA SSR loci. The results show that polyploidization is very popular in *C. lavandulifolium*, even within populations, for polyploids exist in each population while diploids not. No IBD patterns are detected for this complex populations. The highest morphological and genetic diversity are found in the populations of southern Taihang Mountains based on leaf, cpDNA and SSR analyses. Meanwhile, phylogeographic analysis show that ancestral lineages of this complex are also located this region. This suggests that southern Taihang Mountain region is a critical area for the evolution of *C. lavandulifolium* complex. In addition, *C. dichrum* is an extreme type of *C. lavandulifolium* complex, and it is not yet a good species taxonomically according to our morphologic and population genetic analyses. Strong gene flow is found from Taihang Mountains populations to ones in Lvliang Mountains. Niche modeling analysis shows that there are two refuges in the northern and southern Taihang mountains during glacial periods, respectively. Survivors from these refuges spread along Taihang moutains during interglacial time, also expand to Lvliang Mountains. Polyploidization occurs by auto-polyploidy and hybridization-polyploidy in this process.

A148

Phylogenetic analysis of *Pohlia* Hedw. using chloroplast and ITS sequences

Jing-Yuan Niu[1,2], *Shuo Shi*[1], *Lin Li*[1], *Hui Li*[1], *Xiao-Rui Wang*[1], *Yong-Ying Liu*[3], *Yu-Lu Niu*[4], *Xu-Hong Duan*[1], *Jian-Cheng Zhao*[1]
1. Hebei Normal University
2. Xinxiang Medical University
3. Jiaozuo Teachers College
4. Hengshui University

The genus *Pohlia* Hedw. have become one of the largest moss genus in the past years. It has been placed in the Bryaceae as traditionally circumscribed and has been traditionally divided into three subgenera or sections, *Pohlia, Mniobryum and Cacodon*. However, the molecular phylogenetic analysis indicated that the genus *Pohlia* is more closely allied with genera traditionally classified in the Mniaceae or Mielichhoferiaceae. In this study, we performed a molecular phylogenetic analysis, using evidence from four chloroplast regions (*atp*B-*rbc*L, *rps4*, *trn*G, *trn*L-*trn*F) and one nuclear ribosomal intragenic spacer regions (ITS), with different analyses (BI, MP, ML). Two large clades, outgroup clade and ingroup clade, were well supported in all datasets. In the ingroup clade, the traditionally defined species of Bryaceae, including *Anomobryum gemmigerum*, *Brachymenium pendulum*, *B. caespiticium*, *B. capillare* and *Rhodobryum ontariense*, formed a monophyletic clade (Clade A) with high support. Clade B corresponds with the Mielichhoferiaceae-Mniaceae complex with a high support. All samples of *Pohlia*, *Mielichhoferia* and Mniaceae were included in the clade. The most noticeable result of the phylogenetic analysis is that the genus *Pohlia* is non-monophyletic. *Pohlia* were dividing into three parts: Clade C, Clade D and *P. wahlenbergii*. Clade C was divided into two clades, Clade C1 and Clade C2. Clade C1 including *P. minor*, *P. crudoides*, *P. elongata*, *P. gedeana*, *P. nutans* and two samples of *Mielichhoferia*. *Mielichhoferia mielichhoferiana* and *M. elongata* formed a monophyletic clade with high support. Clade C2 included *P. bolanderi*, *P. cruda*, *P. hyaloperistoma*, *P. longicollis*, *P. laticuspes* and *P. lutescens*. And *Pohlia annotina*, *P. flexuosa* and *P. proligera* formed a monophyletic clade (Clade D) with high support. The results represents that the subgenra/sections of *Pohlia* are more closed to the infrageneric classification opinion of Hill and all species included in Clade C1 can be treated as the new circumscribed genus *Pohlia*. The analysis is identical with the conclusion that *Pohlia* are more close to the genera of Mielichhoferiaceae and Miniaceae. Comparing morphological characters, the species of *Mielichhoferia* and *Minum* are distinct from one another. *Pohlia* is morphologically very different from most genera of Mniaceae. We concur with the opinion that Mielichhoferiaceae and Minaceae can be divided into independent families and *Pohlia* is included in Mielichhoferiaceae. Our work was funded by the National Natural Science Foundation of China (No. 31370237 & No. 31070184), Specialized Research Fund for the Doctoral Program of Higher Education of China (No. 2013130312005) and Research Foundation of Hebei Normal University (No. L2015B13).

A149

Re-establishment of species from synonymies based on DNA barcoding and phylogenetic analysis using *Diplopterygium simulans* (Gleicheniaceae) as an example

Jiang-Ping Shu
Shanghai Chenshan Plant Science Research Center, Chinese Academy of Sciences

Because synonymy treatment traditionally relies on morphological judgments, it usually causes many problems in species delimitation and in the biodiversity catalogue. For example, *Diplopterygium simulans*, which belongs to the Gleicheniaceae family, has been considered to be synonymous with *D. glaucum* or *D. giganteum* based mainly on the morphology of its pinna rachis and blade. In the absence of molecular evidence, these revisions remain doubtful. DNA barcoding, which is considered to be a powerful method for species-level identification, was employed to assess the genetic distance among 9 members of the *Diplopterygium* genus. The results indicate that *D. simulans* is an independent species rather than a synonymy of *D. glaucum* or *D. giganteum*. Moreover, phylogenetic analysis uncovered the sisterhood of *D. simulans* and *D. cantonense*, which is supported by their geographical distributions and morphological traits. Incorrect synonymy treatment is prevalent in the characterization of biological diversity, and our study proposes a convenient and effective method for validating synonym treatments and discovering cryptic species.

A150

Species delimitation and speciation of *Orinus* (Poaceae)

Xu Su[1,2], *Yuping Liu*[1,2], ***Ting Lv***[1,2]
1. School of Geography and Life Science, Qinghai Normal University
2. Key Laboratory of Medicinal Plant and Animal Resources in the Qinghai-Tibetan Plateau, Qinghai Normal University

Orinus is an alpine endemic genus to the Qinghai-Tibet Plateau (QTP) and its adjacent regions in the grass family. This genus is the key or unique taxa growing under extremely sandy habitats in these regions. *Orinus* is of the great importance in the ecological restoration and potential usages in breeding new genetic resources. Since *Orinus* was established, six species were described for this genus. However, the boundary and taxonomic treatments of these species remain disputed and their genetic variations between and within species have never been reported. Moreover, the speciation of *Orinus* is still blank for the present. So, it provides a good model to study species delimitation and speciation of new species under the extremely sandy and alpine habitats. Hereby, in this study, we conduct an extensive field exploration for the total genus and then delimitate species boundary based on studies in morphological statistics and DNA barcoding markers at the population level to answer these unsolved questions. Simultaneously, the speciation history of the re-delimited *Orinus* species was studied together with using 10 SSR marker loci and 10 sets of nuclear gene sequences. We collected 786 individuals from 102 populations of six previously-recognized species for niche, morphological and genetic analyses. We sequenced four DNA fragments, three chloroplast DNAs (*mat*K, *rbc*L, *trn*H-*psb*A) and one nuclear ITS. In contrast to the six species previously recognized, statistical analyses based on character variation, molecular data and niche differentiation identified only two well-delimited clusters, together with a third possibly originating from relatively recent hybridization between, or historical introgression from, the other two. Based on the principle of the integrative species delimitation to reconcile different sources of data, our results together provide compelling evidence that the six previously recognized species of the genus should be reduced to two, with new circumscriptions, while the third, identified in this study, should be described as a new species. Meanwhile, we reported this new species and a complete taxonomic revision of the genus. Besides, the results of speciation history of three redefined *Orinus* species showed that *Orinus* species had a high interspecific divergence based on the AMOVA analysis. The genealogical relationships based on the haplotypes identified from 11 nuclear loci suggested that *Orinus intermedia* and *O. anomala* were more closely related to each other than to *O. thoroldii*. Models test of 10 SSR loci based on approximate Bayesian computation analyses supported the hybrid origin of *O. intermedia*. Divergence time of the speciation event between *O. thoroldii* and *O. anomala* was estimated to be around 2.51 Ma, while the other speciation event of the origin of *O. intermedia* occurred around 0.689 Ma. Furthermore, the above time was slightly later than the divergence time of 2.58 and 1.01 Ma based on the nuclear ITS sequence variations. The sustained uplifts and Quaternary climatic oscillations of the QTP, may have together derived the allopatric divergence in *Orinus* and introgression after divergence between them. The habitat differentiation due to the Pleistocene climatic changes may have leaded to the speciation of *Orinus*.

A151

Seed characters and their taxonomic implications in Molluginaceae (Caryophyllales)

Alexander P. Sukhorukov[1], *Ming-Li Zhang*[2], *Maria Kushunina*[1], *Maya V. Nilova*[1], *Anastasiya A. Krinitsyna*[1], *Maxim A. Zaika*[1], *Yuri Mazei*[1]
1. Moscow M.V. Lomonosov State University
2. Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences, Urumqi

The seeds of 75 species belonging to all 11 genera of Molluginaceae

ceae were studied. Several fruit and seed characters were found to characterize certain genera or major clades within the family. ‘Polpoda – Adenogramma + Psammotropha’ subclade is the only lineage where the one-seeded fruits have evolved: *Polpoda* and *Psammotropha* produce both several- and one-seeded fruits, but only the one-seeded fruits are found in *Adenogramma*. The genus *Pharnaceum* in its recent circumscription is carpologically heterogeneous, and all seed characters of *Pharnaceum namaquense* and *P. pusillum*, which were transferred into this genus based on the morphological similarities, indicate their position within *Hypertelis*. *Mollugo spathulata*, a species with uncertain generic status, may also belong to *Hypertelis*. The generic placement of *Pharnaceum serpyllifolium* is also ambiguous, since this taxon is characterized by creeping stems and reticulate seed ornamentation unusual for *Pharnaceum*. The genus *Kewa* (Kewaceae, previously considered within *Hypertelis*) shares many carpological homoplasies with Molluginaceae. The most important characters (seed number, ornamentation and presence of stalactites in the outer walls of the testa cells) were reconstructed using molecular phylogeny. The reconstruction of evolutionary history of the seed number suggests that dry multi-seeded fruit (probably capsule) was an ancestral character state in all Molluginaceae, and one-seeded fruit is an autapomorphic character state in the subclade ‘Polpoda – Psammotropha + Adenogramma’ within Molluginaceae. The presence of ‘stalactites’ in the outer walls of the testa cells seems to be an ancestral character state for the whole Molluginaceae, which is retained in the large ‘Trigastrotheca + Mollugo – Glinus’ clade. It is also observed in the ‘Paramollugo’ clade. The loss of the ‘stalactites’ in ‘Hypertelis’ and ‘South African’ clades is presumably connected with the reduction in the testa thickness.Although Molluginaceae is not a species-rich family, a number of distinctive morphological seed characters is found compared to other core Caryophyllales. However, the anatomical seed characters, albeit diversified in the major lineages of Molluginaceae, appear to be uniform among the entire core Caryophyllales. Taxonomically significant fruit and seed characters are either genus-specific, applicable for the groups of genera (major clades), or to the species with uncertain taxonomic status.

A152

Leaf shape and classification in *Rosaceae*

Xuanting Sun

Huanggang Normal University

Leaf shape is one of the most significant traits of plants. Rosaceae, a diverse and big family in anthophyta of higher organisms, has variable leaves shapes. Traditional classfication divided it into 4 parts: Maloideae, Prunoideae, Rosoideae, Spiraeoideae by distinguish similar morphology. However, after APGIV in 2016, morphological classification in Rosoideae by using these traits face challenges. This new classification by using molecular data based on geography and chromosome number, divided it into 3 parts: Dryadoideae, Rosoideae, Amygdaloideae. Some species in Dryadoideae are N-fixers, but *Dryas integrifolia* seems to be unable to fix nitrogen (Markham, 2009). The genus *Rubus* is very complicated as well, particularly in subgenus, the blackberry with polyploidy, hybridization, leading systematic botany still has to cope with grand challenges. So I chose Rosoideae and its leaf shape as materials in order to comfirm and clarify the relationship between APGIV and traditional morphological classfication in Rosaceae. With the Angiosperm Phylogeny Website, eFlora and FNA, *etc*, I collect data of leaf shape in more than 750 species in Rosoideae and paint line charts in all thirty-three genus relying on APGIV. After rank all charts relying on new classification and also, Wikipedia. I found some genus has much more variable leaf shape than several genus. For instance, in *Sibbaldia*, leaflets are obovate-oblong or oblong, base rounded to broadly cuneate. Leaves pinnate or palmately 3- 5- foliolate. *Rubus*, is a large and diverse genus of flowering plants in the rose family around the world, also, has diverse leaf shape. They has pinnately compound leaves, dentate, oval leaves. Moreover, their leaflets 0 or 3, 5, 7, or 9, terminal ovate to elliptic to obovate, roughly crenate, dentate to doubly dentate, or serrate to doubly serrate. *Chamaerhodos*, even though in Rosoideae, have less traits. Their leaf blade 1- 3 times 3- parted into narrow segments and pinnately compound leaves or simply. In this way, statistics and plot in more than 750 data is a reliable tool to figure out the leaves of Rosoideae show highly various patterns. These diverse leaves shapes indicate following morphological data, such as the shape of the leaves, do not appear to produce a same phylogenetic classification based on APGIV and only using one fundamental feature of plants can not make sure how they evolve and class them.

Evolutionary dynamics of *S*-alleles in *Malus sieversii*, the wild ancestor of domesticated apple

Xiang Ma[1], *Zhe Cai*[2], *Wei Liu*[2], *Song Ge*[2], ***Liang Tang***[1,2]

1. Institue of Tropical Agriculture and Forestry, Hainan University

2. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Science

Self-incompatibility present in angiosperm can prevent self-fertilization, and it is generally controlled by a single genetic locus which encodes for the determinants of both pistil (*S*-allele) and pollen specificity. In this study, we surveyed the diversity of *S*-alleles in *Malus sieversii*, the primary wild ancestor of domesticated apple, via PCR amplification of four consensus primers. The evolution of *S*-alleles was investigated by phylogenetic inference and comparative population genetic analyses between the *S*-allele and previous reported microsatellite data. We identified 14 distinct *S*-alleles in *M. sieversii*, compared to nearly 40 *S*-alleles present in its close relative, *M. sylvestris*. Approximately 15% of amino acid sites from the Maleae self-incompatibility ribonucleases were detected under selection. In addition, this study shows that population differentiation at the *S*-locus in *M. sieversii* is substantially lower than the microsatellite loci, suggesting the action of balancing selection. In summary, our study not only elucidates the constituents and number of *S*-alleles in *M. sieversii*, which will facilitate future germplasm conservation and apple breeding, but also illustrated the potential utility of *S*-locus polymorphism in demographic inference for plant species with self-incompatibility.

Phylogenetic study of *Lindera* based on single copy nuclear gene

Xiangyu Tian, *Hongfang Wang*, Lei Bao, Jianping Ge*

Ministry of Education Key Laboratory for Biodiversity Science and Engineering, School of Life Sciences, Beijing Normal University, Beijing, China

Morphology-based classification is possible confused by convergent evolution. The problem appears serious in *Lindera* and *Litsea* complex. Traditionally, *Lindera* was identified as different genera from *Litsea* only by cell numbers in anthers. *Lindera* was further divided into eight sections based on shortened brachlets, inflorescenses, and venation. However, previous phylogenetic study based on chloroplast revealed very poor support between genus or between sections within genus. Chloroplast is haploid and evolved much slower than nuclear genome, which might be the reason for the poor resolution.Therefore, the true phylogenetic relationship of genus *Lindera* is largely uncertain. In this study, to betterunderstand the phylogenetic relationship between *Lindera* species as well as related genus, we plan to employ more than 20 nuclear single copy genes. We have collected 62 *Lindera* species, covered all eight sections of the genus. To reflect the relationship between *Lindera* and other related genus, we also collected 10 *Litsea* species and 25 other Lauraceae species. To be more representative, more than one individuals from different population are collected for many species. Species tree based on *Beast or BPP is planned to be applied. Currently, we have successfully sequenced about 100 individuals for each of the 20 nuclear loci. Only few loci have been aligned and thus we only reported phylogenetic results based on single locus (*GPN*) in this abstract. Our results indicated that except few individuals of some species, most species of Sect. *Daphnidium*, Sect. *Aperula*, Sect. *Polyadeni*, and Sect. *Cupuliformes* are grouped in four separate supported clades. All sampled individuals from Sect. *Uniumbellae* are within the same supported group with Sect. *Daphnidium*. Species of Sect. *Lindera* are found in at least four supported clades and mixed with species from another section or even another genus. Two species of Sect. *Lindera* located in the basal of all *Lindera* species. Species from *Litsea* or *Parasassafras* can be found in some of the above supported clades. Collectively, our preliminary results support the messy status of the genus *Lindera*. Nonetheless, supported clades found in many sections support the phylogenetic signal of those traditional morphology traits. Carefully check will be conducted in the next step for different individuals of the same species with divergent phylogenetic position.

Hoya carandangiana, Hoya bicolensis, and *Hoya camphorifolia* (Apocynaceae) species delineation: Insights from leaf architecture

Jay Torrefiel, *Inocencio Jr. Buot*

Institute of Biological Sciences, University of The Philippines, Los Bańos, College

Three species of *Hoya* namely, *H. carandangiana*, *H. bicolensis*, and *H. camphorifolia* under the family Apocynaceae, which are superficially similar and consequently, controversial were studied and delineated. For the past decades there were numerous studies that were able to utilize leaf architecture such as in systematic studies aimed at resolving certain taxonomic issues and in fossil (paleobotanical) studies. In this present study, leaf architectural characters were utilized to examine the similarities and differences between the three *Hoya* species. There were unifying leaf architectural characters exhibited by the three *Hoya* species however, characters such as blade shape and class, base shape, apex shape, secondary vein category, and tertiary vein category and course were the characters separating them. Cluster analysis was also done to illustrate relationships between the three *Hoya* species by using unweighted pair-group average (UPGMA) and Single linkage. The results showed that *Hoya carandangiana, Hoya bicolensis* and *Hoya camphorifolia* are three distinct species and hence, leaf architectural characters has the capacity to serve as good taxonomic markers.

The obtainment of complete chloroplast genome sequence of *Gentiana veitchiorum* base on transcriptome

Jiuli Wang[1,2]*, Faqi Zhang*[1]*, Shilong Chen*[1]

1. Northwest Institute of Plateau Biology, Chinese Academy of Sciences

2. University of Chinese Academy of Sciences

The structure and sequences of chloroplast (cp) genomes have precious information to investigate biodiversity, evolution, and inter or intraspecific phylogeny of plants. It is found that the entire cp genome is transcribed in higher plants. *Gentiana veitchiorum* Hemsl. is a perennial herb with greatly ornamental and medicinal value. To obtain the complete cp genome of *G. veitchiorum*, we mined its chloroplast DNA sequences from its transcriptome gained previously and assembled them; coherently, gaps were filled by PCR and sequencing. The total genome of *G. veitchiorum* length was 140,020 bp (42,883 A, 26,853 C, 26,158 G, and 44126 T) with a pair of inverted repeat regions of 24,794 bp each that separate an large single-copy region of 78,942 bp and an a small single-copy (SSC) region of 11,490 bp. The genome consisted of 134 annotation genes, with 89 protein coding genes, 37 transfer RNA genes, and eight ribosomal RNA genes. The phylogenetic analysis of cp genome from *G. veitchiorum* and other six tribe Gentianeae taxa (*Swertia mussotii* Franch., *G. tibetica* King ex Hook. F., *G. robusta* King ex Hook. F., *G. straminea* Maxim., *G. lawrencei var. farreri* (Balf.f.) T.N.Ho, and *G. crassicaulis* Duthie ex Burkill) indicated *G. veitchiorum* has a close relationship to *G. lawrencei* var. farreri.

Genome constitution and taxonomy of *Elytrigia lolioides* inferred from *Acc1*, ITS, *trn*L-F sequences and molecular cytogenetics

Long Wang[1]*, Qinghua Shi*[2]*, Xing Fan*[1]*, Yi Wang*[1]*, Lina Sha*[1]*, Houyang Kang*[1]*, Haiqin Zhang*[1]*, Yonghong Zhou*[1,3]

1. Triticeae Research Institute, Sichuan Agricultural University

2. State Key Laboratory of Plant Cell and Chromosome Engineering, Institute of Genetics and Developmental Biology, Chinese Academy of Science
3. Key Laboratory of Genetic Resources and Crop Improvement, Ministry of Education, Sichuan Agricultural University

Elytrigia lolioides, a hexaploid (2n=6x=42) wheatgrass distributing in Russia and Kazakhstan, was classified into *Elytrigia* and *Lophopyrum* by taxonomists based on different taxonomic principles. However, genome constitution of *Elytrigia lolioides* is still unknown. In present study, single copy nuclear gene *Acc1*, multicopy nuclear spacer DNA ITS, chloroplast gene *trn*L-F in concert with fluorescence and genomic in situ hybridization were employed to investigate genome constitution and taxonomy of *E. lolioides*. Data from cpDNA showed that *Pseudoroegneria* is maternal donor of *E. lolioides*. Despite widespread homogenization of ITS sequences, two distinct lineages (*Pseudorogneria* and *Hordeum*) were identified by the results of ITS data. *Acc1* data suggested that besides *Pseudorogneria* and *Hordeum*, *Lophopyrum* was the third potential donor of *E. lolioides*. However, data from special FISH marker for St genome displayed that *E. lolioides* has two sets of St genomes. The data from GISH were congruent with the results of FISH marker and confirmed that the third genome has been contributed by *Hordeum*. When E genome was used as the probe, there were no any signals on the forty-two chromosomes. The E-like copy of *Acc1* sequences were detected in *E. lolioides* which might due to introgression from E genome species. Accession W6-26586 from Kazakhstan of *E. lolioides* has one set of H genome that one of chromosomes has St genome signals in centromeric and pericentromeric regions. Combining with results from phylogenetic and in-situ hybridization, genome formula of *E. lolioides* was designed as StStStStHH. This species should be classified into the genus *Elymus* L. and renamed as *Elymus lolioides* (Kar. er Kir.) Meld.

Systematic observations on the development of gametophyte and embryo of one species of *Microlepia*

Xin Wang, *Baodong Liu**
Harbin Normal University, Key Laboratory of Plant biology, College of Heilongjiang Province, Harbin 150025, the People's Republic of China.

The embryo development was the important process of plant reproduction. It was not only necessary for classification, but the important basis of discussing the plant origin and evolution. Pteridophyte was an important group in plant evolution, but the researches on embryo were lack. One species of *Microlepia* was chosen for the experiment. The spores were cultivated with modified Knop's solid medium; the cultivation of gametophyte was taken in simulation natural conditions. With paraffin method, the whole process of embryo development was recorded. Spore of the species of *Microlepia* was homosporous with perisporium. The spore grew into the protonema in 20d. The gamephytes generally developed into the heart shape. The division mode of the embryos belonged to the shape of "XZY". Meanwhile, six-cell embryo was observed. During sixteen-cell embryo, the apical cell of embryos came out. With the division of the apical cell, the first leaf primordium formed and then developed into the first leaf. The root apical cell began to split during the development of the first leaf primordium, and then grew into the first root primordium. The apical cell of the second leaf was developing into the second leaf primordium when the first young root formed. This article summarized the initial split mode and the characteristics of the zygote splitting and predicted the process of embryo in Leptosporangiopsida. It emphasized the appearances order of the leaf and the root, vascular bundle characteristics. It was not only significant for accumulating more detailed information of fern embryology research, but also the solution of system classification.

Species diversity of *Trichoderma* in China

*Kai Chen, **Wen-Ying Zhuang**, Zhao-Xiang Zhu, Wen-Tao Qin*
State Key Laboratory of Mycology, Institute of Microbiology, Chinese Academy of Sciences

Trichoderma Pers. is a wide-spread fungal genus that can be easily found in soil, on decaying wood or on other fungi. Species of this genus play an important role in agriculture and industry, such as biocontrol of plant diseases and production of enzymes. Some species were reported as causal agents of green mold disease of mushroom in cultivation and opportunistic human pathogens. Progress in taxonomy of the genus *Trichoderma* has been achieved in recent years along with introduction of molecular techniques. Species number of the group increases rapidly. Up to now, more than 270 species are known in the genus, of which about 120 species are known in China. In the five-year investigations to assess species diversity of *Trichoderma* in China, we collected more than 500 specimens on woody substrates and 750 soil samples from 29 provinces of the country. A total of 150 species have been identified by our group based on integrated studies of morphology, culture characteristics and phylogeny. Among them, 66 new species have been discovered, which are distributed in eight major clades of the genus plus several scattered terminal branches in the phylogenetic tree. Discovery of these new taxa updated our knowledge of the group, and provided rich natural resources for consideration of future use of these fungi in biocontrol and enzyme production. Our results also indicate that China is a biodiversity hotspot of *Trichoderma*. We expect to find more species in the unexplored areas.

Taxonomy and phylogeography of *Bruguiera* species using both chloroplast and nuclear markers

Zhengzhen Wang[1], *Zixiao Guo*[1], *Norman Duke*[2], *Zhang Zhang*[1], *Shaohua Xu*[1], *Suhua Shi*[1]
1. Sun Yat-sen University
2. James Cook University

The typical mangrove genus *Bruguiera* consists of five pure species and two hybrid species. *B. gymnorhiza* distributes widely in the Indo-West Pacific (IWP) region, while *B. sexangula*, *B. cylindrica* and *B. parviflora* are more restricted in the eastern IWP region including Indo-Malesian, Papua and northern Australia.

Notably, *B. exaristata* is only found in some places of Northern Australia. *B.* × *rhynchopetala* is a fertile hybrid between *B. gymnorhiza* and *B. sexangula*, capable of backcrossing with both parents, and *B.* × *hainesii* was recently reported as the hybrid between *B. gymnorhiza* and *B. cylindrica*. This study aimed to examine the hybridization events in the *Bruguiera* genus and compare the genetic composition of populations from different geographical sites for each species. Samples of *Bruguiera* were collected in 13 places from Thailand to Australia where at least one species was found. The sequencing of a nuclear gene *23715* and the chloroplast gene *rbc*L advocated the established taxonomic relationships in the genus. Both nuclear and chloroplast genes showed clear boundaries between the five species. Moreover, the chloroplast gene indicated that all the individuals of *B.* × *hainesii* were F_1 hybrids between *B. gymnorhiza* and *B. cylindrica*, with *B. cylindrica* being the maternal parent, while all the individuals of *B.* × *rhynchopetala* were F_1 hybrids between *B. gymnorhiza* and *B. sexangula,* both of which could be the maternal parent. Within each species, population structure was observed between populations from Australia and Malayan Peninsula, between population from east and west side of Malayan Peninsula or both. In the species that had smaller propagule including *B. cylindrica* and *B. parviflora*, the barrier of Malayan Peninsula affected greater than the geographical distance between Thailand and Australia. Yet in the species that had larger propagules including *B. gymnorhiza* and *B. sexangula*, the geographical distance seemed to contribute more to population differentiation. Geographical isolation such as the Malayan Peninsula played an important role in shaping the extent population structure of these species. The clarity of taxonomic and population structure problems in this genus provides valuable knowledge for reconstructing its evolutionary history and crucial guidance of genetic diversity conservation.

Notes on gemmae diversity of bryophytes from karst mountain area, Guizhou Province, China

Zhihui Wang, *Zhaohui Zhang*
Guizhou Normal University

Bryophytes have a characteristic feature which is their tendency towards extensive vegetative reproduction such as the production of gemmae. Supported by the National Natural Science Foundation of China (NSFC. No. 31360043;31360035), a sires of survey were carried out at Lu Chonggan Karst Mountain Area, Guizhou province, China. These experiment focused on the diversity of bryophyte gemmae, which was in the form of asexual reproduction of the bryophytes in the bare land, and its relationship with the environment under the karst mountainous area to explore the connection between the output of bryophytes' gemmae and microhabitat. The shape, the location, the color and the output were recorded for bryophytes with gemmae. The experiment showed that gemmae will appear in the shape of bud, round ball, rod-shaped, torch and disc; the gemmae mainly locate in the axilla and gemma cups of bryophytes, and the specific locations of gemmae in axilla have little differences; the main color of gemmae is green; the output of gemmae of bryophytes has large span in quanlity. The *Marchantia paleacea* Bertol. subsp. *dipteera* (Nees et Mont) Inoue which has the maximum density reaches hundred million in 1 m^2, which is more than four hundred times than the *Barbula rigidula* (Hedw) Mild that has the the minimum density. The research also found that the bryophytes that grow under the environment which is full of moisture and has weaker illumination intensity are easy to form gemmae.

Some gemmiferous species of bryophytes and their ecological response to soil metals in the karst bauxites mine in southern China

Zhihui Wang[1], *Zhaohui Zhang*[1,2]
1. Guizhou Normal University
2. Guizhou Key Laboratory for Mountainous Environmental Information and Ecological Protection

The production of gemmae is a widespread means of asexual reproduction in both liverworts and mosses in some industry ores areas. For example, there are a rich bryophyte flora with gemmiferous taxa at some karst bauxites mines in southern China. Supported by the National Natural Science Foundation of China (NSFC. No. 31360043;31360035), 780 specimens were collected from karst bauxites in Guangxi and Guizhou. Among them, 24 gemmiferous species of bryophytes belong to12 genera and 3 families were recorded. These genera found more the production of gemmae, including *Marchantia, Barbula* and *Hydrogonium* (4 species).We observed that there are more gemmiferous species in human- active environments of bauxites areas than that in the natural environments. The number of gemmae produced inconsistent, *Molendoa japonica* and *Bryum bornholmense* generated a minimum number of gemmae while *Barbula rigidula* and *Barbula ditrichoides* generated a maximum number of gemmae. By the method of the CCA, it was found that Al played a little rule for affected on bryophytes with gemmae in two province, Ca and Mg were the main factors which affected the distribution of the gemmiferous species in Guangxi while Pb, Cr and Cu were the main factors which affected the distribution of the gemmiferous species in Guizhou. On the soil environment, there was higher adaptation of Ti in *Bryum dichotomum* of Guangxi and Guizhou, and it can grow in the soil environment with high concentration of Ti. In karst bauxites areas of Guangxi, there were higher adaptation of Ca and Mn in *Weissia planifolia* and *Hyophila javanica*. It was hinted that the distribution of bryophytes with gemmae were affected by soil metal elements.

Study on the diversity of succulent plants from Kenya, East Africa

Neng Wei[1,2,3], *Guangwan Hu*[1,3], *Qingfeng Wang*[1,3]
1. Wuhan Botanical Garden, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences
3. Sino-Africa Joint Research Center, Chinese Academy of Sciences

Succulent plants, also known as succulents, are plants with fleshy and thickened vegetative organs retaining water to adapt to dry environment and intermittent rainfall patterns. Owing to their striking and unusual appearance and life habits, they are widely used in horticulture. Based on former research and relatively narrow definition of succulents (horticultural definition exactly), Kenya shows a high diversity of succulents (428 taxa in total, among which nearly 30 percent are endemic in Kenya) and 428 taxa is an under-estimate of the possible total. During the last decade, some new succulent taxa have been found and named. In addition, the welcomed APG system, at some parts, considerably differs from the previous classification system, even at order level. Therefore, a new version of check-list of Kenyan succulents is needed. Now, we are carrying on studies on succulents' diversity and evolution in Kenya adopting an evolutionary definition. Initially, to fully understand the composition of Kenyan succulents, we made schedules to effectively conduct field investigations and paid more attention to neglected groups and potential high species-richness areas. We are going to integrate the information of specimens into BRAHMS database, which is formerly built by East Africa Herbarium. Secondly, we will sample and sequence a specific group of taxa at genera level or families level, trying to elaborate the evolutionary mechanism of character evolution about succulents by dating the origins of succulents lineages and inferring the times of succulence occurrence. Finally, we will collect and sequence all the succulents occuring in a particular area, evaluating their species diversity (SD) and phylogenetic diversity (PD). By means of this way, we will provide scientific and proper measures and suggestions to protect those threatened succulents by the ways of *in situ* conservation and *ex situ* conservation.

Systematics and historical biogeography of *Diplazium* (Athyriaceae)

Ran Wei

Institute of Botany, Chinese Academy of Sciences

The twin-sorus fern genus *Diplazium* (Athyriaceae), with a pantropical distribution, represents an important component of the tropical and subtropical rainforests in the world. We reconstructed the phylogenetic framework and biogeographic history of *Diplazium* to explore the phylogenetic relationships and mechanisms of its tropical disjunctions based on a world-scale species sampling and multilocus phylogeny. The phylogenetic results indicate a paraphyly of *Diplazium* together with *Allantodia*, *Callipteris* and *Monomelangium*, which calls for a broadly defined genus (*Diplazium s.l.*) to accommodate this group of ferns based on morphological synapomorphies, such as continuous grooves on rachis and costae and 'diplazioid' sori. In light of molecular and morphological evidence, an infrageneric classification with four subgenera (i.e. subgenera *Diplazium*, *Pseudallantodia*, *Sibirica* and *Callipteris*) of *Diplazium* is proposed. Molecular dating analysis and ancestral area reconstruction were run using a Bayesian Markov chain Monte Carlo (MCMC) strategy and likelihood dispersal–extinction–cladogenesis method, respectively. Our results indicate a Eurasian origin of the crown group of *Diplazium* during the Eocene. The evolutionary history of *Diplazium* involves a variety of biogeographical scenarios. Subgenus *Diplazium* (with subgenera *Pseudallantodia* and *Sibirica*) originated from the Eocene and probably migrated from Eurasia through the boreotropics to tropical America. The following amphi-Pacific disjunctions within subgenus *Diplazium* correlated to the disruption of the boreotropical belt because of the drastic global cooling from the late Eocene. In contrast, subgenus *Callipteris* diversified during the late Oligocene and middle Miocene, and island-hopping and transoceanic dispersals could be invoked for the pantropical disjunctions. The subsequent diversification of the Neotropical clade of subgenus *Callipteris* may be triggered by the major uplift of the Andes and global temperature optimum during the middle Miocene.

Comments on the APG's classification of angiosperms

***Wei Wang**, Xiao-Xia Zhang, Zhi-Duan Chen, An-Ming Lu*

Institute of Botany, Chinese Academy of Sciences

With the rise of plant molecular systematics, tremendous progress has been made in understanding phylogenetic relationships within angiosperms. With the basic phylogenetic framework of angiosperms established, a DNA phylogeny-based angiosperm classification system at the order and familial levels was proposed by Angiosperm Phylogeny Group (APG) in 1998 and has been updated for three times. In this paper, we summarize the major achievements of the APG system: (1) proving the repeatability of APG system and the predictability of interrelationships of angiosperms; (2) clarifying the systematic positions of some segregate taxa which were not placed based on morphological characters; (3) demonstrating the non-rationality of the dividision of dicots and monocots; (4) demonstrating the importance of tricolpate/tricolporate pollen and derivatives for angiosperm classification; (5) proving that the centrifugal development of stamens in polyandrous groups have evolved independently many times and should not be used to define classes or subclasses of angiosperms; (6) proving that most of the families delimited by broad morphological characters are natural; and (7) falling apart some families which are traditionally regarded as natural. We then point out some problems that need to be resolved in the future: (1) how to harmonize the APG system and the system integrating morphological and molecular data; (2) new morphological evolution theories need to be established on the basis of the APG system; (3) whether it is enough only using "monophyly"as a criterion to circumscribe orders and families; (4) what morphological synapormorphies of those orders in the APG system are; and (5) how to compile a key to distinguish the orders and families of the APG system and to list their diagnostic characters for the orders and families. In addition, we propose the suggestions for the phylogenetic relationships and taxonomic status of some taxa mainly distributed in Asia, especially East Asia, including each of Illiciaceae, Acanthochlamydaceae, Tetracentraceae, Leeaceae, Rhoipteiaceae, Hippcastenaceae, Aceraceae, Bretschneideraceae as familial status, and that Cornaceae *sensu lato* should be divided into Cornaceae *sensu stricto* and Nyssaceae *sensu lato*.

Leaf architecture of genus *Prunus* L. *sensu lato* (s. l.) and its taxonomic significance

Wenxin Huang, *Baohuan Wu, Xuming Zhao, Dafang Cui, Wei Li*
South China Agricultural University

Prunus L. *sensu lato* (s. l.) is the largest genus of stone fruit, including *Amygdalus*, *Armeniaca*, *Prunus*, *Cerasus*, *Padus*, *Laurocerasus*, *Pygeum*. It comprises roughly 200 species, and more than 100 species can found in China. The taxonomy of *Prunus* is still controversial. In this paper, leaves of 78 species from *Prunus* were studied. 41 leaf architectural characters were examined and conducted clustering analysis research with UPGMA method (unweighted pair-group method with arithmetic means) to discuss the intergeneric classification and definition of species. Our results are as follows: 1) *Prunus* had a common set of traits: simple leaf with glands; leave margins mostly with teeth; pinnate and major secondary vein mostly reaching the margin; areolation present; freely ending veinlets presented. There were also distinctive characteristics which could be used to identify subgenus and species. The genus can be divided into 7 subgenus: *Amygdalus, Prunus, Cerasus, Padus, Laurocerasus, Maddenia and Pygeum.* 2) The leaf architecture was significant for evolution of *Prunus*. Leave tooth, glands, major secondary vein framework, areolation and freely ending veinlets were different in complicated degrees and showed the evolvement characters of the *Prunus*. In the process of migration from north temperate to subtropical and tropical, leaves of *Prunus* became untoothed, at the same time the raised glands on the leaf teeth became flat glands on the abaxial surface, vein density decreased and freely ending veinlets with more branches. Meanwhile, the temperate taxa continued to evolve, the number of orders of teeth was increased, the glands on teeth showed various types, the types of the quaternary and quinternary and freely ending vein were diverse. 3) Considering the clustering analysis of leaf architecture, other morphological and molecular evidences, a revision of the *Prunus* was provided here. *P. triloba* was supported be a member of subgenus *Prunus*; Excluded the section *Microcerasus* from the subgenus *Cerasus*; *Maddenia hypoxantha* was as conspecific with *P. wilsonii*, because a wide range of variation was found on the lower leaf pubescence which is the differences between two species; *P. gongshanensis* differs from *P. himalayana* only in its almost glabrous lower leaf surfaces, it'd better to be treated as a variety of *P. himalayana*; *P. pananensis* was highly similar to *P.dielsiana* in morphology, so it should be new distribution of *P. dielsiana* in Zhejiang; *Cerasus xueluoensis* also was highly similar to *P. serrulata* in morphology, it may be a dwarf form of *P. serrulata* growing at high altitude.

A167

Numerical taxonomy study on *Prunus* L. subgenus *Cerasus* (Mill.) A. Gray in East Asia

Baohuan Wu, *Wenxin Huang, Wenting Shi, Haijun Yang, Dafang Cui*
South China Agricultural University

Prunus L. subgenus *Cerasus* (Mill.) A. Gray is a group wildly grow in the temperate regions of the northern hemisphere, especially in east Asia. It's also a controversial group in taxonomy, plant taxonomists havn't reached a consensus on the classification system and the definition of some species yet. In this paper, 30 morphological characters were analyzed, using numerical taxonomic method, to discuss the infra-subgeneric and species classification. The result of UPGMA (unweighted pair-group method with arithmetic means) clustering analysis shows that 41 species are divided into 11 groups, 6 of them only contains 1 species, and others includes 2 or more species. *Prunus conradinae* Koehne, *Prunus glabra* (Pamp.) Koehne, *Prunus henryi* (C.K. Schneid.) Koehne, *Prunus duclouxii* Koehne, *Prunus yunnanensis* Franch., *Prunus pseudocerasus* Lindl. and *Prunus pusilliflora* Cardot are 7 controversial species. Most of the time, they are separated into different sections or series, but sometimes species in different sections or series were combined as 1 species. These 7 species are in 1 group in the clustering analysis, indicating their related relationship; It would be appropriate to put them in 1 section or serie. *Prunus pleiocerasus* Koehne used to be combined into *Prunus conadenia* Koehne, however, the clustering analysis shows that their distance on the morphology is not close enough to treat them as 1 species. *Prunus clarofolia* C.K. Schneid., *Prunus polytricha* Koehne, *Prunus tatsienensis* Batalin are in a group with close distance in clustering analysis. The disciform glands in the margin of bracts is the distinguishing characters of *Prunus tatsienensis* to other 2 species, but it's not found in the original literature and type specimen. And the densely villous of the *Prunus polytricha* is indistinguishable to other 2 species. The 3 species are proposed to be combined to 1 species.

The monophyly of *Delphinium* subg. *Delphinium* remains unresolved, owing to the controversial systematic position of the monotypic, eastern Asian endemic *D.* sect. *Anthriscifolium*. The other sect. of the subgenus, *D.* sect. *Delphinium*, is distributed in the Irano-Turanian (IT) region extending westward to the

Mediterranean Basin. Recently, a new genus endemic toTurkey, *Pseudodelphinium*, was described and considered related with *Delphinium* (Delphinieae) or *Garidella* (Nigelleae). In this study, we first conducted a broad phylogenetic analysis within Ranunculaceae using *mat*K sequences and placed *Pseudodelphinium* in Delphinieae. We then performed a series of analyses using four molecular markers (*trnK*-*mat*K, *trn*S-G, *trn*L-F, and ITS) focused on the tribe. The phylogenetic analyses based on the four-marker dataset indicate that *Pseudodelphinium* is embedded within sect. *Delphinium*. The Swofford-Olsen-Waddell-Hillis tests also reject the exclusion of *Pseudodelphinium* from *Delphinium* and sect. *Delphinium*. The monophyly of subg. *Delphinium* is not recognized because sect. *Anthriscifolium* unites with *D.* subg. *Delphinastrum* and *Consolida*. Based on molecular, morphological, and karyological data, we raise sect. *Anthriscifolium* to subgeneric status, whereas sect. *Delphinium* composed subg. *Delphinium* s.str. An integration of phylogenetic, molecular dating, and biogeographical methods indicates that the subgenus s.str. originated in East Asia during the latest Oligocene and began to diversify in the IT region at 8.45 Ma. Subsequently, the westward colonization events occurred at 7.06 Ma from the IT region to the Italian and Balkan Peninsulas and at 5.4 Ma fromItalyto North Africa. A dispersal from North Africa to the Iberian Peninsula was inferred in the late Pliocene, supporting a hypothesis of trans-sea dispersal. Within the Mediterranean Basin, climate aridification and eustatic sea-level changes could have initiated the westward stepwise expansion of *Delphinium*.

Phylogeography and allopolyploidization of *Magnolia* section *Gynopodium* (Magnoliaceae) in subtropical China

Long-Qian Xiao[1], *Qing-Qing Li*[2]

1. College of Biological and Food Engineering, Huaihua University

2. Life Science College, Southwest Forestry University

Magnolia section *Gynopodium* is an evergreen tree aggregate which includes five species exhibiting three different ploidy levels: diploid, tetraploid and hexaploid. These species have a broad distribution throughout subtropical China and extend to adjacent regions of Indochina. The chloroplast *psb*A-*trn*H sequences were used to examine the genetic structure and phylogeographical patterns for elucidating the glacial refugia and migration history of species within section *Gynopodium*, and the single copy nuclear gene *LEAFY* sequences were cloned to retrieve the different distinct allelic sequences for inferring the polyploid origins. Seven chloroplast distinct haplotypes were identified for all the individuals within section *Gynopodium*. The ancestral haplotypes were confined to the eastern edge of Yun-Gui Plateau, Emei Mountain and the northwest Yunnan. All examined nuclear *LEAFY* allelic sequences were clustered into three distinct clades. Those of two diploid species were recovered as monophyletic and nested within the same clade; whereas those of the tetraploid and hexaploid species were placed into two and three different clades, respectively. The clear-cut geographical distributions of ancestral chloroplast haplotypes indicated multiple potential refugia for species whithin the section *Gynopodium*; the chloroplast haplotype distribution patterns suggested that these species experienced different migratory histories. The nuclear *LEAFY* phylogenetic pattern, combined with evidence from chloroplast data, showed that both allopatric differentiation and allopolyploid origin involving hybridization likely took part in the rapid evolution of the section *Gynopodium*.

Analysis on the morphological variation in the flowers and fruits of *Sinojackia rehderiana*

Guowen Xie, *Leyi Weng, Jinwei Gao, Yisheng Zheng, Xueying Guo, Yunong Tian, Xiaodong Jin*

School of Life Sciences, Guangzhou University

Sinojackia rehderiana belongs to Styracaceae. It is an endangered species, endemic to the subtropical area of China. It mainly distributes in northern Guangdong, Hunan, and Jiangxi province. In the article, *S. rehderiana* population distributed in Yongxiu county was studied, and some fruit variation was founded. Using numerical classification analysis of fruits and flowers on morphology, the fruit variation in the population was explored. The flowers phenotypic data analysis showed that significant differences were existed on the corolla longitudinal diameter, the number of stamens, the anther length, and the diameter of the ovary. The order of variation coefficient of phenotypic characters was calyx length (17.58%) > bud vertical diameter (12.87%) > calyx wide (12.56%) > ovary length (11.53%) > bud lateral diameter (10.05%) > anther length (9.61%) > ovary diameter (9.49%) > stamen number (8.72%). The CV order among 4 fruit types was big tilt type (10.85%) < big long type (11.42%) < big short type and narrow type (11.61%). Anther length and bud vertical diameter, bud vertical diameter and bud lateral diameter, bud vertical diametere and ovary length, bud lateral diameter and ovary length were significantly correlated. Cluster analysis divided the population into three groups, they were big short type, narrow type and big tilt type, and bit long type. Principal component analysis showed that big short type subpopultion was separated from big long type subpopultion at principal component. Big tilt type subpopulation obviously separated from big long type subpopulation and big short subpopulation at principal component, only narrow type and big tilt type mixed together. The fruits phenotypic data analysis showed that all fruit phenotypic traits of *S. rehderiana* were significantly different between subpopulations. The order of variation coefficient of phenotypic characters was beak length (30.68%) > fruit weight (25.85%) > length-width ratio (13.69%) > fruit width (11.58%) > fruit length (11.55%) > bending (3.30%). The CV order among 4 subpopulations was big short type (14.25%) < big long type (16.34%) < big tilt type (16.82%) < narrow type (17.03%). Fruit width and fruit weight, length-width ratio and fruit width, fruit length and beak length, fruit length and length-width ratio were significantly correlated. Cluster analysis divided the population into five groups, they were big short type, big long type, big tilt type, narrow type and mixed type of big tilt type and narrow type. Principal component analysis showed that narrow type subpopulation was obviously separated from other three subpopultions. Big short type subpopulation separated from big long type subpopulation and big tilt subpopulation, only big long type and big tilt type mixed together. The variation of fruits and clustering results were in accordance with their geographical distribution. The narrow type subpopulation and big short type subpopulation are located respectively on both edges of the sample area, big tilt type and big long type are located in the middle transition zone. *S. rehderiana* has good adaptability and wide range of natural distribution. Some phenotypic variation was resulted from genomic hybridization because of high gene flow existed in the breeding.

Lowest latitude fossil record of *Asplenium* from the early Eocene of South China

Kewang Xu, *Xiaoyan Liu, Wenbo Liao, Jianhua Jin*
Sun Yat-sen university

Extant Aspleniaceae Newman is one of the most species-rich groups among leptosporangiate ferns, with about 700 species, and one of the most widespread fern groups, principally distributed in temperate and tropical regions, some species even extending into Arctic and arid areas. *Asplenium* L. is one of the largest fern genera, but the megafossil record of *Asplenium* is limited. Up to now, identifiable megafossils of *Asplenium* have been reported from the Early Cretaceous to the late Eocene of Northeast China, East and Central Russia, Japan, Greenland and Seymour Island and King George Island of Antarctica. South China is one of the *Asplenium* distribution centers, but no fossil records of this genus have yet been reported from this region. In this study, we described some new *Asplenium* fossil specimens recovered from the early Eocene Huachong Formation of Sanshui Basin, Guangdong Province, South China. They were assigned to *Asplenium* mainly based on its bipinnate frond shapes. Fronds are 14 - 8 cm long, ovate-oblong?preserved parts exhibit a maximum length of 15 cm. The main rachis is flat or shallowly sulcate with a raised supravascular ridge on the adaxial side, abaxially flat. The pinna rachis is more slender than the main rachis. Pinnules arranged alternately at angle of about 70° on the main rachis and about 0.8 - 1.5 cm apart, 5 - 9 pairs, linear, 3 - 4 cm long and about 1 cm wide, widest in the middle-lower part, tapering to the apices. The apex of the ultimate pinnule is acute. There is only one vein in the ultimate pinnule with no lateral veins. It is raised abaxially and does not reach the margin. This is the lowest modern latitude fossil record for the genus and the first fossil record of *Asplenium* reported from South China. These fossil specimens demonstrate that *Asplenium* had already spread into South China by the early Eocene. Furthermore, these specimens combined with previous fossil spore-pollen records indicate a warm and humid climate in the Sanshui Basin during the early Eocene.

A172

A preliminary study on postmating reproductive isolation between *Oryza rufipogon* and *O. nivara* based on crossing experiments

Xun Xu, *Qing-Lin Meng, Mu-Fan Geng, Fu-Min Zhang, Song Ge*
Institute of Botany, Chinese Academy of Sciences

Reproductive isolation (RI) is a unique character that reduces gene exchange between populations and is thus the prerequisite for origin of new species. To determine the forms and underlying mechanisms of reproductive isolation, therefore, is critical to the understanding of speciation. *Oryza rufipogon and O. nivara* are two closely related species that are evolutionary young and distinct in morphology and ecology, representing incipient species at the early stage of speciation. Although previous studies found that the two species differed significantly in flowering time, suggesting strong premating RI, the postmating RI between the two species remains unclear despite a few of attempts. To uncover the potential postmating RI and its impact on gene flow between species, we evaluated seed setting rate of different combinations of crosses based on three pairs of *O. rufipogon* and *O. nivara* populations that were sampled from Nepal, Laos, and Cambodia, respectively. We conducted three categories of crosses: intra-population, inter-population within-species, and inter-species. First, based on the crosses involved 4,560 spikelets on 266 panicles, we found that seed set of inter-species did not differ significantly from the other two categories, implying that no obvious postmating RI is present between species. Second, we observed that inter-species crosses using *O. nivara* as the maternal parent generated higher rate of seed sets than that of the crosses using *O. rufipogon* as the maternal donor. In another word, *O. rufipogon* was less fertile than *O. nivara* in terms of female productivity, while the male fertility did not differ significantly between species. This result may arise from the decrease of pistil fertility of *O. rufipogon*, although the tradeoff between vegetative and seed propagations need further investigation. Finally, we found that the seed setting rates were significantly different between the panicles with and without castration, which may explains the inconsistent results arising from previous studies. Investigation on F1 viability and fertility of the crosses is still underway, which may provide additional insights into the RI of the speciation in this group of species.

The functional characterization of KCS genes involved in the synthesis of erucic acid using evo-devo strategy

Jia-Yu Xue, *Guang-Can Zhou, Yue-Yu Hang*
Institute of Botany, Jiangsu Province and Chinese Academy of Sciences

The 3-ketoacyl-CoA synthase (KCS) is the rate-limiting enzyme in the synthesis of fatty acid and genes encoding this enzyme are thereby named as KCS genes. The erucic acid is a sort of very-long-chain fatty acid (VLCFA) and a characteristic component in synthesized Brassicaceae plants. The KCS gene family consists of 21 members in Brassicaceae and different members have evolved functional specificity towards the synthesis of different VLCFAs. However, to date only one member of this gene family—*FAE1* has been confirmed to be involved in the synthesis of erucic acid. Other KCS genes have also been functionally characterized by heterologous expression experiments in yeast and *Arabidopsis*, but none participate in the synthesis of erucic acid. However, it is noteworthy that all those genes are evolutionarily distant to *FAE1*, and have diverged as early as the landing of plants. They share less sequence identity with FAE1, and are more likely to acquire distinct function. Our previous evolutionary study found that six

KCS gene were close relatives to *FAE1* in Brassicaceae, and they all emerged (including *FAE1*) after the split of Brassicaceae by duplication and have not been functionally characterized. Regarding this, we transferred to yeast to express them and erucic acid was detected in the yeast products of two genes, indicating that the two KCS genes (other than *FAE1*) were also functionally involved in the synthesis of erucic acid.

A multispecies phylogeography of the Himalayan blue poppy in sky-islands: Implications for speciation and species delimitation

Fu-Sheng Yang[1], *Yu-Cheng Liu*[1], *Zheng-Xiang Wang*[2], *Xiao-Quan Wang*[1]

1. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences

2. Faculty of Resources and Environmental Science, Hubei University

The Eastern Himalayas (EH), also called “the Earth’s third pole”, belongs to one of the global biodiversity hotspots. It barbors a high concentration of endemic species, especailly on sky-islands inaccessible to human. The Himalayan blue poppy (*Meconopsis*) is a flagship genus for the EH; however, species delimitation within the genus is often controversial. We carried out an extensive field investigation of *M. betonicifolia* s.l. and *M. simplicifolia* s.l., two closely related species complexes distributed on the EH’s sky-islands. And then, a multilocus phylogeographical analysis was conducted to analyze the genetic diversity and retrieve the evolutionary history of the congeneric species. Interestingly, all haplotypes of *M. simplicifolia* s.l. are population-specific, demonstrating that seed-mediated gene flow is blocked completely. Similarly, pollen-mediated gene flow is blocked among the three narrow areas of *M. betonicifolia* s.l. Phylogeographical analyses of plastid and nuclear genes reveal extensive biogeographic structure among populations examined, and reciprocal monophyly of *M. simplicifolia* s.l. and *M. betonicifolia* s.l. is largely supported although some incongruence resulted from hybridization/introgression was detected. These results indicate that lower environment surrounding the EH’s sky-islands acting as barriers could have greatly affected the evolutionary history of local plants, and geographic isolation and repeat range shifts by climatic oscillation have promoted population genetic differentiation, allopatric speciation, and hybrid speciation in the Himalayas. Our results do not support a taxonomic separation of *M. betonicifolia* s.l. into more species based on genetic structure, and *M. nyingchiensis* should be treated as a synonym of *M. simplicifolia*. A taxonomic treatment of the closely related species of *Meconopsis* is proposed.

Construction of database of Higher Plant Specimens at National Herbarium (PE), Institute of Botany, Chinese Academy of Sciences

Qi Lin[1], *Zhirong Yang*[1], *Bojian Bao*[1], *Yun Lin*[2], *Xiaobing Zhang*[3]

1. Institute of Botany, Chinese Academy of Sciences

2. Hunan Food and Drug Vocational College

3. Taiyuan Normal University

National Herbarium (PE), Institute of Botany, Chinese Academy of Sciences was established in 1928, and it is one of the oldest herbaria and the largest in Asia. In the beginning of its establishment, there were only 335,000 specimens, part of the collection dates back to the early 18th century. With the growth of the collections, curation and collection management practices evolved, up to now, PE Herbarium contains more than 2.67 million specimens, ranging from bryophytes, pteridophytes and seed plants, and herein 77% have been digitized in database. This study is based on a database of PE Herbarium records and information system, and makes more detailed introduction to the construction of the database of collection, and provide valuable and useful information regarding collections of vascular plant of PE. In additions, through the statistical analysis to the database, it is indicated that there are 2,056,722 collections recorded at PE, including bryophytes 158,218, pteridophyta 168,231, gymnosperms 29,530 and angiosperms 1,698,035, representing 363 families, 8,368 genera, 84,158 species, 16,466 subspecies, varieties and forms. The specimens were collected from 34 provinces, autonomous regions, municipalities and special administrative regions ofChinaand 147 other countries and regions. There are 18,885 type specimens, representing 195 families, 1,156 genera, 8,711 species (including subspecies, varieties and forms) recorded. The construction of database of PE Herbarium will contribute to realizing the sharing of some specimen, improving the utilization efficiency of the resources, and providing basic platform for the scientific research and social development.

Floral nectaries in *Euonymus* and the origin of echinate fruit surface

Chi-Yuan Yao, ***Jin-Shuang Ma***, *Cheng Du*, *Yun-Juan Zuo*

Shanghai Chenshan Plant Science Research Center, Chinese Academy of Sciences

Euonymus is a morphologically diverse and cosmopolitan genus in Celastraceae. It was argued to modify the most recent classification diagrams in previous work. Studies focused on floral nectaries of *Euonymus* were rather rare in spite of the availability of comprehensive publications dealing with anatomical and morphological aspects. The present study was undertaken to describe the variation of nectaries among the sections of *Euonymus* for the first time. In addition, we also provided a detailed analysis of the origin of echinate fruit surface.The morphology and development of floral nectaries in 21 taxa belonging to the genus *Euonymus* (19 species) and *Glyptopetalum* (2 species) were investigated using light microscopy and scanning electron microscopy. A conspicuous nectary disk is common in *Euonymus*. Organ initiation of the nectary occurred at a primordial floral stage when the flower bud was still quite small. Two types of receptacular nectaries, the intrastaminal type and a combination of inter- and extrastaminal type, were distinguished on the basis of their location. The nectary disk of the first type may form a congenitally united collar together with the stamen bases (such as *E. acanthoxanthus*, *E. pseudovagans*, *E. theifolius*, *E. fortunei*, *E. centidens*, *E. tingens* and

E. microcarpus). However, the disk of the second type extends between the corolla and the stigma, and thus also encompasses the stamen bases (such as *E. sanguineus*, *E. schensianus*, *E. verrucocarpus*, *E. wilsonii*, *E. actinocarpus*, *E. balansae*, *E. alatus*, *E. hukuangensis*. *E. yunnanensis*, *E. wui*, *E. nitidus*, *E. oblongifolius*, *G. continentale* and *G. longipedicellatum*). Variations of modified stomata were found on the apex of the nectary. The nectarostomata are sunken in pits of *E. sanguineus*, *E. centidens*, *E. alatus*, *E. hukuangensis*. *E. nitidus* and *E. oblongifolius*; and located on distinct convexities forming characteristic like chimneys or volcanoes in all species of *E.* sect. *Echinococcus* and *E.* sect. *Ilicifolia*, as well as *E. tingens* (*E.* sect. *Euonymus*); and level with adjacent epidermal cells in *G. continentale*, *G. longipedicellatum*, *E. schensianus*, *E. yunnanensis*, *E. wui*, and *E. microcarpus*. Species in *E.* sect. *Echinococcus* and *E.* sect. *Ilicifolia* exhibit a number of similarities, of which the nectarostomata are raised like chimneys or volcanoes. The nectaries in *E.* sect. *Echinococcus* continue to grow and change to appendages after anthesis, hence the difference emerges in fruit surface which is smooth in *E.* sect. *Ilicifolia* but echinate, prickly or tuberculate in *E.* sect. *Echinococcus*. What is more, it can be observed clearly that each protrusion has a nectarostomata on the top. The great diversity of floral nectaries originates in the numerous adaptations which are the consequence of the co-evolution between plants and their pollinators. This study of floral nectaries undoubtedly contributes to a better understanding of the relationships among the sections of *Euonymus*.

A177

Sharp genetic discontinuity in an arid-sensitive species *Lindera obtusiloba* (Lauraceae): Solid evidence supporting the Tertiary floral subdivision in East Asia

Jun-Wei Ye

Natural History Research Center of Shanghai Natural History Museum, Shanghai Science & Technology Museum

Aim Unravelling phytogeographic divides is essential to a better understanding of flora evolution. Tertiary relict floras in East Asia have been subdivided into two northern (NEA) and southern (SEA) regions separated by an eastward arid belt. The division has been studied infrequently since it was first proposed in 2002. To test the hypothesis, we investigated the evolutionary history of a Tertiary relict species, *Lindera obtusiloba*. Location East Asia. Methods Chloroplast DNA and nuclear microsatellites (nSSRs) were genotyped among 34 populations. Regional genetic diversity was compared, and genetic differentiation between and within regions was calculated. Bayesian phylogeny and Bayesian clustering were employed for phylogeographic reconstruction. Both the most recent common ancestor (MRCA) and population divergence time of the two regions were estimated. Historical gene flow was calculated using the maximum-likelihood method. Potential habitat at present, the Last Glacial Maximum (LGM) and Last Interglacial (LIG) were predicted by ecological niche modelling (ENM). Results Both markers revealed sharp genetic discontinuity and limited migrations between regions. The MRCA and population divergence time probably occurred in the Pliocene. A clear genetic structure was found within each region. Genetic diversity of both markers and the age of chlorotypes decreased as the longitude increased within SEA. The Japanese population harboured the highest genetic diversity, with abundant private and ancestral chlorotypes within NEA. NEA had higher genetic diversity than SEA in nSSRs, while the opposite was true for cpDNA. ENM in LGM and LIG probably supports long-term isolation in multiple locations in both regions. Main conclusions Our study provides solid evidence for the proposed floral subdivision along the arid belt within East Asia. Populations in both regions remained stable over a long-term period and sustained multiple glacial refugia. Westernmost SEA and easternmost NEA sustained ancestral populations. A clear eastward expansion within SEA was detected.

UPLC-QTOF MS characterization of sesquiterpene pyridine alkaloids of *Monimopetalum chinense*

***Min Yin*[1], *Ming Wang*[1], *Xu Feng*[1], *Qizhi Wang*[1], *Yu Shan*[1], *Yu Chen*[1]**

1. Institute of Botany, Jiangsu Province and Chinese Academy of Sciences

2. Nanjing Botanical Garden, Mem. Sun Yat-Sen

Monimopetalum chinense (Celastraceae) is listed as one of the Chinese national grade 2 protective rare and endangered species. Little knowledge of its chemical composition is available. 11 new compounds of *β*-dihydroagarofuran sesquiterpenes from *M. chinense* were first identified by UPLC-QTOF MS in this paper. These compounds are characterized by a 5-carboxy-N-methyl-2-pyridone (CNMP) ring attached to the sesquiterpene nucleus, although only three members of this class of alkaloids have been isolated from *Maytenus emarginata* (Celastraceae), *Loeseneriella merrilliana* (Hippocrateaceae), *Hippocratea excels* (Hippocrateaceae), respectively. The taxonomic position of the family Hippocrateaceae has been debated. According to Robson, the Hippocrateaceae genera are not a natural group, being derived in two separate lines from the Celastraceae. The connection between these families has been reinforced by the presence of some common chemotaxonomic markers such as the quinonemethide triterpenoids, dulcitol, and sesquiterpene pyridine alkaloids. This gives support for the botanical classification in which the two families are grouped as only one family, is united with Celastraceae, the name Hippocrateaceae is rejected in favor of Celastraceae.

Morphological study on flowers and fruits of genus *Schoenoplectus* (Cyperaceae)

Hui–Ying Yu

School of Nature Conservation, Beijing Forestry University

Three morphological characters on flowers and fruits of seven species of the genus *Schoenoplectus* from Shandong were observed and studied using anatomical lens. According to the color, size and shape, two types of scales were divided, i.e. I. elliptico-ovate scales of *S. ehrenbergii*, *S. triqueter* and *S. tabernaemontani,* II. rhombi-ovate of *S. jingmenensis, S. juncoides, S. hotarui* and *S. jiuxianshanensis*. Bristles of *S. ehrenbergii* were found to be longer than nutlets with statistical significance, but those of *S. triqueter*, *S. tabernaemontani*, *S. jingmenensis*, *S. juncoides, S. hotarui* and

S. jiuxmianshanensis were approximately equal to nutlets. For the fruit shape, obvious differences were found between the trigonous nutlets of *S. ehrenbergii* and plano-convex obovate ones of *S. triqueter*, *S. tabernaemontani*, *S. jingmenensis*, *S. juncoides, S. hotarui* and *S. jiuxianshanensis*. In conclusion the bristles length and fruits shape are important to the species limitation among the genus *Schoenoplectus*, while the scales morphology has failed to distinguishing those species. The results added description to these 7 kinds of plants, while also provided new evidences for taxonomic revision of the genus *Schoenoplectus*.

Repeated fluctuating climate drives plant evolution: Enlightenment from distribution of fleshy-fruited species in China

Shunli Yu
State Key Laboratory of Vegetation and Environmental Change, Institute of Botany, Chinese Academy of Sciences

In the evolutionary history of vascular plants, plant phyla with multiple anatomical and morphological innovations are thought to have emerged during cool-dry climate episodes of the earth's history. However, it is not fully understood (i) why plants continually evolved novel resource acquisition systems (e.g., from protostele to eustele) and why propagule evolved from spores to naked seeds and then to seeds enclosed by fruit pericarp, and (ii) why there is a synchronicity in the emergence of novel traits and evolution of plant phyla, non-synchronicity in origin and radiation of plant phyla. A hypothesis was provided that cool-dry climate episodes stimulated the evolution of more efficient resource acquisition systems, e.g. for water uptake. Clades with such innovative resource acquisition systems could diversify and radiate faster and more effectively owing to increasing niches once climate ameliorated, thus forming the genetic foundations for the evolution of future clades when cool-dry conditions reappeared. This hypothesis is proposed on basis of enlightenment from a macro-ecological analysis of the distribution of fleshy-fruited species in the flora of China. A high proportion and richness of species with high-water content fleshy fruits are associated with the high resource (e.g. water) availability of warm-humid climates and with the strong resource acquisition systems of woody plant growth forms. Thus, the evolution of propagules may be the result of the co-evolution of efficient resource acquisition (or utilization) systems and other vegetative apparatus such as leave. Consequently radiation of angiosperms and diversification of their propagules were stimulated by increased ability to occupy vacant ecological niches and attract frugivores as seed dispersers. Repeated fluctuating climate may drive plant evolution process. Our study offers further evidence with which to resolve Darwin's second "abominable mystery" about angiosperm origins and rapid dominance in the earth's terrestrial flora and vegetation.

Taxonomic combination and a new species of *Epimedium* from Wuling Moutians of central China

Cheng Zhang, *Ze-Long Nie, Ke-Gang Li*
Jishou University

Epimedium Linnaeus is the largest herbaceous genus of Berberidaceae, well known for its ornamental and medicinal value. The genus is comprised of 60 species disjunct distributed between the Mediterranean region and eastern Asia. China is the most important diversity center of *Epimedium*, with ca. 80% of the total species found in central-southeastern China. Moreover, all are endemicin China except for *E. koreanum* Nakai. Chinese species (sect. *Diphyllon*) was classified into four series according to flower morphology. However, phylogenetic studies could not confirm the classification based on pollen types, flavonoid types, karyotypes, and molecular marker. Although the AFLP evidence suggested that five well-supported clades are recognized in sect. *Diphyllon*, the backbone phylogeny of the whole section is still unclear. Species delimitation in *Epimedium* has been problematic because of high levels of morphological variation, especially for the Chinese species with wide variations in petal type, the form and relative size of the inner sepals and petals, and flower dimension. The Wuling Mountainsis one of the most important diversity center of *Epimedium* with 26 species found there, 16 of which are regional endemic to this region. However, it is extremely controversial for the taxonomy of the species in this region due to the poor quality of type specimen, intermediate characters of morphological variation, inadequate investigation for some species. To clarify some species taxonomy in Wuling mountains, we provide a few taxonomic combinations for some species complex group based our field investigations and herbarium works together with references of molecular evidences. (1) *E. baojingense* Q. L. Chen et B. M. Yang and *E. franchetii* Stearn are treated as synonyms of *E. hunanense* (Handel-Mazzetti) Handel-Mazzetti. Both *E. baojingense* and *E. franchetii* share similar overall morphology with *E. hunanense. E. hunanense* differs from *E. baojingense* with 2 trifoliolate opposite leaves while the latter with simple leaves. However, extensive field examinations in Jishou and Zhangjiajie from Hunan suggested that *E. baojingense* has predominantly trifoliolate and only occasionally unifoliolate leaves. *E. franchetii* differs from *E. hunanense* in that petals of *E. franchetii* without a distinct petaloid. However, the difference between these two species is not clear. (2) *E. shennongjiaensis*is Yan J. Zhang & J. Q. Li treated as a synonym of *E. leptorrhizum* Stearn. We find that *E. shennongjiaensis* is special ecotype with its flower similar as *E. leptorrhizum* but frozen-like. (3) *E. jingzhouense* G. H. Xia & G. Y. Li is a synonym of *E. coactum*. We have carefully examined its type specimen and plants in type locality and find it has no difference with *E. coactum*. A distinctive and undescribed species, *E. zhangii* C. Zhang, Z. L. Nie & K. G. Li sp. nov., is found from Wuling Mountainsin Hunan province. Molecular evidence indicates that the new species is closely related to *E. parvifolium* and *E. sagittatum*, but differs from them by its long stout rhizomes, flowering stem with 2 opposite leaves, trifoliolate, paniculate inflorescence, flowers purple, and petals with short spur.

Phylogeny and generic circumscriptions of Chinese cheilanthoid ferns

Gangmin Zhang[2], *Wenli Yang*[2]
1. Beijing Forestry University
2. Hebei Agricultural University

Cheilanthoid ferns, which constitute the subfamily Cheilanthoideae of Pteridaceae, have been one of the most contentious fern groups in terms of phylogeny and classification due to morphological convergence driven by adaptation to xeric environments. Using five DNA sequences of chloroplast makers (*rbc*L/ *trn*L–*trn*F/ *rps4*/ *rps4*–*trn*S/ *trn*G–*trn*R) and two nuclear DNA markers (*CRY2*/*IBR3*), combined with the studies of spore morphology and cytology, we addressed the phylogeny of Chinese cheilanthoid ferns. The results were as follows: (1) Pellaea connectens *C. Christensen*, a rare and Chinese endemic species, was robustly embedded in the newly segregated genus Argyrochosma. In addition, it is a sexual tetraploid species with 64 spores per sporangium and with a base chromosome number of x = 27, which is consistent with Argyrochosma and different from other cheilanthoid ferns. (2) *Cheilanthes tenuifolia* (N. L. Burman) Swartz and *C. nudiuscula* (R. Brown) T. Moore formed a fully supported clade (BP=100%) and distantly related to other species of Asian "Cheilanthes" group, so the two species may have an Oceania origin and represent separate evolutionary lines. (3) Except the above two species, all taxa previously placed in Leptolepidium, Aeuritopteris, Cheilosoria, Sinopteris, and the Asian species of Mildella, were intermingled together in the phylogenetic trees and constitute the Asian "Cheilanthes" group. This implies that the above small genera do not merit generic recognition and should be combined into one.

Parasitic angiosperms in China: Diversity, distribution and ecology

Guangfu Zhang
Nanjing Normal University

Parasitic plants play a significant role in influencing ecosystem structure and function, and thus they are generally known as key stone species and ecosystem engineers. Due to vast territory and rich climate-zones, China harbors approximately 31,000 vascular plant species, only second to Brazil in the world. However, little is known concerning the floristic composition, geographical distribution and ecological features of parasitic plants in China. Here, based on reviewing literature reports and checking herbarium records, we provide a nationwide list of parasitic plant species native to China for the first time. The list comprised a total of 678 parasitic plant species belonging to 12 families and 50 genera. The parasites accounted for 2.28% of total angiosperms (29,716 species) in China, 15.07% of the total parasites (ca 4,500 species) worldwide. The most dominant family was Scrophulariaceae with 486 species, accounting for 71.68% of parasitic plants; the most dominant genus was *Pedicularis* with 441 species, accounting for 65.04% of parasitic plants. In addition, 428 of the whole flora were endemic to China, accounting for 63.13%. Most of the 678 species identified were herbs (having 573 species, 84.51%), followed by shrubs (85, 12.54%), then subshrubs (11, 1.62%), and lianas (9, 1.33%) in order. The number of parasitic plant species in 29 province floras ranged from one (In Chongqing) to 283 (in Yunnan), indicating that the parasites were distributed unevenly in China. Additionally, no parasites were recorded in five of 34 provinces. The ecotypes of these parasites can be divided into four categories: root hemiparasites (having 516 species, making up 76.11%), root holoparasites (62, 9.14%), stem hemiparasites (87, 12.83%), stem holoparasites (13, 1.92%) in light of parasitic position and host dependency. Therefore, the flora of parasitic plants is characterized by a great diversity, a predominant family or genus, various life forms and ecotypes. More attention should be focused on distribution and ecology of parasitic plants in China, especially concerning species of dominant families or genera.

Inaccessible biodiversity on limestone cliffs: *Aster tianmenshanensis* (Asteraceae), a new critically endangered species from China

Guo-Jin Zhang, *Tian-Gang Gao*
Institute of Botany, Chinese Academy of Sciences

Aster tianmenshanensis G. J. Zhang & T. G. Gao, a new species of Asteraceae from southern China is described and illustrated based on evidence from morphology, micromorphology and molecular phylogeny. The new species is superficially similar to *Aster salwinensis* Onno in having rosettes of spatulate leaves and a solitary, terminal capitulum, but it differs by its glabrous leaf margins, unequal disc floret lobes and 1-seriate pappus. The molecular phylogenetic analysis, based on nuclear sequences ITS, ETS and chloroplast sequence *trn*L-F, showed that the new species was nested within the genus *Aster* and formed a well supported clade with *Aster verticillatus* (Reinw.) Brouillet *et al.,* The new species differs from the latter in having unbranched stems, much larger capitula, unequal disc floret lobes, beakless achenes and persistent pappus. In particular, *A. tianmenshanensis* has very short stigmatic lines, only ca. 0.18 mm long and less than 1/3 of the length of sterile style tip appendages, remarkably different from its congeners. This type of stigmatic line, as far as we know, has not been found in any other species of *Aster*. The very short stigmatic lines plus the unequal disc floret lobes imply that the new species may have a very specialized pollination system, which may be a consequence of habitat specialization. The new species grows only on the limestone cliffs of Mt. Tianmen, Hunan Province, at the elevation of 1,400 m. It could only be accessed when a plank walkway was built across the cliffs for tourists. As it is known only from an area estimated at less than 10 km^2 and a walkway passes through this location, its habitat could be easily disturbed. This species should best be treated as Critically Endangered based on the International Union for Conservation of Nature Red List Categories and Criteria B2a.

Plastid phylogenomics and adaptive evolution of *Gaultheria* series *Trichophyllae* (Ericaceae), a clade from Sky Islands of the Himalaya-Hengduan Mountains

Ming-Ying Zhang[1], *Peter W Fritsch*[2], *Peng-Fei Ma*[1], *Hong Wang*[1], *Lu Lu*[1], *De-Zhu Li*[1]
1. Kunming Institute of Botany
2. Botanical Research Institute of Texas

Gaultheria series *Trichophyllae* Airy Shaw is an angiosperm clade of high-alpine shrublets endemic to the Himalaya-Hengduan Mountains and characterized by recent species divergence and convergent character evolution that has until recently caused much confusion in species circumscription. Phylogenetic relationships among species in the group remained largely unresolved, although multiple DNA sequence regions have been employed previously. Here we examined the effectiveness of plastid genome for improving phylogenetic resolution within the *G.* series *Trichophyllae* clade. Plastid genomes of 31 samples representing all the 19 recognized species of the series and three outgroup species were sequenced with Illumina Sequencing. Maximum likelihood (ML), Maximum parsimony (MP) and Bayesian inference (BI) phylogenetic analyses were performed with various datasets, i.e., that from the whole plastid genome, coding regions, noncoding regions, large single-copy region (LSC) and inverted-repeat region a (IRa). The partitioned whole plastid genome with inverted-repeat region b (IRb) excluded was also analyzed with ML and BI. Tree topologies based on the whole plastid genome, noncoding regions, and LSC region datasets across all analyses, and that based on the partitioned dataset with ML and BI analyses, are identical and generally strongly supported. *Gaultheria* series *Trichophyllae* diverged into a clade with three species and one variety, and its sister comprising the remaining 16 species which subsequently diverged into seven main subclades. Interspecific relationships within the series are strongly supported except for those based on the coding-region and IRa-region datasets. Eight divergence hotspot regions, each possessing > 5% percent variable sites, were screened across the whole plastid genome of the 28 individuals sampled in the series. Morphological character evolution reconstruction supports several clades, and for two of these, i.e., plant habit and number of leaf marginal teeth, hypotheses of adaptive evolution are postulated.

Phylogenetics of Papilionoideae (Fabaceae) using pultiple genome-scale sequence

Rong Zhang[1,2], *Jian-Jun Jin*[1,2], *Ting-Shuang Yi*[1]
1. Kunming Institute of Botany, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Papilionoideae contains Ca. 500 genera and 14,000 specie, which is the most species-rich subfamily of Fabaceae. The papilionoid legumes have global distribution in a wide range of habitats, many species are economically valued. Papilionoideae is strongly supported as monophyletic group. However, phylogenetic relationships among basal nodes ("early branching papilionoids") and some key lineages within the Papilionoideae remained poorly resolved. Therefore, it is important to reconstruct a backbone phylogeny of the subfamily of Papilionoideae. Including 253 species from 232 genera, Maximum Likelihood and Bayesian phylogenetic analyses were carried out on the complete plastome, most mitochondrial genome and nuclear 18S-5.8S-26S rDNA produced by genome skimming. Most deep relationships were fully resolved with high supports. The Swartzioid clade was strongly supported as a monophyletic group, which was sister to the remaining taxa. Then, the ADA clade, including the *Angylocalyx* clade, the Dipterygeae clade and the Aldinoid clade, was monophyletic with robust support, which was resolved as sister to the remaining taxa. Within the ADA clade, each subclade was strongly supported as a monophyletic group, and the *Angylocalyx* clade was sister to the other two subclades. Next, The *Cladrastis* clade, the *Andira* clade and the Lecointeoid clade were strongly supported to be monophyletic. The Lecointeoid clade was strongly supported as the sister to the large 50-kb inversion clade. Within the 50-kb inversion clade, a few nodes (the genus *Dermatophyllum*, the Vataireoid clade, the Dalbergioid clade and the Genistoid clade) were not well resolved, but some large clades were well supported as the Mirbelioid clade, the Millettioid/Phaseoloid clade and the Hologalegina clade, and some unplaced genera were primely resolved as *Ormosia*, *Bowdichia*. We plan to build a fully resolved and strongly supported backbone including most genera. The robust phylogenetic backbone we provided establishes a framework for future comparative studies on classification and evolution of the Papilionoideae.

Floral scent shapes pollinator-mediated selection in Orchidaceae pollination systems

Wufan Zhang
Institute of Botany, CAS

Insects process floral scent through their olfactory system and generate decision making in insect pollination system, which induces the attraction behavior to host plants. Different plant species releases volatile organic compounds (VOCs) varies in different components and concentration, which raises attraction to different insect pollinators and formats the pollination system. We studied the Orchidaceae plants in Huanglong Nature Reserve in Sichuan Province, analyzed the variety of orchid odor components and their pollinator system. In this study we revealed the differences in odor responses between pollination systems composed by bees and flies, and indicated the selection of pollinators by odor signals from the ecological perspective.

Historical geography and palaeoenvironment of *Liriodendron*

Shuang-Xing Guo[1], *Min Deng*[2]
1. Department of Palaeobotany and Palynology, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
2. Shanghai Chenshan Plant Science Research Center, Chinese Academy of Sciences

Liriodendron is a small genus of Magnoliaceae adapting to humid and warm temperate to subtropical climates. This genus is only composed by two extant species, of which *L. chinense* is native to eastern China, and *L.tulipifera* is native to eastern the United States. There are 32 fossil species of genus *Liriodendron* recorded in Northern Hemisphere. The earliest fossil records were found in early Late Cretaceous in North America. At that period, *Liriodendron* maintained high species diversity level and most of the species grew under a warm temperate to subtropical climate. The species diversity of the genus kept dropping prominently since Palaeogene. The distribution range of *Liriodendron* in Palaeogene shrank significantly. The fossils of Palaeogene and Miocene of the genus existed in subtropical to warm temperate coastal humid area, with large number of the co-occurring subtropical evergreen elements. Although, in Miocene, *Liriodendron* had most abundant fossil localities and widest distribution in Cenozoic (between Lat.43-58°N in Europe and reaching to its southern most boundary as Lat.36°N in coastal regions of Asia and North American), but fewer fossil species were found than in Palaeogene. In Pliocene, *Liriodendron* species were still found in northern subtropical and warm temperate climates, but the distribution range and the abundance of evergreen elements in the fossil assembles showed significant reductions. During the Quaternary climate fluctuation, the global cooling at the glacial period forced *Liriodendron* species migrated to the southern refuge, and also caused massive local extinction, which eventually led to current relic disjunctive distribution pattern of the genus surviving in warm temperate to subtropical regions in present-day East North American and East Asia.

Miocene fossil leaves of *Homonoia* (Euphorbiaceae) from Tiandong County in Guangxi Province, South China

Shuang-Xing Guo[1], *Yi Zhang*[2]

1. Department of Palaeobotany and Palynology, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

2. College of paleontology, Shenyang Normal University; Key Laboratory for Evolution of Past Life in Northeast Asia, MLRC

Leaf fossil specimens were collected at Yan-e village from Tiandong County in Guangxi province of South China in Miocene period. Their foliar physiognomies show petiole 5–10 mm, leaves simple, symmetrical, blade linear or narrowly lanceolate, 6–13 cm long and 1–2.2 cm wide, base cuneate or obtuse; apex acuminate to acute, margin entire or sparsely glandular-serrulate, texture papery to thin coriaceous. Venation pinnate, camptodrome, midvein stout and stright; secondary veins 11–14 pairs, alternate, base stout, sparseal, thinning upward, diverging at angles of from 35^o to 45^o, curving up to leaf margin, looped and closed near the margin; tertiary veins thin, reticulate network, quaternary veins fuzzy. The above characters of fossil specimens are closely similar to living *Homonoia riparia* Loureiro of Euphorbiaceae. However, the leaf blades of living species are bigger in size, number of lateral veins more and diverging angles between the lateral veins and midvein is greater. These features are distinct from leaf fossils. Therefore, these leaf fossils can be identified as a new species, *Homonoia guangxiensis* sp. nov. The living *Homonoia riparia* Lour. as a rheophyte, grows on riverbanks, rocky and gravelly stream beds, sandbars; below 1,000 m lowlands in Provinces of Guangxi, Guangdong, Guizhou, Hainan, Sichuan, Taiwan, Yunnan of South China and Counties of Cambodia, India, Indonesia, Laos, Malaysia, Myanmar, Philippines, Thailand, Vietnam of Southeast Asia. The new species of fossil plants, recorded in Tiandong County, Guangxi, probably also selected similar lowlands for living.

Transcriptome analyses provide insights into the phylogeny and adaptive evolution of the mangrove fern genus *Acrostichum*

Zhang Zhang[1], *Ziwen He*[1], *Shaohua Xu*[1], *Xinnian Li*[1], *Wuxia Guo*[1], *Yuchen Yang*[1], *Cairong Zhong*[2], *Renchao Zhou*[1], *Suhua Shi*[1]

1. Sun Yat-sen University

2. Hainan Dongzhai Harbor National Nature Reserve

Mangroves are a group of plants which can survive and adapt to the extremely unstable marine intertidal zone under harsh conditions, such as high salt concentrations, tidal rhythms and long-term climate changes. The genus *Acrostichum* L. (Pteridaceae) is the only fern genus growing in this environment, including three species: *A. danaeifolium*, *A. aureum* and *A. speciosum*. *A. danaeifolium* and *A. speciosum* are restricted within the Atlantic East-Pacific (AEP) area and Indo West-Pacific (IWP) area, respectively, whereas *A. aureum* is the only species of mangroves that is widely distributed in both areas. In the IWP area, *A. aureum* and *A. speciosum* often occur sympatrically but occupy different habitats with respect to light and salinity. To explore the phylogenetic relationships, origin and molecular mechanisms underlying adaptations on the genomic level, we sequenced the transcriptomes of *A. aureum* and *A. speciosum*, as well as a species in the sister genus, *Ceratopteris thalictroides*. A total of 47,517, 36,420 and 60,823 unigenes of the three ferns have been obtained, and 24.39% – 45.63% of unigenes were annotated using public databases. We reconstructed the phylogenetic tree and estimated divergence times based on the orthologous genes and chloroplast genes among six species, including published genomic data and sequences in NCBI. The calculations showed that the *Acrostichum* genus diverged from its closest relatives approximately 88.1 million years ago. However, the sister species *A. aureum* and *A. speciosum* suggested a very close relationship and diverged approximately 5.1 million years ago. The earliest fossil record was dated to the Maastrichtian in the late Cretaceous (66.0 – 72.1 million years ago), in which the aerenchyma tissue was found, and fossils of other coastal species had also been found in this region or nearby, indicating that *Acrostichum* originated in the late Cretaceous and might be one of the earliest members in mangrove ecosystem. As the two *Acrostichum* species have different preferences for intertidal habitats, it is interesting to explore the molecular mechanisms and detect whether some positively selected genes contribute their adaptations. By using two methods, the modified branch-site model and the K_h method, we identified 15-31 positively selected genes. Some of them, such as SKIP gene, NPH3 family protein, PBCP gene *etc.*, were related to stress resistance and responses to light stimulus, which may participate to their differential adaptations. Our study provides abundant transcriptome data and new insights into the evolution and adaptations of mangrove ferns in the inhospitable intertidal zone.

Biodiversity of bryophytes and their monitoring for metal pollution of karst bauxite area in the Guangxi, China

Zhaohui Zhang[1,2], *Zhihui Wang*[1]

1. Guizhou Normal University

2. Guizhou Key Laboratory for Mountainous Environmental Information and Ecological Protection

Karst bauxite was one of the most important aluminum mines in China, which covered with limestone and dolomite. For the studying the biodiversity of bryophytes and their monitoring for metal pollution of karst bauxite in the southern China, a series of bryological surveys were carried out at karts area in Guangxi Autonomous Regions from 2014 to 2016. Following are some results: (1) About 753 samples and specimens of bryophytes were collected from five karst bauxite mines in Pingguo, Jingxi and Debao counties in Guangxi Autonomous Regions, China; (2) We found that the bryoflora consists of 112 species belong to 49 genera and 23 families. Among them, there are 6 species are liverworts belonging to 6 genera of 6 families, 106 species are mosses belonging to 43 genera of 17 families while no hornworts. (3) There were four life-forms of bryophytes in karst bauxite mines. They are turfs, wefts, mats and pendants. The turfs accounts for 72.56% of the species whereas the pendants are only 2.65%. (4) There were 10 phytogeogrphical elements of bryophytes in research areas. Among them, East Asia elements (20.59%) is the most, and East Asian and North Ameircan disjuncted elements elements (0.98%) is the least. (5) By means of applying ICP and Atomic Absorption Spectrometry and Atomic Fluorescence Spectrometry, the metal content of Al, Fe, Mn, Mg, Ca and Ti of mosses and their substrates were analyzed . Relationship between distribution bryophytes and bauxite pollution were assessed. It was concluded that the bryophytes can be used as indicator species in karst bauxite mines we studied area. This research was supported by the National Natural Science Foundation of China (NSFC. No.31160042;31360035).

Studies on biodiversity of mosses and their biogeochemistry from Carlin gold mines in China

Run Liu[1], *Zhaohui Zhang*[1,2], *Zhihui Wang*[1], *Dengfu Wang*[1], *Qimei Wu*[1]

1. Guizhou Normal University

2. Guizhou Key Laboratory for Mountainous Environmental Information and Ecological Protection

The Carlin type gold deposit is one of the most important industry ores in the karst area of Guizhou province, China.The Carlin-type Mines are characterized by very fine-grained gold and are associated with mercury, arsenic, antimony and thallium. Supported by the National Natural Science Foundation of China, the Science Fund for Distinguished Overseas Chinese Scholars of MHRSS and the Foundation of the Department of Science and Technology of Guizhou, following works were carried out. Based on a series of bryological investigation in our fieldwork, about 1026 specimens and samples were collected from nine carlin gold deposits in Guizhou. The results are showed as follow: 241 species in 80 genera of 25 families were found from the carlin gold mines. Some families such as Pottiaceae, Bryaceae, Hypnaceae, Brachytheciaceae and Thuidiaceae were the dominate group while *Barbula*, *Bryum*, *Brachythecium*, *Hydrogonium*, *Trichostomum* and *Hyophila* were the dominate genera. There were only four types life-forms of mosses in this areas, which were Short turfs, Wefts, Cushions and Pendants. Short turfs was the dominate moss life-form.There were fourteen moss phytogeogrphical elements were found in study region. Among them, North Temperate Zone elements, Tropical Asia elements, Eastern Asia elements and Endemic to China were the dominate elements. By using Atomic Absorption Spectrophotometer (AA-800) and Atomic Fluorescence Spectroscopy (AF-640), eight species of mosses with their soils were tested on the content of Au, Tl, Cu, Pb, Zn, Ca, Mg, As, Hg in them. The relationship between the distribution and biochemistry of mosses and the carlin gold mines were discussed. The results may have some certain directive function on prospecting for some valuable heavy metal deposits those are very difficult to be prospected by general methods.

A193

Floristic characteristics of bryophytes and their biomonitoring for metal pollution environment in the karst bauxite mines in Guizhou province, China

Zhaohui Zhang[1,2], *Dengfu Wang*[1,2], *Qimei Wu*[1,2]

1. Guizhou Normal University

2. Guizhou Key Laboratory for Mountainous Environmental Information and Ecological Protection

Guizhou karst bauxites is one of the largest distribution regions of karst bauxites ores and bauxite mining industry in China. With over half of one century years history of karst bauxite mining activities and thousands of abandoned sites, bauxite pollution are bringing more and more serious environmental problems for local environment and society. Supported by the National Natural Science Foundation of China (NSFC. No.31160042;31360035), we carried a series of study about the bryological flora and its biomonitoring for metal pollution in karst bauxite of Guizhou. (1) From December 2013 to December 2016, we made a lot of comprehensive survey of the bryophytes in karst bauxite mines area of central Guizhou, China. Totally, 1,340 specimens and samples were collected: (2) 182 species belong to 39 genera and 21 families, of which 8 species are Hepaticae species belonging to 6 genera of 5 families, 1 species in 1 genus is Anthocerotae, 173 species are Musci belonging to 32 genera of 15 families. Among families, Pottiaceae, Brachytheciaceae, Hypnaceae, Polytrichaceae and Bryaceae were the dominant families. the dominant genera are *Polytrichum, Brachythecium, Bryum* and *Barbula* in the karst bauxite in Guizhou. (3)For reproductive systems, more than 21 gemmiferous species of bryophytes were recorded . (4) There were four types of life-forms of bryophytes in research area, they were Short turfs, Tall turfs, Wefts and Mats. The short turfs was the majority typed. (5) Through the Shannon-Wiener index, richness index and Simpson index, obtained trends in each karst bauxite. The results showed that, three index in different areas of bauxite were different changes. High canopy density, small human activities, habitat air was relatively humid, the bryophytes were relatively more, the biomass was large and grew well; and human activities, low vegetation coverage around, were the mainly reasons to reduced diversity of bryophytes. (6) With the method of ICP and AAS, eight metal elements (including Al, Ca, Fe, Ti, Mg, Cr, Cu, Ni, and Pb) of the bryophytes and their soil metal elements were studied. The correlation between the bryophyte and their environmental factors were Canonical correspondence analyzed. We suggest that the floristic characteristic, distribution patterns of bryophyte communities together with their biochemistry can be used as effectively tool to monitor some metal pollution around karst bauxite area in the Guizhou karst area.

Phylogeny of the climbing figs (*Ficus* subgen. *Synoecia*)

Zhen Zhang, Xiao-Mei Wang, Jian-Hang Zhang, ***Hong-Qing Li***
School of Life sciences, East China Normal University

With species diversification, reproductive system complexity and long-term coevolutionary background with fig wasps, *Ficus* (Moraceae) remains an unclear lineage in terms of its internal phylogenetic history. Berg restated subgen. *Synoecia* (including sect. *Rhizocladus* and sect. *Kissosycea*), which were split from Corner's subgen. *Ficus* according to their climbing habit mainly. To inspect the phylogenetic nature of these climbing fig trees in subgen. *Synoecia*, 68 taxa out of subgen. *Synoecia* and its allies (over 1/2 species in this group, and representing all the subsections), and additional 26 species from other subgenera to reconstruct phylogenetic relationship based on two nuclear sequences (internal transcribed spacer and external transcribed spacer). Phylogenetic analysis showed that neither subgen. *Synoecia* nor subgen. *Ficus* is monophyletic. However, the two subgenera together (except subsect. *Ficus*) compose a well-supported monophyly. In accordance with present infrageneric names, subdivision on the level of subsections is reorganized. The monophyly consists of two clades, i.e., 1) subsect. *Frutescentiae* (sect. *Ficus* subgen. *Ficus*) + subsect. *Plagiostigma* (sect. *Rhizocladus* subgen. *Synoecia*), and 2) sect. *Eriosycea* (subgen. *Ficus*) + the remains of subgen. *Synoecia*. In the first clade, subsect. *Plagiostigma* (as two separate lineages) is embedded in subsect. *Frutescentiae*. And in the second clade, a high support subclade consists of subsect. *Puntulifoliae*, subsect. *Trichocarpeae* and sect. *Kissosycea*; the other subclade includes sect. *Eriosycea* with subsect. *Pogonotrophe* (namely *F. laevis*) inserted. These results revealed that climbing habit has occurred at least 4 times and couldn't be regarded as a plesiomorphy, and the subgeneric system of *Ficus* needs further revision.

T2

A195

Molecular phylogeny of the *Ficus auriculata* complex (Moraceae)

Li-Fang Zhang, Zhen Zhang, Xiao-Mei Wang, Hai-Yan Gao, Huai-Zhen Tian, ***Hong-Qing Li***
School of Life sciences, East China Normal University

The closely related species in *Ficus* with continuous variation have been making taxonomists, co-evolutionary researchers and other related scientists confused. The boundary between species in the complex of *F. auriculata*, *F. oligodon*, *F. hainanensis*, *F. beipeiensis* and *F. variegata* is unclear for a long time. To clarify this problem, the nuclear loci ITS and *G3pdh* and chloroplast loci *trn*H-*psb*A, *trn*L-*trn*F, *trn*S-*trn*G and *psb*K-*psb*I as well as 15 pairs of SSR markers were applied to restructure the phylogeny and review their genetic background. Our results indicated that *F. variegata* should be an independent species of subsect. *Neomorphe*, sect. *Sycomorus*, which, together with *F. auriculata*, *F. oligodon*, *F. hainanensis* and *F. beipeiensis*, composes a monophyly. The last four species of this complex are of small genetic distances with indistinct differentiation, shared haplotypes and mainly overlapped geographic distribution, and should be treated as one single species.

A196

Generic recircumscription of *Ptilagrostis* (Poaceae, Stipeae) as inferred by phylogenetic and morphological data

Zhongshuai Zhang[1]*, Shanwen Jiang*[1,2]*, Linglu Li*[1]*, Wenli Chen*[1]
1. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, The Chinese Academy of Sciences
2. University of the Chinese Academy of Sciences

The species of *Ptilagrostis (*Stipeae, Poaceae*)* are key elements in alpine grassland ecosystem and formed a diversification centre in Qinghai-Tibet Plateau. But generic delimitation and morphological evolution within it remain highly disputed. In this study we present a comprehensive phylogenetic study on *Ptilagrostis* and its most related genus in Stipeae. Eight chloroplast DNA fragments (representing more than 5,000 bps of the sequence) and nuclear ITS region of 46 species and 2 varieties from these genera were sequenced. The cytology, embryology, lemma epidermal micromorphology and macromorphology of these genera were studied extensively. Evidence from different disciplines coincided with each other. *Ptilagrostis* is recognized as a distinct genus which close to *Stipa* s.s. Its generic boundaries with *Stipa*, *Achnatherum, Piptatheropsis, Orthoraphium* and *Trikeraia* are redefined and the synapomorphies of each group have been given and discussed. Our study highlights the importance of molecular evidence and detailed re-examination of cytology, micromorphology and macroscopical traits that are previously neglected in defining monophyletic and natural genera.

A197

Taxonomic revision of the genus *Didymodon* Hedw. (Pottiaceae, Bryophyta) in Mongolian Plateau.

Dong Ping Zhao[1]*, Tong Rui Zhang*[1]*, Jian Nan Wang*[1]*, Xue Liang Bai*[1]*, Tsogiin Tsegmed*[2]
1. School of Life Science, Inner Mongolia University, Hohhot 010021, China.
2. Institute of Botany, Academy of Science of Mongolia, Ulaanbaatar-51, Mongolia.

Mongolian Plateau is composed mainly of Inner Mongolia in China and Mongolia. The moss genus *Didymodon* Hedw. is revised for Mongolian Plateau and 28 taxa were found: *Didymodon acutus*, *D. asperifolius*, *D. australasiae*, *D. baii*, *D. constrictus* var. *constrictus*, *D. constrictus* var. *flexicuspis*, *D. cordatus*, *D. ditrichoides*, *D. fallax*, *D. ferrugineus*, *D. gaochenii*, *D. giganteus*, *D. glaucus*, *D. hedysariformis*, *D. icmadophilus*, *D. johansenii*, *D. leskeoides*, *D. mongolicus*, *D. perobtusus*, *D. rigidulus* var. *rigidulus*, *D. rigidulus* var. *subulatus*, *D. rivicola*, *D. rufidulus*, *D. subandreaeoides*, *D. tectorum*, *D. tophaceus*, *D. vinealis*, *D. zanderi*. Among these, *Didymodon baii* and *D. mongolicus* are described as a new species, *D. rigidulus* var. *subulatus* and *D. rufidulus* are new to Mongolia. *Didymodon cordatus* is new to China on

the basis of comparison of Chinese material with that of Europe, previous reports being erroneous. *Didymodon anserinocapitatus*, *D. luridus*, *D. michiganensis*, *D. nigrescens* and *D. validus* are excluded from the bryoflora of Mongolian plateau. In the flora area, *Didymodon tectorum* is the most common species, and *D. australasiae*, *D. glaucus*, *D. leskeoides*, *D. rigidulus* var. *subulatus* and *D. subandreaeoides* are know only from Mongolia, while *D. baii*, *D. ditrichoides*, *D. fallax*, *D. giganteus* and *D. rivicola* are know only from Inner Mongolia of China. The key, descriptions, illustrations, distribution data, LM and SEM photographs are provided.

Taxonomy of Mielichhoferiaceae (Bryopsida) in China

Xiaorui Wang, *Shuo Shi, Min Li, Lin Li, Jiancheng Zhao*
Hebei Normal University

Mielichhoferiaceae Schimp. belonging to Bryales of Bryopsida, is a archaic group of bryophyte. Mielichhoferiaceae, with six genera (*Mielichhoferia* Nees & Hornsch, *Pohlia* Hedw., *Pseudopohlia* Williams, *Schizymenium* Harv., *Synthetodontium* Cardon, and *Epipterygium* Lindberg) and ca. 290 species, is a cosmopolitan family, and most species grow in mountain, plain, marsh and arid desert. Mielichhoferiaceae group were traditionally classified in the family Bryaceae. However, the recent phylogenetic researches clearly indicated that some species of Mielichhoferiaceae are closer to the family Mniaceae than Bryaceae. In this paper, morphological characters of more than 4,500 specimens of Mielichhoferiaceae and its related groups were analyzed. Phylogenetic studies using Maximum parsimony (MP), Maximum likehood (ML) and Bayesian inference (BI) analyses based on chloroplast (*rps4*, *trn*L-F, *atp*B-*rbc*L, *trn*G) and nuclear (ITS) sequences of 58 specimens for 44 species were presented. The molecular trees based on chloroplast sequences showed that the Mielichhoferiaceae group was nested within the Mniaceae, whereas the molecular trees based on nuclear sequences showed that the Mielichhoferiaceae group, including genera *Pohlia* and *Mielichhoferia*, composed a distinct lineage which was separated from Bryaceae and Mniaceae. In addition, the morphological features of Mielichhoferiaceae, such as plant size, leaf size and shape, type of leaf lamina cells, peristome configuration, *etc*., are different from the Bryaceae and Mniaceae. Combining morphological and molecular data in the analyses, we drew a conclusion that Mielichhoferiaceae is a natural monophyletic group, and we transferred two Chinese species of *Mielichhoferia*, *M. himalayana* Mitt. and *M. sinensis* Dix. to genus *Haplodontium* (Bryaceae) as *H. himalayanum* (Mitt.) X. R. Wang et J. C. Zhao and *H. sinensis* (Dix.) X. R. Wang et J. C. Zhao separately. Currently, there are a total of five genera, *Mielichhoferia* (one species), *Pohlia* (28 species), *Pseudopohlia* (one species), *Synthetodontium* (two species) and *Epipterygium* (two species), 34 species of Mielichhoferiaceae in China. This project was financially supported by the National Natural Science Foundation of China (No. 31370237 & No. 31070184).

Plastid phylogeny and biogeography of the Paleotropical woody bamboos (Poaceae: Bambusoideae)

Meng-Yuan Zhou[1,3], *De-Zhu Li*[1,3], *Thomas Haevermans*[2]
1. Kunming Institute of Botany, Chinese Academy of Sciences
2. Muséum National d'Histoire Naturelle
3. University of Chinese Academy of Sciences

Paleotropical woody bamboos (PWB) are widely distributed in tropical and subtropical areas of Asia, Africa and Oceania, and they are phylogenetically and taxonomically intractable. Because of deficient sampling or lacking informative characters, phylogenetic relationships among the PWB remain incompletely resolved. Thus there are little biogeographical estimations about this group of bamboos because of ambiguous phylogeny and fossil records. This study presents the most extensively sampled phylogeny of the PWB with 18 plastid regions. Plastomes were sequenced and assembled for representative taxa in each major clade to further investigate unresolved relationships in the 18-region phylogeny. In addition, divergence time and ancestral ranges of the PWB were estimated. Results confirmed Melocanninae as the earliest diverging lineage from the rest of the group. Malagasy Hickeliinae (include *Nastus* s.str.) diverged after Melocanninae. Subtribe Bambusinae was phylogenetically heterogeneous and consisted of the *Dinochloa*-*Greslania*-*Mullerochloa*-*Neololeba*-*Sphaerobambos* (DGMNS) assemblage, *Temburongia* and the core Bambusinae clade. Malesian and Oceanian endemic *Nastus* s.l., DGMNS and Racemobambosinae formed a well-supported clade which was sister to *Temburongia*. The core Bambusinae might be redefined to include a basal grade, which contained *Kinabaluchloa*, *Holttumochloa*, *Bonia*, *Neomicrocalamus*, *Temochloa* and *Soejatmia*, and the *Bambusa*-*Dendrocalamus*-*Gigantochloa* (BDG) complex. The BDG complex was extremely diverse in morphology and was subdivided into six subclades according to topology, taxa composition, geographical distribution and network analysis. Within the Melocanninae clade, *Ochlandra*, *Davidsea* and *Neohouzeaua* were closely related to *Schizostachyum*, and the only two sympodial bamboos with long-necked rhizome, i.e. *Pseudostachyum* and *Melocanna*, had closer affinity in phylogeny. The PWB were estimated to have been originated during the late Oligocene, and their common ancestors were widely distributed across the Old World except for Africa. The extant geographical distribution patterns of major lineages were mostly evolutionary results of vicariance, within-area subset speciation and subsequent dispersal events. Diversification rate of the PWB was constant through time until ca. 5-7 Ma since when diversification rate increased rapidly. The rise of diversification rate is suspected to be due to the diversification rate shifts estimated to have occurred in the BDG complex. The intractable phylogenetic relationships within the BDG complex were potentially caused by a recently rapid radiation and frequent hybridizations among them as inferred from divergence time and diversification rate estimations of the PWB and previous studies.

Taxonomic status of genus *Elytrigia* Desv. (Poaceae: Triticeae) and biosystematic study on its species

Yonghong Zhou[1], *Haiqin Zhang*[1], *Yan Yang*[2], *Long Wang*[1]
1. Sichuan Agricultural University
2. China West Normal University

Elytrigia Desv. is one of the important perennial genera in the tribe Triticeae (Poaceae). Desvaux first established it based on *Triticum repense* L. in 1810 because of the strongly rhizimaous chracter, and the type species is *Elytrigia repens* (L.) Nevski. Since then, the strongly rhizimatous, long-anthered, and cross-pollinating species were included in this genus. Nowaday, many taxonomists consider *Elytrigia* as an independent genus. It includes about 40 species in the world, and is distributed in the subtropical and warm temperate countries of both hemispheres. Species in *Elytrigia* are excelent fodder plants, and some species are used in wheat breeding program through distant hybridization as the genetic germplasm resources for disease and drought resistance, and salt tolerance. *Elytrigia* is historically a very difficult and controversial genus in taxonomy. The definition of the genus and its precise taxonomic treatment are still under discussion. We carried out the taxonomic status of *Elytrigia* and biosystematic study on its species through morphological characters, geographic distribution, intergeneric and interspecific hybridization, fertility, cytogenetic characterization, genomic in situ hybridization (GISH) and molecular systmatic studies in nearly ten years. The main results are as follows: (1) *Elytrigia repens*, the type species, contains StStH genomes, and should be treated as *Elymus repens*. Therefore, *Elytrigia* is a invalid genus. (2) In *Elytrigia* sensu lato, the species with St genome should be included in *Pseudoroegneria*, the species with StH genomes should be trated as *Elymus*, StE species should be included in *Trichopyrum*, and EE genome species should be combined as *Lophopyrum*. (3) *Elytrigia repens* and *E. lolioides* contain StH genome, and should be treated as *Elymus*. *E. pungens* and *E. pycnantha* are with StEP genomes and should be included in *Pasmmopyrum*. *E. intermedia*, *E. geniculata* subsp. *pruinifera* and *E. geniculata* subsp. *scythica* contain StE genomes and should be treated as *Trichopyrum*. *E. pontica* contains EEEEE genomes and should be included in *Lophopyrum*. (4) *Elytrigia* s.l. contains St, E^e, E^b, H, and P basic genome. E^e genome comes from *Lophopyrum elongatum*, E^b from *Thinopyrum bessarabicum*, St from *Pseudoroegneria*, H from *Hordeum*, and P from *Agropyron*. Therefore, *Elytrigia* is an invalid genus. The species in it should be treated as species in *Elymus*, *Lophopyrum*, *Trichopyrum* and *Pasmmopyrum* respectively according their genomic constitutions.

Genome-wide analysis of the cellulose synthase gene superfamily in *Gossypium* cotton

Xianyan Zou
1. State Key Laboratory of Cotton Biology
2. Key Laboratory of biological and genetic breeding of cotton, The Ministry of Agriculture; Institute of Cotton Research, Chinese Academy of Agricultural Sciences

The cellulose synthase superfamily including the cellulose synthase (Ces) and cellulose synthase-like (Csl) families is involved in the synthesis of cellulose and hemicellulose. In *Gossypium* cotton this family plays a decisive role in fibre development. Using a series of bioinformatic methods, 210 *Gossypium* cotton *Ces*/*Csl* genes were identified and grouped into 10 subfamilies by phylogenetic analysis. Subsequently, gene structure, chromosomal location, and syntenic analyses were performed. Selection pressure ranged from 0.039 to 0.195 among the gene subfamilies indicating that the *Ces*/*Csl* genes had undergone purifying selection. The expression patterns of the tetraploid *CesA* genes in transcriptomic and qRT-PCR analyses revealed different expression among genes in different *CesA8* subclades. Further analysis showed differences in promoter *cis*-elements and cellulose_synt domains (PF03552) among these genes that may explain their differential expression. This study provides novel insights into the evolutionary relationships, domain structures, and expression patterns of the *Ces*/*Csl* gene family of *Gossypium* cotton.

Flow cytometric measurements reveal endopolyploidization phenomenon of *Phalaenopsis*

Zuo Li[1,2], *Zhongjian Chen*[3], *Fubing Lv*[1,2], *Wenfang Xiao*[1,2], *Heming Chen*[1,2]
1. Environmental Horticulture Research Institute of Guangdong Academy of Agricultural Sciences
2. Guangdong Provincial Key Laboratory of Ornamental Plant Germplasm Innovation and Utilization
3. Agro-biological Gene Research Center of Guangdong Academy of Agricultu

Orchidaceae species are well-known ornamental plants all over the world because of their charming flowers and various flower characteristics. Inter-specific and inter-generic hybridization within and between species of the *Orchidaceae* has increase the genetic diversity substantially. In orchid family, as popular potted flower plants, *Phalaenopsis* species have attracted a great deal of attention worldwide, regarding their long-lived and vivid flowers and various polyploidy patterns. Polyploidy has been recognized as one of the most important factors promoting speciation in the plant species, numerous genera including polyploid species complexes are well known for their high morphological variability. The endopolyploidization as a universal phenomenon existing in the higher plant, which on plant cells maintained a faster growth rate, is an important way of increasing copies of function genes. However, the understanding of polyploidy and endopolyploidization in *Phalaenopsis* genus remains limited and few research have been done. In this study, *Phalaenopsis* species were used to determine the endopolyploidization level in five kinds of tissues, including leaf tip, root tip, flower bud, blossom flower and peduncle, respectively, using the technique of flow cytometry (FCM). Meanwhile by using conventionl tabletting method, the chromosomes number of those *Phalaenopsis* samples were analyzed to help verify the FCM investigated results. The results showed that in *Phalaenopsis* the feature of endopolyploidization was specific for tissues, moreover the endopolyploidization level varied in different *Phalaenopsis* species of the same genus, even those samples owed the same chromosomes numbers. The research on the feature of plant endopolyploidization phenomenon would be helpful for regulating efficiently differentiation of organs and accelerate the formation of valuable organs. Although our research was limited to *Phalaenopsis*, the need to find a suitable tissue for FCM detection to all endopolyploid species.

Molecular phylogeny of eastern Sumatran species of *Mangifera* L. (Anacardiaceae): Taxonomic implication

Ibna Hayati, *Fitmawati Fitmawati, Nery Sofiyanti*
Universitas Riau

The phylogenetic relationships of the genus *Mangifera* with emphasis on eastern Sumatran species were estimated using sequence data from internal transcribed spacer (ITS) regions of nrDNA. The separation of the two traditionally accepted subgenera was not well supported. The monophyly of each section of *Deciduae, Perennes, Marchandora, Euantherae, Rawa,* and *Mangifera* within genus remained unclear. To clarify the phylogenetic relationship, we examined four different methods of phylogenetic tree reconstruction with the addition of outgroups and sequences of *Mangifera* from the NCBI GenBank as representative species of each section. The resulting tree topologies were mostly consistent with one another. Judging from the phylogenetic tree some of section should be fused. We also provide the molecular description for the common mango species found in Sumatra and create comparison among them. The result was support the resurrection of species *Mangifera sumatrana* Miq. Nucleotide variation among *Mangifera* species should be interpreted as modification of environment. Molecular data support placement of species within the genus.

New Taxonomic Evidence for *Mangifera laurina* Bl. (Anacardiaceae)

Fitmawati Fitmawati[1], *Alex Hartana*[2], *Mien Achmad Rifai*[4], *Bambang S Purwoko*[3], *Ibna Hayati*[1]
1. Biology Department, Universitas Riau
2. Department of Biology, Bogor Agricultural University
3. Departement of agronomy, Bogor Agricultural University
4. Lembaga Biologi Nasional

The relationship between *M. laurina* Bl. and *M. indica* L. were remain unclear. *M. laurina* Bl. is closely related to *M. indica* L. They shared similar leaves. In flower, *M. indica* could be distinguished by its flower in glomerulous and being densely pubescent while in *M. laurina* it has lax, non-glomerulate, almost glabrous inflorescence. Previous study also suggested *M. laurina* as synonymy of *M. indica* whereas *M. laurina* is an accepted name recently. Therefore we provide new evidence to clear *M. laurina* based on morphology, anatomy and molecular data using cpDNA such as *trn*L-F Intergenic Spacer and *rbc*L sequence and also nuclear ribosomal DNA of ITS Sequence and E-RAPD marker. The phylogenetic tree were also obtained from the combination between morphology and E-RAPD marker and as well as combination of cpDNA and nrDNA sequences. The results showed *M. laurina* Bl. as independent species. The result also suggested *M. laurina* as the common ancestor of *M. indica* L. Here we supported the idea about strict separation of *M. laurina* Bl. from *M. indica* L. based on these new taxonomic evidence.

A Jurassic wood providing insights into the earliest step in *Ginkgo* wood evolution

Zikun Jiang[1], *Yongdong Wang*[2], *Marc Philippe*[3], *Wu Zhang*[4], *Ning Tian*[5], *Shaolin Zheng*[4]
1. Chinese Academy of Geological Sciences
2. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
3. UMR 5023 of the CNRS and Université Lyon 1
4. Shenyang Institute of Geology and Mineral Resources
5. College of Palaeontology, Shenyang Normal University

The fossil record of Ginkgo leaf and reproductive organs has been well dated to the Mid-Jurassic (170 Myr). However, the fossil wood record that can safely be assigned to Ginkgoales has not yet been reported from strata predating the late Early Cretaceous (ca. 100 Myr). Here, we report a new fossil wood from the Mid-Late Jurassic transition deposit (153–165 Myr) of northeastern China. The new fossil wood specimen displays several Ginkgo features, including inflated axial parenchyma and intrusive tracheid tips. The transition from early wood to late wood is gradual, with an intermediate type occupying most of the ring. The axial cells in cross-section are irregular in size and shape, and the tracheids are mostly quadrate to elliptical in the early wood, and more regularly narrowly rectangular in the late wood. Intercellular spaces are often distinct, and the tracheid wall is thick, even in the early wood, suggesting a compression wood type. The tracheid walls are destroyed in some fungi infected areas. In a tangential section, xylem rays are homogeneous, relatively low, (1) 2–4 (15) cells high and are often associated with inflated axial parenchyma. The tracheid tips are often contiguous to the ray margin or associated to inflated axial parenchyma. In the radial section, some tracheid bunches are present, with storied tips bent alongside wood rays, and the tips sometimes overlap one another. The tracheid radial pits are mostly uniseriate, round and distant, sometimes contiguous and somewhat flattened, and locally biseriate. The pattern of biseriate pits is variable, from alternate crowded to sub-opposite crowded or opposite distant, sometimes with Sanio's rims. Ray cells in each crossing field yield 4–6 tracheids in the early wood, and ray cell transverse walls are thin and unpitted, often resiniferous; cross-fields with (1) 2–4 cupressoid oculipores, with an oblique aperture. Oculipores are ordered in columns and lines. The axial parenchyma are abundant and well distributed within the ring, with possible crystalliferous chambers. Trabeculae are locally preserved, whereas resin canals are not observed. Because it is only slightly younger than the oldest recorded Ginkgo reproductive organs (the Yima Formation, 170 Myr), this fossil wood very probably represents the oldest bona fide fossil Ginkgo wood and the missing ancestral form of Ginkgo wood evolution.

An evolutionary continuity principle for evolutionary system of organism divisions

Da-Li Fu[1], *Hao Fu*[2]
1. Chinese Academy of Forestry
2. Central South University of Forestry and Technology

Evolutionary research is guided by the scientific basis of organism evolution. To overcome the limitations of being partial and subjective in the tree of life or phylogenetic system, the authors proposed a basic principle of organism evolution, evolutionary continuity principle. Based on this principle, the evolutions can be divided into two basic forms: vertical evolution and horizontal evolution. The vertical evolution is that evolution of the structures and features of organisms from non-existent to entirety, from simple to complex, or from primitive to advanced. The evolutionary course of vertical evolution can be divided into two or three significantly different phases, such as plants: the non-vascular → the vascular, non-seed → Gymnospermophyta D. L. Fu & H. Fu, phyl. nov. → Fructophyta D. L. Fu & H. Fu, phyl. nov., and the animals: Proenteratozoa D. L. Fu & H. Fu, phyl. nov. → Coelenteratozoa → Euenterata, non-chordata and non-gnatha → Chordato-gnathozoa D. L. Fu & H. Fu, phyl. nov. → Vertebrognathozoa D. L. Fu & H. Fu, phyl. nov. The horizontal evolution is that evolution of structures and features from loose to compact, from inefficient to efficient, or from primitive to advanced, which can also cause significant organism changes, such as Nudembryophyta D. L. Fu (Plantae) → Proenteratozoa D. L. Fu & H. Fu, phyl. nov. (Animalia), Bacterophyla D. L. Fu & H. Fu, phyl. nov. → Acytophyla D. L. Fu. Based on the continuity principle, the new evolutionary taxonomical system of divisions was established and the evolutionary diagram was drawn. The new system includes 20 divisions in three kingdoms, and 11 of those divisions are new. These are: I. Regnum Microbia D. L. Fu: 1.Cyanoalgophyla D. L. Fu & H. Fu, phyl. nov., 2. Bacterophyla D. L. Fu & H. Fu, phyl. nov., 3. Acytophyla D. L. Fu, 4. Monoalgophyla D. L. Fu & H. Fu, phyl. nov., 5. Monomycophyla D. L. Fu & H. Fu, phyl. nov., 6. Eualgophyla D. L. Fu & H. Fu, phyl. nov., 7. Fungophyla D. L. Fu & H. Fu, phyl. nov.; II. Regnum Plantae Haeck.: 8. Nudembryophyta D. L. Fu, 9. Bryophyta, 10. Pteridophyta, 11. Gymnospermophyta D. L. Fu & H. Fu, phyl. nov., 12. Fructophyta D. L. Fu & H. Fu, phyl. nov.; III. Regnum Animalia L.: 13. Proenteratozoa D. L. Fu & H. Fu, phyl. nov., 14. Coelenteratozoa, 15. Nematodozoa, 16. Annelidozoa, 17. Arthropodozoa, 18. Echinodermatozoa, 19. Chordato-gnathozoa D. L. Fu & H. Fu, phyl. nov., 20. Vertebrognathozoa. D. L. Fu & H. Fu, phyl. nov. The new evolutionary theory, new evolutionary taxa and new evolutionary system can provide scientific bases for Evolutionomy, a new science of organism evolution.

Study on pollen morphology of Asteraceae family at Universitas Indonesia, Depok

Rachmi Luthfikasari, *Salamah Andi*
Universitas Indonesia

Research about study on pollen morphology of Asteraceae family at Campus Universitas Indonesia, Depok conducted during October until December 2015. Eighteen species from 18 genus and 9 tribes was found and used in the research. Pollen of 14 species from 8 tribe has successfully isolated by acetolysis method. Pollen was categorized by some characters such as polarity, symmetry, pollen grains compound, shape, surface, aperture, pore shape, and size. The result from pollen analysis shows that Asteraceae has pollen with isopolar polarity, radial isopolar symmetry, monad grain, spheroidal shape on polar and equator, echinate surface, tricolporate, tetracolporate, and fenestrate aperture, circular and rectangular pore, and has medium until big size pollen. The polarity, symmetry, pollen grains compound, shape, and pollen surface characters can be used as differentiating features between Asteraceae and other families. Aperture character can be a differentiating feature between tribe in one family. Pore shape and size of pollen could not be a character to differentiate between tribes, but maybe can be used to differentiate the taxa below the tribes. Results of this study can become a reference on the regrouping of taxa especially in Asteraceae family.

Impact of horizontal gene transfer in the early evolution of plants.

Qia Wang[1], *Hang Sun*[1], *Jinling Huang*[1,2]
1. Kunming Institute of Botany, Chinese Academy of Sciences
2. East Carolina University

Horizontal gene transfer (HGT) refers to the movement of genetic information across normal mating barriers between more or less distantly related organisms. HGT allows recipient organisms to circumvent the slow process of ab initio gene creation and thereby accelerates genome innovation and evolution. In order to further understand the scale and evolutionary significance of HGT in multicellular eukaryotes, particularly in Plantae, we detected horizontally acquired genes in the genome of *Selaginella moellendorffii* and *Klebsormidium flaccidum* based on genome screening and phylogenetic analyses. Our study indicate that multiple gene families in *Selaginella moellendorffii* and *Klebsormidium flaccidum* were horizontally acquired from bacteria, archaea, viruses or fungi. Some of these acquired genes are involved in important processes of plant development and adaptation, such as Carbohydrate metabolism, hormone signaling, and response to stresses. These findings suggest that HGT might have facilitated the adaptation of plants to terrestrial environments and the expansion of their ecological niches.

Progress in study on early seed plants from China

Deming Wang
Peking University

The earliest seed plants have been mainly recorded from the Upper Devonian of Euramerica. South China is one of the centers for evolutionary radiation of early vascular plants but has lacked evidence in Devonian seeds. Our recent years' work in South China results in some knowledge of earliest seed plants: 1) We found the earliest seed in China and East Asia-*Cosmosperma*, thus expanding the geographic distribution of early seed plants. 2) *Latisemenia* bears cupulate ovules that are terminal as well as opposite on the fertile axis. It is the earliest plant with lateral ovules and may foreshadow the diverse ovule arrangements found among younger seed plant lineages. Following the telome theory, *Latisemenia* demonstrates derived features in both ovules and cupules. 3) Famennian synangia, especially *Placotheca*, do not support the current understanding that the earliest pollen organs closely resembled the fructifications of the ancestral progymnosperms. *Placotheca* is highly derived and indicates earlier diversification of pollen organs than previously expected. In contrast, the prepollen remained primitively spore-like. 4) Beyond Euramerica, we found the well preserved anatomy of earliest seed plants-*Yiduxylon*. This taxon suggests the transitional features between the early seed plants and their ancestral aneurophyte progymnosperms.

Hypoxis L. (Hypoxidaceae): Molecular systematics of the genus and related genera

Sanele Shiba*, Michelle Van Der Bank*
University of Johannesburg

The family Hypoxidaceae within the 'asteloid' clade of the monophyletic order Asparagales is represented by 10 genera. Of these, four are endemic to southern Africa and remain poorly studied, lacking molecular data. This is especially true for *Hypoxis* the largest genus in the family with about 90 species. The popularity of *Hypoxis* as an alternative remedy has resulted in unsustainable harvesting practices of rhizomes from the wild. This exploitation of target and related species has accelerated the need for correct species names. However, species delimitation in *Hypoxis* is problematic and despite several attempts, the systematics of the genus remains largely unresolved. This is mainly due to the lack of distinct morphological boundaries separating species. Therefore, in this study phylogenetic relationships within Hypoxidaceae, with an emphasis on *Hypoxis*, were reconstructed using four plastid DNA regions (*rbc*L*a*, *trn*L-F, *ycf1*, and *trn*S-G) for 90 taxa. Data were analysed using Maximum Parsimony and Bayesian methods. Findings from our study indicate that *Hypoxis* is not monophyletic and is represented by at least three lineages scattered throughout the family. Preliminary results of the phylogenetic analyses will be presented.

Comparative analysis of transcriptomes in Rhizophoraceae provides insights into the origin and adaptive evolution of mangrove plants in intertidal environments

Wuxia Guo[1]*, Haidan Wu*[1]*, Zhang Zhang*[1]*, Chao Yang*[2]*, Ling Hu*[1]*, Xianggang Shi*[1]*, Shuguang Jian*[3]*, Suhua Shi*[1]*, Yelin Huang*[1]
1. School of Life Sciences, Sun Yat-sen University
2. Department of Neurosurgery, First Affiliated Hospital of Sun Yat-sen University
3. South China Botanical Garden, Chinese Academy of Sciences

Mangroves are woody plants that grow in tropical and subtropical intertidal zones, where they exist in extreme environments of high salinity, extreme tides, strong winds, high temperatures, and muddy, anaerobic soils. As a key mangrove family, Rhizophoraceae has developed several morphological and physiological adaptations to these extreme conditions, representing an ideal system for the study of the origin and adaptive evolution of mangrove plants. In this study, we characterized and comprehensively compared the transcriptomes of four mangrove species, from all four mangrove genera, and a terrestrial relative in Rhizophoraceae, using RNA-Seq. We obtained 41,936–48,845 unigenes with 61.42–69.48% annotated for the five species in Rhizophoraceae. Orthology annotations of Gene Ontology, Kyoto Encyclopedia of Genes and Genomes, and Clusters of Orthologous Groups revealed overall similarities in the transcriptome profiles among the five species, whereas enrichment analysis identified remarkable genomic characteristics (e.g., overrepresentation of genes related to stress response and embryo development) that are conserved across the four mangrove species compared with their terrestrial relative, probably reflecting mangrove-specific gene components that are essential for their adaptation. Based on 1,816 identified orthologs, phylogeny analysis and divergence time estimation revealed a single origin for mangrove species in Rhizophoraceae, which diverged from the terrestrial lineage approximately 56.4 million years ago (Mya), suggesting that the transgression during the Paleocene–Eocene Thermal Maximum may have been responsible for the entry of the mangrove lineage of Rhizophoraceae into intertidal environments. Evidence showed that the ancestor of Rhizophoraceae may have experienced a whole genome duplication event approximately 74.6 Mya, which may have increased the adaptability and survival chances of Rhizophoraceae during the Cretaceous–Tertiary extinction through providing extra genomic materials for selection. The analysis of positive selection identified 10 positively selected genes from the ancestor branch of Rhizophoraceae mangroves, which were mainly associated with stress response, embryo development and regulation of gene expression. Positive selection of these genes may be crucial for increasing the capability of stress tolerance (i.e., defense against salt and oxidative stress) and development of adaptive traits (i.e., vivipary) of Rhizophoraceae mangroves, and thus plays an important role in their adaptation to the stressful intertidal environments.

Hybridisation and polyploid evolution in whitebeams

Rosalia Piñeiro*, Tim Rich, Mike Fay*
Royal Botanic Gardens, Kew

In this project we investigate how polyploid evolution occurs in nature. This topic is understudied due to the limitations of Sanger technology. However, the emergence of Next Generation Sequencing (NGS) opens exciting opportunities to study complex genomes in non-model plants. British whitebeams (*Sorbus aria* aggr., Rosaceae) are an emblematic case study of ongoing polyploid evolution in natural tree populations. SW Britain is a worldwide 'polyploid hotspot' for the genus. Only in this area, thirty highly endemic polyploid taxa occur. Three widespread species (the sexual diploid *S. aria* and the polyploid species *S. rupicola*, and *S. porrigentiformis*) have been postulated as the potential parents of most of these high endemics. Using cutting-edge DNA technology (RADseq makers and 25 NGS-sequenced nuclear microsatellites) and ploidy level measurements we have estimated the genetic diversity, compared populations sympatric and allopatric to the polyploid zone, and traced the origin of 500 trees across Britain. Conservation policies have traditionally focused on the preservation of the local endemic polyploids. However, a deep understanding of the evolution of the complex may allow preserving the polyploidisation process by protecting the parental species, even if they are widely distributed.

A545

Evolutionary history of *Vitis* based on genotyping-by-sequencing data

Laura Klein
Saint Louis University

As concerns mount about sustainable agriculture in a changing climate, attention is focusing on understanding diversity and diversification in crop wild relatives. The domesticated European grapevine (*Vitis vinifera*) is among the most economically important berry crops in the world and is becoming an increasingly valuable component of rural agricultural development. In many areas of North America and around the world, grapevine cultivation includes not only *V. vinifera* but also abiotic and biotic stress resistant native North American *Vitis* species, which, aside from being grown outright, contribute to hybrid scions and rootstocks. Despite this, relatively little is known about geographic patterns of variation among natural *Vitis* populations or the evolutionary processes shaping them. The evolutionary history of the grapevine genus has been notoriously challenging, in part due to likely rampant hybridization of sympatric species. Within subgenus *Vitis*, a large North Temperate group that includes ~50 *Vitis* taxa (~18 in North America), it appears that most species are interfertile. In North America it is common for two, three, or up to five *Vitis* species to grow in sympatry, further increasing the likelihood of interspecific hybridization. In this study, we leveraged living germplasm collections maintained by the United States Department of Agriculture Agricultural Research Service (USDA-ARS) Grape Genetics Research Unit (Geneva, NY) and National Clonal Germplasm Repository (Davis, CA) to investigate relationships among *Vitis* species. Single nucleotide polymorphisms (SNP) were identified using genotyping-by-sequencing. After sequencing and filtering we generated a dataset of 358 individuals representing 17 *Vitis* species (12 from North America, the European *V. vinifera*, and four Asian species) and three *Ampelopsis* species. Individuals were genotyped at approximately 11,000 sites with a minimum mean depth of coverage of 10. To infer phylogeny, we used the Geneious Tree Builder software and the RaxML plugin with the GTRCAT model and rapid bootstrapping. Preliminary results provide support for previously recognized groups including 1) monophyletic *Vitis*; 2) monophyletic subgenus *Vitis*; 3) within subgenus *Vitis*, a monophyletic group of Eurasian species. In addition, these data suggest close relationships between *V. acerifolia, V. arizonica, V. riparia* and *V. rupestris*, and close relationships between *V. cinerea, V. palmata,* and *V. vulpina*. In some cases, sampled individuals from a single species did not cluster together in these analyses. This could represent misidentification within the USDA system; alternatively (or in addition), it is likely that interspecific hybridization is contributing to reticulate patterns of evolution within the genus *Vitis*. Future areas of work should include detailed population level sampling, and morphological and genetic analyses of *Vitis* populations where multiple species occur in sympatry as well as in regions where each of the species occur in isolation.

Effect of habitat heterogeneity on reproductive characters in distylous species *Primula nivalis*

Aysajan Abdusalam[1,2], *Qingjun Li*[1]
1. Key Laboratory of Tropical Forest Ecology, Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Menglun Town, China
2. Key Laboratory of Ecology and Biological Resources in Yarkand Oasis, College of Biology and Geography Sciences, Kashgar University, Kasghar, China

Distylous plant is a special group of angiosperm which has reciprocal stigma and anthers high within a species. Comparative investigations of breeding system of distylous species on different elevation can be revealing the relationship between distylous plant evolution and their environments. *Primula nivalis* is a native primrose in Xinjiang, NW China, it has significant differences in plant size and seed set ratio in the populations at different elevation. In order to investigate the comparative effect of habitat heterogeneity on frequency of morphs in different populations, morphological characters of flowers, pollination characteristics, mating patterns, offspring fitness and inbreeding depression of plants were quantified at different elevation habitats in this research. The study results will clarify the reproductive strategies and adaptation mechanisms of *P. nivalis* at different elevational environments. The investigations on effect of heterogeneous habitats on *P. nivals* floral phenotype suggested that frequency of LS flower in high elevation grassland population was higher than SS flower. The floral morphological characters of LS flower among populations in different ecological conditions were significant different. The length of corolla tube and stamen, and stamen-stigma spatial distance of LS flowers were different in high elevation grassland population. This revealed that variation of LS floral characters at different population decreased the relative herkogamy level of both morph flowers sexual organs in high elevation grassland populations. Floral traits (corolla tube length, anther-stigma separation) and pollinator activities were significantly correlated with altitude both in the LS and SS individuals. Efficiency of long tongue pollinators was higher than that of short tongue pollinators, and pollination efficiency on the SS flower was lower than that on the LS. The selfing rate of the LS flower was higher than the SS flower, but pollen limitation of the LS flower was lower than that of the SS flower. Selfing and pollen limitation were correlated with anther-stigma separation, suggesting that elevation changes in stigma-anther separation evolved before self-compatibility of LS flower. Fruit set of SS flower was lower than that of LS morph at different elevation populations. Seeds from cross-pollinated flowers had higher quality than those from self-pollinated and natural pollinated flowers. *P. nivalis* seeds have a certain degree of physiological dormancy. Temperature and light conditions significantly influence the germination of seeds. Seeds from LS have higher germination rates than those of SS morphs on three different treatments. Fitness of seeds (seed germination) from cross-pollinated flowers was higher than that of seeds from natural and self-pollinated flowers of both morphs. Fitness for seeds from LS morphs was higher than that of seeds from SS in each elevation. Seed germination level inbreeding depression was increased for SS flower with the increase of elevation, but it did not differ significantly for LS flowers with increased elevation.

Structural and dynamic characteristics of *Eremurus anisopterus* populations in areas with different levels of disturbance

Jing An, *Ling Wu, Shaoming Wang, Xia Zhang, Chaoliang Jiang, Xiang Zhao, Zhiyong Zhang*
Shihezi University

Eremurus anisopterus (Liliaceae) is a perennial ephemeral geophyte herb. In China, *E. anisopterus* grows on fixed and semi-fixed sand dunes of the Gurbantunggut Desert of Xinjiang Uyghur Autonomous Region. This kind of ephemeral plant contributes greatly to the stabilization of sand. But increasing human activity has fragmented the primary habitat of the *E. anisopterus* population in the southern Gurbantunggut Desert, resulting in numerous separate population patches. And the frequent human activities, including engineering, reclamation of waste land, industrial discharge and over grazing, severely influence the survival and reproduction of ephemeral plants, more and more ephemeral plants are dying out. The goal of our study was to determine the current survival rates of *E. anisopterus* populations in different patches. Therefore, we surveyed 19 plots and analyzed age structure, constructed a time-specific life table, produced survivorship and mortality curves, as well as survival analysis function curves. Our results indicated that because of the various levels of human disturbance and habitat fragmentation, population dynamics of *E. anisopterus* in the 19 plots exhibited different structural features and trends. The age structure of *E. anisopterus* populations differed among the plots. The age classes within the populations were incomplete, and this phenomenon occurred more frequently in the plots in highly fragmented areas. The age structure of the b-type and c-type patches, based on the degree of fragmentation and human disturbance, exhibited a stable to declining growth trend. Population structure of the a-type patches in the most disturbed areas exhibited greater instability, with the population at higher risk of decline. The a-type population exhibited stability in the early and populations, declines in the early phase and stability in the intermediate and later phases occurred, whereas the c-type populations were stable. Therefore, it is critical to decrease or halt external disturbances in areas subjected to the greatest levels of human intermediate phases according to the survivorship curve, and in the early, intermediate, and later phases according to the survival analysis function curve. The plant population structure is the common result of the survivability of individuals and the impact of environmental conditions, and may also provide important information on the past and present regeneration of species. So the decline in *E. Anisopterus* populations likely resulted from habitat loss in the later phase. For the b-type disturbance. Studies should examine the effects of different combinations of disturbance factors on population status in different habitats to formulate scientific and practical protection and recovery strategies.

On-line determination of ammonia concentration and deposition at three research platforms with contrasting landscapes

Yunhua Chang[1], *Jianlin Shen*[2], *Yanlin Zhang*[1]
1. Nanjing University of Information Science and Technology
2. Institute of Subtropical Agriculture, Chinese Academy of Sciences

Ammonia (NH_3) is among the most important species in terms of forming secondary inorganic aerosols and enhancing environmental nitrogen input. High time-resolution monitoring of ambient ammonia and landscape-specified consideration of deposition parameters are in urgent need of capturing the sources and processes governing short-term fluctuations of ammonia concentrations, and accurately assessing the magnitude of ammonia deposition and its detrimental effects on various ecosystems. To this end, hourly continuous observation of ammonia and a full suit of auxiliary factors were simultaneously performed at three regional research platforms, covering urban (Pudong or PD site), rural (Qingpu site), and natural (Dongping National Forest Park in Chongming island or CM site) settings in Eastern China since 2014. This ongoing project is part of the Networking Evaluation of Ammonia in China (NEAChina) program, aiming to systematically elucidate the sources, transport, and fate of atmospheric ammonia across China, with a particular interest in non-agricultural ammonia emissions over the city clusters of the Yangtze River delta region. Here we reported our on-line measurement of ammonia concentrations at these three locations with contrasting landscapes between April 2014 and May 2016 and calculated ammonia deposition fluxes using a well-tested bi-directional ammonia exchange model with empirical parameters.

A new gene *B1L* regulates cold tolerance and delays flowering time in *Arabidopsis*

Tao Chen
Lanzhou University, Lanzhou, China

The process from vegetative growth to reproductive growth is pretty crucial for plants normal development and progeny reproduction. Instead of moving away like animals, plants suffer fluctuant ambient stimuli and change their development process to adapt different environmental conditions. In *Arabidopsis*, we identified *B1L*, a novel gene, was involved in cold stress pathway and flowering determination. *BIL* T-DNA inserted mutant (*b1l*) was sensitive to freezing treatment, and B1L-overexpressing transgenic plants could increase the tolerance. *b1l* plants also had an early flowering phenotype, which was restored by introducing into *B1L* sequence with its own promoter, and *B1L*-overexpressing transgenic lines delayed flowering time. It means that *B1L* positively regulates freezing tolerance and delays flowering time. To elucidate the mechanism underlying the cold response of *B1L,* we measured the expression pattern of *B1L* under low temperature. The expression of *B1L* was initially (after 1 hour) induced after treated with cold stress (4°C). GUS staining of *B1L::GUS* transgenic plants were turned more deepened after cold treatment

(4°C, 6 h), which is consistent with Q-PCR result. We tested the expression of C-repeat (CRT)-binding factors (CBFs) pathway genes which play important roles in cold stress, and found that the expression of these genes were reduced in *B1L* mutants, but increased in *B1L*-overexpressing transgenic plants. To explore how *B1L* functions in the cold resistance and flowering determination, we used yeast two hybrid system (Y2H) to screen for *B1L*-interacting proteins, and used BiFC to confirm it. GRF is one of the proteins that interacts with *B1L*, and belongs to a protein family related with many biological processes, such as plant development, biotic stress and abiotic stress. As GRF proteins usually bind to phosphorylated proteins, we then tested whether *B1L* had any phosphorylated sites that affected the interaction. A potential phosphorylated site in serine 213 was identified by bioinformatics analysis and was mutated to alanine ($B1L^{S213A}$) and phenylalanine ($B1L^{S213D}$), respectively, to mimic the nonphorylation and autophosphorylation of *B1L*. $B1L^{S213A}$ did not abolish GRF binding, but the interaction of $B1L^{S213D}$ and GRF was much stronger than any other groups. Also, we found that N-terminal of *B1L* which contains serine 213 was enough for the interaction with GRF. It reveals that Serine 213 in N-terminal of *B1L* may plays an important role for the interaction between *B1L* and GRF. *GRF/B1L* double mutations restored early-flowering of *B1L*, but not cold sensitivity, which demonstrates that the function of *B1L* in regulating flowering time requires GRF. All these data indicate that *B1L* participates in plants freezing resistance by regulates the expression of cold-regulated genes in the CBF pathway and also represses flowering in *Arabidopsis thaliana*, and GRF plays an important role for *B1L* function.

Community structure and species diversity of *Loropetalum subcordatum* in Maolan National Nature Reserve

Xiaoxi Chen, *Jiuxiang Huang*

South China Agricultural University

In order to provide a scientific basis to protection, ex-situ conservation and near natural-forest construction for the natural forest community of *Loropetalum subcordatum* which was rare and endangered. Community structure and species diversity of *Loropetalum subcordatum* in Maolan National Nature Reserve, Guizhou were studied by plot method. There are 142 species belongs to 60 families and 104 genera in the 4 plots with an area of 400 m^2. The dominant families were Lauraceae, Theaceae, Moraceae, Euphorbiaceae and Rubiaceae. Among them, the tropical distribution elements at genus level for 72%, and then 27% for temperate distribution elements. Species diversity results showed that there was the highest species richness in shrub layer, and the lowest one in herbal layer; Species diversity and evenness were highest in shrub layer, and the lowest one in tree layer; *Loropetalum subcordatum* population in Maolan National Nature Reserve was lack of seedling and the natural regeneration was difficult, indicating that it was a declining population. The age structure states clearly that the amount of *Loropetalum subcordatum* seedling is scarce, *Loropetalum subcordatum* may be replace by other species and became extinct; Which is urgently required for the consercation and utilization by strengthening in situ conservation, population reconstruction, propaganda and education.

Preference for ammonium and nitrate by four plant species during different growth stages

Jihan Cui, *Shunguo Li, Xueyan Xia, Yu Zhao, Meng Liu, Shijia Song*

Institude of Millet Crops, Hebei Academy of Agricultrual and Forestry Sciences

Uptake of ammonium and nitrate by plants at different growth stages was investigated by using four crop species (i.e., forage oat, alfalfa, common vetch and highland barley), which were commonly cultivated in the Tibetan farmlands. Plant uptake of $^{15}NH_4^+$ and $^{15}NO_3^-$ were studied by injecting dilute (1.66 mmol ^{15}N in 10 ml distilled water) solutions of respectively labeled N source into the pots and harvesting plants 24 h later. Measurements of ^{15}N in plants showed that the investigated plant species or functional groups differ in their N uptake patterns. The legumes plants showed a preference for NO_3^- at all three growth stages. By comparison, the grasses plants showed a preference for NH_4^+ at the early growth stages, and shifted its preference for NO_3^- at the later growth stages. It suggests that plant functional groups affect N uptake by plants. In spite of the controlling of two plant functional groups on N preference, it is particularly worth mentioning that N preference by both of two plant functional groups lie on the dominant N source in soil to meet their N demands, which was derived by the close relations between ratios of NH_4^+:NO_3^- uptake by plant and ratios of NH_4^+:NO_3^- in soil in the current study. Nitrogen utilization efficiency (NUE) had a close relation with ratios of NH_4^+:NO_3^- uptake which strongly depending on plant functional groups: the NUE were increased linearly with increasing ratios of NH_4^+:NO_3^- uptake in grasses plants, however, the NUE were decreased linearly with increasing ratios of NH_4^+:NO_3^- uptake in legumes plants. This confirms that uptake of N form (NH_4^+ vs. NO_3^-) has effects on plant NUE. The relations were varied by different plant functional groups because plant functional types can modify soil N cycle by absorbing and utilizing the N sources in air and soil. Study and explanation of these relations among preference for N, ratios of NH_4^+:NO_3^- and plant NUE are much ecological significance for plant adaptation mechanism of the deficiency of N in the environment, and the inherent mechanism still needs further research.

A211

Reproductive biology of *Trichocereus bridgesii* (Cactaceae) an endemic cacti from dry valleys (La Paz-Bolivia)

Mariela Escobar-Torrez

Herbario Nacional de Bolivia

In recent years it has been suggested that exist a geographic dichotomy in pollination system for columnar cacti. In extratropical regions the columnar cacti show more open and generalized pollination system, meanwhile, in tropical regions columnar cacti tend to have specialized pollination system. As pollination data for South America are scarce, the aim of this study was to analyze the reproductive biology of *Trichocereus bridgesii* an endemic cactus in Ananta a dry valley located in La Paz (Bolivia). An exclusion experiment was conducted to measure the breeding systems, and the relative contribution of nocturnal and diurnal floral visitors to fruit set and seed set, also, I observe the floral visitors, their frequencies and behaviors. In addition I evaluated if *T. bridgesii* has a specialized pollination system or generalized pollination system. The experiment revealed that *Trichocereus bridgesii* exhibits a complementary general pollination system demonstrating that both pollination groups (diurnal and nocturnal) were important for plant reproduction. The importance of floral visitors on the breeding system indicates an obligate xenogamous system, self-incompatible. Seeds produced in the experimental treatments: control, xenogamy and obligate xenogamy were viable, except for the treatment of geitonogamy. During the day native bees (*Ischnomelissa* sp.*, Habralictus* sp.) and the introduced *Apis mellifera* were the most frequent visitors and during the night Nitidulidae beetles, moths or bats were not registered. *T. bridgesii* shows more affinity with columnar cacti from extratropical regions than with those from tropical regions, these results demonstrated that as latitude increases in tropical regions of South America, cactaceae have a generalist pollination system. Therefore, I recommend to carry out comparative studies from cacti species located within and outside the tropics according to variations in their geographic distribution. It is expected that in very isolated fragments of vegetation, two possible consequences are generated: 1) existence of specialized pollination systems when the main pollinator is abundant and 2) existence of generalized pollination systems when the main pollinator is scarce, in this case comparative studies in disturbed and conserved areas are recommended.

A212

Ecological stoichiometric in litter and soil under forest gap of *Castanopsis kawakamii* natural forests

Xueping Feng[1,2,3], *Jinfu Liu*[1,2,3], *Buajan Supaporn*[1,2,3], *Zhongsheng He*[1,2,3]

1. Fujian Agriculture and Forestry University

2. Cross-strait Nature Research Center

3. .Key Laboratory of Fujian Universities for Ecology and Resource Statistics

Ecological stoichiometry of the carbon (C), nitrogen (N), phosphorus (P), and potassium (K) in litter and soil are great significance to research the rule which was nutrient cycling of the forest ecosystem. The aims of this study is to study the ecological stoichiometry of C, N, P, and K ratios in litter and soil of different forest gap sizes using the Redundancry Analysis method (RDA). The results showed that the contents and stoichiometric ratios of C, N, P, and K in litter were significant difference between gap sizes and relevance in *Castanopsis kawakamii* natural forest. Values of the N:P ratio of 16 usually indicated the growth of plant was limited by N and P. Values of the N:P ratio was higher than 16 in small and non-gaps, indicating that the growth of plants was limited by P. Values of the N:P ratio is between the 14 and 16 in medium gaps, indicating that the growth of plants was limited by N and P. Values of the N:P ratio is lower than 14 in large gaps, indicating that the growth of plants was limited by N. We can fertilize some N and P that could promote the plant growth in gaps. The results from this study provide the knowledge of the nutrient status, which an evidence for sustainable management in *C. kawakamii* forest.

A213

A primary inquiry on the microRNA of *Caragana korshinskii* along a precipitation gradient on the Loess Plateau, China

Chunmei Gong*, Sun Yingying, Zhou Wenfei*

College of Life Science, Northwest A&F University

There are some adverse effects on the survival and growth of plants due to drought. *Caragana korshinskii* is widely distributed on the Loess Plateau, China. *C. korshinskii* has excellent soil and water conservation capacity because of its drought resistance. However, it is not clear about the stress response mechanisms of *C. korshinskii* in waterless environments. MicroRNAs have been implicated in the regulation of plant responses to several types of biotic and abiotic stress. Here, we describe the miRNAs of wild *C. korshinskii* from Huangling, Yulin, and Dalad Banner, which distributed across a precipitation gradient on the Loess Plateau. Using RNA-sequencing technology and BLAST analysis, nearly 500 conserved miRNAs and about 100 novel miRNAs were characterized from the sRNAome data, with key functions determined using Gene Ontology and Kyoto Encyclopedia of Genes and Genomes pathway analyses. Then we designed stem-loop RT-qPCR to validate the expression patterns of several conserved miRNAs that obviously responded to water stress in plants grown under natural conditions with drought aggravated and found that the expression levels of miRNA were negatively correlated with their predicted target genes. This study supplied a view of miRNA may mediated gene expression to strengthen the stress responses in wild *C. korshinskii* with decreasing precipitation.

High phenotypic plasticity does not imply high salt stress tolerance: A case study of two pioneer species from the Yellow River Delta

Xiao Guo[1,2], *Xiao-Huang Ren*[2], *Franziska Eller*[3], *Ming-Yan Li*[2], *Ren-Qing Wang*[2], *Ning Du*[2], *Wei-Hua Guo*[2]

1. Qingdao Agricultural University

2. Shandong University

3. Aarhus University

A greenhouse experiment was conducted in which two leguminous species commonly used in the Yellow River Delta for vegetation restoration, *Robinia pseudoacacia* and *Amorpha fruticosa*, were subjected to the five salt treatments: 0, 50, 100, 150 and 200 mmol L^{-1}. We aimed at investigating which of the two species would be better suited for growth in a saline environment, and whether the acclimation capacity to salinity resulted from an inherently higher phenotypic plasticity of the species. The results showed that salinity affected most growth parameters and biomass parameters but had no effects on most leaf traits and physiological parameters of the two species. Height, relative growth rate of crown area, root biomass and leaf mass ratio of *R. pseudoacacia* were reduced by higher salinity while *A. fruticosa* was not affected. Chlorophyll a to chlorophyll b ratio and total antioxidative capacity of *A. fruti-*

cosa increased with higher salinity while those of *R. pseudoacacia* remained unchanged. Root mass ratio and vitamin C concentration of both species were not affected by salinity, whereas vitamin C concentration of *A. fruticosa* overall was higher than that of *R. pseudoacacia*. Methane dicarboxylic aldehyde concentration of *R. pseudoacacia* increased with the increase of salinity while that of *A. fruticosa* was not affected. Root to shoot ratio of *A. fruticosa* was higher than of *R. pseudoacacia* at most salt treatments. Of all leaf traits, only leaf area differed among the different salinities. *Robinia pseudoacacia* generally exhibited a greater plasticity than *A. fruticosa* in response to salinity, but *A. fruticosa* was more resistant to the higher salinities, compared to *R. pseudoacacia*, and is thus a better candidate for vegetation restoration in saline areas.

A215

Evaluation of ten Chenopodiaceae species from the Tarim Basin for tolerance to salt and drought stress during seed germination

Zhan-Jiang Han, Long Cheng, ***Zhijun Li***

College of Life Science, Xinjiang Production and Construction Corps Key Laboratory of Protection and Utilization of Biological Resources in Tarim Basin, Tarim University

Seeds of ten species with wide distribution and of feed and medicinal value were subjected to salt and drought stress by germinating them on a substrate enriched with NaCl, $NaHCO_3$ or PEG6000. Final germination (G_F) and radicle length were reduced for all species, and mean germination time (MGT) was extended to varying degrees as concentrations of NaCl and $NaHCO_3$ increased. Once stress was withdrawn, seeds of *Suaeda rigida*, *Halocnemum strobilaceum*, *Halostachys caspica* and *Salicornia europaea* germinated irrespective of whether the source of stress had been NaCl or $NaHCO_3$ whereas those of *Suaeda glauca* and *S. heterophylla* were able to germinate when the source of stress had been NaCl. The G_F and radicle length of seeds of were inhibited while MGT extended continuously in various degrees with osmotic potentials descending and drought intensifying in ten species. Seeds of *Suaeda glaeda*, *S. rigida*, *S. heterophylla*, *Halocnermum strobilaceum*, *Halostachys caspica*, *Salicornia europaea* and *Halogeton arachnoideus* obtained their germination recoveries after relieving drought stress. Degree of salt or drought tolerance during germination was evaluated comprehensively through subordinate function analysis, G_F, MGT, radicle length and recovery. Overall ranking of species in descending order of tolerance to NaCl was as follows: *Halocnemum strobilaceum*, *Suaeda rigida*, *Halostachys caspica*, *S. arcuata*, *Halogeton arachnoides*, *Salicornia europaea*, *Suaeda heterophylla*, *S. glaeda*, *Chenopodium aristatum* and *S. stellatiflora*; the ranking for tolerance to $NaHCO_3$ was *Halocnemum strobilaceum*, *Halogeton arachnoides*, *Halostachys caspica*, *Suaeda rigida*, *S. arcuata*, *Salicornia europaea*, *Suaeda heterophylla*, *S. glauca*, *Chenopodium aristatum* and *S. stellatiflora*; the ranking for tolerance to drought was *Halostachys caspica*, *Halogeton arachnoideus*, *Halocnermum strobilaceum*, *Suaeda rigida*, *S. heterophylla*, *S. glaeda*, *Salicornia europaea*, *Suaeda stellatiflora*, *Chenopodium aristatum* and *S. arcuata*. The top four plants can be used for soil improvement or gene mining.

A216

Germination response of four alien congeneric *Amaranthus* species to environmental factors

Jian-Hua Hao

Changshu Institute of Technology

Seed germination is the key step for successful establishment, growth and further expansion of population especially for alien plants with annual life cycle. Traits like better adaptability and germination response were thought to be associated with plant invasion. However, there are not enough empirical studies correlating adaptation to environmental factors with germination response of alien invasive plants. In this study, we conducted congeneric comparisons of germination response to different environmental factors such as light, pH, NaCl, osmotic and soil burials among four alien amaranths that differ in invasiveness and have sympatric distribution in Jiangsu Province, China. The data were used to create three-parameter sigmoid and exponential decay models, which were fitted to cumulative germination and emergence curves. The results showed higher maximum Germination (*Gmax*), shorter time for 50% germination (*G50*) and the rapid slope (*Grate*) for *Amaranthus blitum* (low-invasive) and *A.retroflexus* (high-invasive) compare to intermediately invasive *A. spinosus* and *A. viridis* in all experimental regimes. It indicated that germination potential does not necessarily constitute a trait that can efficiently distinguish highly invasive and low invasive congeners in four *Amaranthus* species. However, it was showed that the germination performances of four amaranth species were more or less correlated with their worldwide distribution area. Therefore, the germination performance can be used as a reference indicator, but not an absolute trait for invasiveness. Our results also confirmed that superior germination performance in wide environmental conditions supplementing high seed productivity in highly invasive *A. retroflexus* might be one of the reasons for its prolific growth and wide distribution. These findings lay the foundation to develop more efficient weed management practice like deep burial of seeds by turning over soil and use of tillage agriculture to control these invasive weed species.

A217

Sex-related differences in adaptability to manganese stress in *Populus cathayana* when supplied with different nitrogen forms

Hongxia Zhao

Institute of Mountain Hazards and Environment, Chinese Academy of Sciences

Populus cathayana was employed as a model species to detect sexual differences in plant growth, physiological, biochemical, and ultrastructural responses to manganese (Mn) stress with two different nitrogen sources (NH_4^+ and NO_3^-). Results showed that both NH_4^+-N and NO_3^--N supply forms significantly increased plant growth, gas exchange capacity, SOD and POD enzyme activities in the leaves of both male and female *P. cathayana*. On the other hand, we found that NH_4^+-N supply could improve tolerance to Mn stress in both male and female *P. cathayana* with higher photosynthetic capabilities, biomass accumulation, antioxidant enzyme activities, superoxide radicals (O_2^-) and thiobarbituric acid-reactive substances (TBARS) contents in leaves than the individuals of both sexes under Mn stress. Conversely, female individuals grown under NO_3^- supply exhibited significant lower biomass accumulation, photosynthetic capabilities, antioxidant enzyme activities, which were mainly due to higher Mn accumulation in both above and below ground organs, and also because of higher ROS releasing rate in leaves than did males under the same condition. Moreover, serve damage to cellular ultrastructure was also observed in the leaves of males and females exposed to Mn stress, but more strongly in females with more visible degradation of mitochondrion in plant leave cells. Therefore, the different preferences of male and female *P. cathayana* to Mn stress with different N sources can serve as an important fertilizing strategy for minimizing intraspecific competition between the two genders.

The relationships between above- and belowground biodiversity and ecosystem multifunctionality, and its drivers in the drylands of China

Jianming Deng, *Qiajun Du, Weigang Hu*
Lanzhou University

Biodiversity is the foundation for the maintenance of ecosystems, which are valued for their ability to provide multiple functions and services simultaneously (ecosystem multifunctionality; EMF). However, we have limited knowledge of the links between biodiversity and multifunctionality as well as drivers of these relationships in large-scale natural ecosystems. This gap in our understanding is particularly true for drylands, areas covering 41% of Earth's land surface and supporting over 38% of the global human population, which are among the most sensitive ecosystems to climate change. Here, we present a regional-scale field study conducted along natural aridity gradients across 157 dryland sites from northwestern China. We surveyed plant community by measuring 30 m × 30 m plots, characterized bacterial, archaeal and fungal communities in the soil surface (top 20 cm) by using Illumina Miseq profiling of ribosomal genes and internal transcribed spacer (ITS) markers, gathered a range of key abiotic factors (i.e. climate, elevation, and soil texture), and assessed 14 ecosystem function indicators (aboveground biomass, plant carbon, plant nitrogen, plant phosphorus, soil organic carbon, soil nitrogen, soil phosphorus, nitrate, ammonium, soil available phosphorus, β-glucosidase, urease, phosphatase, and soil microbial biomass) related to soil biogeochemical cycles, soil fertility, biological productivity, and the build-up of nutrient pools. In this study, we aim to elucidate the relationships between above- and belowground biodiversity and multifunctionality, and to illustrate the interactions among abiotic factors and biotic attributes (i.e. above- and belowground biodiversity) in driving multifunctionality. We also evaluate how increases in aridity, as defined by the aridity index, affect biotic attributes and multifunctionality, and further emphasize the role of biological feedbacks on the responses of ecosystem multifunctionality to increasing aridity. This knowledge is essential to predict responses of dryland ecosystems to ongoing global change, and guide conservation and sustainable management efforts in drylands of China.

Combined of multidimension scale - mininum area to study the function of water source conservation of the drinking water area, in Nanning City, China

Liangmei Huang
Guangxi Environmental Monitoring Center

With the multistatistical method, as well as the combined techniques of remote sensing interpretation and ecological landscape analysis, and using field work, water quality monitoring and some research outcomes, the function index of water source conservation, landscape patterns, and the mininum area of water maintainting quantities for the two types of drinking water area, namely river and reservoir, were calculated. Then the relationship among these indices were analyzed, and their data values extracted, so the mechanism between the structure and function of the drinking water area were discussed and discovered clearly. Results showed that: (1) the function of water source conservation of river ecosystem was genernallylow, and increased from 500 m buffer area to 5 km buffer area. The function of water source conservation of reservoir ecosystem was stronger than that of river; (2) the function index of water source conservation shown canonical quantitative relationship with the water resource quantitation, the pollution index, the ration of landscape area and patches numbers, buffer area, catchment area, forest area and pollution discharges; (3) for the current state, only can mininum area of forest ecosystem dominated by soft broad-leaved forest, oak forest, sclerophyllous evergreen broad-leaved forest, bamboo, maintaint the quantitative balance of protective area, catchment area, because of its effective function of water source conservation; (4)issues such as stability of ecological system, security of water quality, and risk of water resources on the drinking water area in Nanning city should be taken into account in the course of the environmental protection and management. Ecological recovery, environmental comprehensive regulation were nacessary to carried out in the following years.

Population genomic study of an introduced mangrove species *Sonneratia apetala* in China using high-throughput sequencing

Haidan Wu, *Hongxian Xie, Weixi Li, Sitan Qiao, Yubin Yan, Wuxia Guo, Yelin Huang*
State Key Laboratory of Biocontrol and Guangdong Provincial Key Laboratory of Plant Resources, School of Life Sciences, Sun Yat-sen University

Sonneratia apetala, a mangrove species, is naturally distributed in Bangladesh, Myanmar, and India, including the Andaman and Nicobar islands. The species was introduced to China in 1985 for restoration purposes from Sundarban in Bangladesh. However, the further use of the species is becoming increasingly controversial as there are emerging signs that it may become invasive in certain locations. Several attempts have been made to characterize genetic variation of *S. apetala* in China. But there are no studies comparing levels of genetic diversity in native vs. introduced populations. In this study, we tried to detect the dynamics of evolution in this species by comparing the genetic diversity of five *S. apetala* populations along the coast of China, and three populations from Sundarban using deep sequencing. The 40 nuclear loci were random chosen from an EST library which were assembled de novo based on 13.8 million paired-end sequence reads for the transcriptome of *S. apetala*. The pooled DNA samples from each of eight *S. apetala* populations were sequenced respectively. The results showed that values of θ in native populations were two times higher than those in introduced populations. The result of coalescent simulation also revealed a sever bottleneck effect during the introduction of *S. apetala*. However, the values of π, which is non-sensitive to low-frequency SNP, were slightly higher in native populations than those in introduced populations. Meanwhile, we founded the extreme high heterozygosity in six founder individuals which displayed similar genetic diversity with the five *S. apetala* populations along the coast of China. No sign of population expansion or contraction after the introduction were detected based on the 40 nuclear loci. These results indicated that the genetic diversity of *S. apetala* remains constant regardless of the nearly 30 years' introduction history in China. The long generation time, high heterozygosity in founder individuals and artificial planting may contribute to slowing down the loss of genetic diversity in introduced populations after a strong genetic bottleneck. We suggested the invasion potential of *S. apetala* should not be underestimated based on its population genetic characteristics, and the long-term ecological monitoring is still needed in order to avoid ecological disaster.

Responds of Songnen grassland soil respiration to doubling CO_2 concentration

Li Jiang, *Xuedun Niu*
Jilin Agricultural University

Long-term doubling CO_2 concentration affect grassland is crucial to predict the future impact of global climate change on terrestrial ecosystems. How the effects of global CO_2 concentration change on grassland productivity are going to be altered by changing the soil respiration. The response of soil respiration and soil organic matter to global change is one of the main factors that affect the carbon budget of terrestrial ecosystem. The sensitivity of soil respiration to temperature (Q_{10}), to a large extent, determines the feedback relationship between global climate change and carbon cycle. This paper simulated CO_2 concentration to 700 ppm. The influence of doubling CO_2 concentration of grassland to soil respiration and sensitivity of soil respiration were measured by LI-6400-09 processing system. Soil carbon content, soil nitrogen content and soil carbon and nitrogen ratio were determinate during 2006 to 2008.The results show that the doubling CO_2 concentration increased the soil respiration rate by 19.31% in three years, compared to the control. Doubling CO_2 concentration treatment increased the Songnen grassland temperature sensitivity by 30.1%, 40.3% and 36.3% in 2006, 2007 and 2008 respectively. The active soil C pool decomposed faster with doubling CO_2 concentration in 2007, while slowly cycling C pools had longer turnover times.

Research of the chemotaxis response of *Plutella xylostella* to the volatile components of *Lepidium sativum* L.

Shicui Jiang, *Jinhua Zhao, Donghao Li*
Key Laboratory of Natural Resources of Changbai Mountain & Functional Molecules (Yanbian University), Ministry of Education

Lepidium sativum L. is a kind of medicinal and edible plant that commonly found in Yanbian area. It is a cruciferous vegetable, yet rarely affected by pests. Previous studies have shown that *Lepidium sativum* L. exerts biological inhibitory effect on *Culex* species. In order to research deeper into the repellent effect of *Lepidium sativum* L. towards insects, a study on the chemotaxis response of *Plutella xylostella* to the volatile components of *Lepidium sativum* L. was conducted. In this study, the sterile samples of *Lepidium sativum* L. were obtained through tissue culture technique and then the real-time chemotaxis response of *Plutella xylostella* under different regulated circumstances (inoculum density, day-age and the induction time) were rapidly and accurately being analysed by GP-MSE/GC-MS. Different inoculum density had different chemotoxis response to *Lepidium sativum* L., and the varied induction time influenced the chemorepellent effect of volatile compounds in *Lepidium sativum* L. This study provides the basic data to evaluate the utilisation of *Lepidium sativum* L. as a form of biopesticide to repel *Plutella xylostella.*

The interactive effect of temperature and light on seed germination of 6 Zygophyllaceae species

Peipei Jiao[1], ***Zhijun Li***[1,2], *Xiao Zhang*[1]
1. Key Laboratory of Biological Resource Protection and Utilization of Tarim Basin, Xinjiang Production and Construction Group, Xinjiang, People's Republic of China
2. College of Life Sciences, Tarim University, Xinjiang, People's Republic of China

The interactive effect of temperature and light on seed germination of 6 Zygophyllaceae species, *Sarcozygiumspecies kaschgaricum* Boriss., *Sarcozygiumspecies xanthoxylon* Bunge, *Zygophyllum brachypterum, Zygophyllum rosovii, Zygophyllum obliquum, and Zygophyllum fabago* were studied under controlled environment conditions. Treatments included two light levels (8:16 h light:dark period and 24 h dark environment), two temperature regimes (fluctuating day : night temperature regimes of 15:5°C, 20:10°C, 25:15°C, 30:20°C and 35:25°C, and constant temperature regimes of 10°C to 30°C with 5°C interval), using a completely randomized block design. There was a higher final germination percentage, shorter mean time of germination and faster germination rate for 6 species in darkness condition than in 8 h photoperiod. 6 species germinated in a wide range of temperature, most of them germinated in all designed temperatures from 10 to 35°C, fluctuating and constant. The most optimal constant temperature regime for all species' germination was 20°C in 8 h:16 h light:dark period and 25°C in darkness, The most optimal fluctuating temperature regime for germination for all species was 30:20 ℃ both in 8 h light and full darkness. The different seed germination syndromes that we found for these Zygophyllaceae species likely contribute to variable seed bank formation and emergence patterns, and species coexistence. The results are consistent with 6 Zygophyllaceae species being a tropical xerophyte species capable of establishing itself in a wide range of environment conditions.

Influence of elevated CO_2 on rhizosphere microbial communities associated with mangrove plant *Kandelia obovata*

__Zhou Jin__, Yin Mengqing, Cai Zhonghua, Lin Guanghui

Division of Ocean Science and Technology, Graduate School at Shenzhen, Tsinghua University

Rhizosphere microbial communities mediate the decomposition of soil organic matter. The amount of carbon that is respired leaves the soil as CO_2 and causes one of the greatest fluxes in the global carbon cycle. How rhizosphere microbial communities will respond to global warming, however, is not well understood. Here, we characterized the effect of elevated CO_2 on soil microbial communities associated with a mangrove plant Kandelia obovata. Elevated CO_2 increased the soil C:N ratio and microbial biomass. 16s rRNA analysis revealed that elevated CO_2 did not affect the soil bacteria community structure. The results of principal component analysis (PCA) and Redundancy analysis (RDA) indicate that elevated CO_2 had no strict specificity with bacterial community diversity. Organic carbon, nitrate nitrogen (NO-N), C/N, total nitrogen (N) and pH were the primary impact factors. The elevated CO_2 increased microbial activity and carbon use, probably in response to increased root exudation. Elevated CO_2 did not affect microbial structure, nor did warming affect the abundances of most microbial groups. In summary, short-term high-CO_2 had no influence on microbial community composition (or rhizosphere Microbial Communities have buffer ability to response CO_2 increase) but increased microbial metabolic activity and hence reduced carbon use efficiency.

Liquid hybridization and solid phase detection: A highly sensitive and accurate strategy for microRNA detection in plants and animals

__Fosheng Li__[1], Lanju Mei[1], Cheng Zhan[1], Qiang Mao[2], Min Yao[1], Shenghua Wang[1], Lin Tang[1], Fang Chen[1,3]

1. Key Laboratory of Bio-resources and Eco-environment, Ministry of Education, College of Life Science, Sichuan University, Chengdu, Sichuan, China

2. Chengdu Botanical Garden, Chengdu, Sichuan, China

3. National and Local Joint Engineering Laboratory for Energy Plant Bio-Oil Production and Application, Chengdu, Sichuan, China

MicroRNAs (miRNAs) play important roles in nearly every aspect of biology, includingphysiological, biochemical, developmental and pathological processes. Therefore, a highly sensitiveand accurate method of detection of miRNAs has great potential in research on theory andapplication, such as the clinical approach to medicine, animal and plant production, as well as stress response. Here, we report a strategic method to detect miRNAs from multicellular organisms, which mainly includes liquid hybridization and solid phase detection (LHSPD); it has been verified in various species and is much more sensitive than traditional biotin-labeled Northern blots. By using this strategy and chemiluminescent detection with digoxigenin (DIG)-labeled or biotin-labeled oligonucleotide probes, as low as 0.01–0.25 fmol [for DIG-CDP Star (disodium2-chloro-5- (4-methoxyspiro{1,2-dioxetane-3,20-(50-chloro)tricyclo[3.3.1.13,7]decan}-4-yl)phenyl phosphate) system], 0.005–0.1 fmol (for biotin-CDP Star system), or 0.05–0.5 fmol (for biotin-luminol system) of miRNA can be detected and one-base difference can be distinguished between miRNA sequences. Moreover, LHSPD performed very well in the quantitative analysis of miRNAs, and the whole process can be completed within about 9 h. The strategy of LHSPD provides an effective solution for rapid, accurate, and sensitive detection and quantitative analysis of miRNAs in plants and animals.

Study on soil biological character of the degradation of *Populus simonii* Plantation in the Loess Plateau

Xiang Wang, __Jinchuan Li__, Jianying Yue, Chunyan Guo, Ning Lu, Juan Dong

Biology Institute of Shanxi

In order to elucidate the soil related factors of the formation of “dwarf and aged” tree, *Populus simonii* on the Loess Plateau and contrast of forest (*Robinia pseudoacacia*) were chosen as the test objects to study their soil nutrient, soil microbial characteristic and soil biological fertility. The results showed that: 1. Wither and fall layer thickness of *Populus simonii* plantation is less than CK, while field capacity, organic matter, total nitrogen, total phosphorus and available phosphorus were significantly lower than that of control; 2. Soil invertase, polyphenol oxidase, alkaline phosphatase of *Populus simonii* plantation is lower than that of the control, while urease and catalase activity were higher than that of control group; 3. The number of *Populus simonii* plantation of soil microorganism were bacteria > actinomycetes > azotobacter> denitrifying bacteria > fungi, the number of bacteria, fungi and denitrifying bacteria were higher than that of control. Furthermore, soil bacterial and fungal diversity of Pupulus simonii plantation were lower than that of control; 4. Principal component analysis and correlation analysis showed that soil nutrient and soil biological fertility of *Populus simonii* plantation were less than that of control, so the soil nutrient and soil biological fertility loss may lead to one of the important reasons about formation of “dwarf and aged” tree in the Loess Plateau.

Responses of productivity and species composition to elevated N deposition in alpine grassland of the Tianshan Mountains

Kaihui Li

Xinjiang Institute of Ecology and Geography, Chinese Academy of

Sciences,

Global climate change and increased nitrogen deposition are significantly altering plant primary productivity and species composition in terrestrial biomes. A 8-year field experiment with four N addition treatments was conducted in alpine grassland of the mid Tianshan mountains in China. Nitrogen addition significantly increased the aboveground biomass of dominant perennial grasses but decreased aboveground biomass of forbs. Low N addition could increase total primary under increasing temperature and growth season precipitation in alpine grassland, while mid and high N addition may suppress it. We found no significant change for species richness. These results suggest that increasing N addition will significantly effect on plant biomass of dominant herbaceous and forbs, while species composition will be not change. Whether current trends continue can only be answered by long-term monitoring. More studies need to be conducted to explain the relationships among primary productivity, climate factors and nitrogen deposition in different grassland ecosystem type.

Effects of foliar trichomes of *Tillandsia brachycaulos* on the retention and resuspension of atmospheric particulates

Ruiwen Zhang, Wei Zhang, Mintian Gu, Guiling Zheng, ***Peng Li***
Qingdao Agricultural University

The surface characteristics of plant leaves have great influence on the retention of atmospheric particulates, but this conclusion is mainly based on the comparison among different plants, not on the direct study of the leaf surface characteristics. In addition, atmospheric particulate matter temporarily stranded on the surface of the plants, and deposition of particulate matter will be back into the atmosphere in the certain weather conditions by resuspension, but resuspension is rare studied. Therefore, *Tillandsia brachycaulos* with typical leaf surface characteristics was selected, and its foliar trichomes were removed artificially to compare the dust retention and resuspension contents under different wind strengths and different time. The results showed that leave dust retention with all the foliar trichomes (13.942 ± 0.197 g/m^2), is significantly higher than those without foliar trichomes (10.122 ± 0.133 g/m^2). More than 94.0% of the atmospheric particulates would be resuspended under the function of wind for those with foliar trichomes, while only 51.2% for those without foliar trichomes. Re-suspension ratio was increased significantly with the increase of wind speed or function time. Therefore, effects of foliar trichomes of *Tillandsia brachycaulos* on the retention and resuspension of atmospheric particulates is reflected not only in the total amount of atmospheric particulates, but also in the process of atmospheric particulate resuspension. Resuspension must be taken into account in the future study in order to accurately assess the relationship between vegetation and atmospheric particulates deposition.

Unique proline-benzoquinone pigment from the colored nectar of *Leucosceptrum canum* functions in bird attractions

Shi-Hong Luo[2]*, Yan Liu*[1]*,* ***Sheng-Hong Li***[1]
1. Kunming Institute of Botany, Chinese Academy of Sciences
2. Shenyang Agricultural University

Floral nectar is the bridge in mediating interactions between plants and flower visitors. In nature, at least 68 taxa have been documented to possess unusual colored nectar, but the pigmented compounds of most plants and their ecological functions are still unknown. *Leucosceptrum canum*, a Himalayan tree (up to 10 m high) with an unusual dark brown nectar, is the only colored nectar plant so far discovered in the Lamiaceae family. It is a favorite species of over 40 kinds of birds, which thus is called “bird’s Coca cola tree” by ornithologists. We have been interested in the specialized metabolites of *L. canum* and their ecological functions, and found that the glandular trichomes harbor defensive sesterterpenoids with a novel C_{25} carbon framework (Luo *et al*, *Angew Chem Int Ed*, 2010, 49: 4471-4475). Our large-scale HPLC analysis of 109 nectar samples with a detection wavelength of 400 nm indicated that all samples contained a predominant peak with maximum UV absorptions at 215, 369, and 525 nm, which was accordingly targeted as the responsible pigmented compound of the dark brown nectar of *L. canum.* However, the compound was unstable which made its isolation and identification very difficult. After two years of effort, we were finally able to obtain 27.5 mg sample of the compound with sufficient purity for identification as a dark brown solid from 645 mL of *L. canum* nectar. Its chemical structure was identified as a unique symmetric proline-quinone conjugate, 2,5-di- (N- (-)-prolyl)-*para*-benzoquinone ((-)-DPBQ) by comprehensive spectroscopic studies including 1D and 2D NMR and HRMS analyses, and the absolute configuration was determined through comparison of the CD curve and optical rotation with those of (-)-DPBQ and (+)-DPBQ that were synthesized in this study. Color comparison of (-)-DPBQ in water at different concentrations with *L. canum* nectar confirmed that (-)-DPBQ, rather than the so-called 5-hydroxyflavylium characterized only by UV and mass spectral methods (Zhang *et al*, *New Phytol*, 2012, 193: 188-195), is the major cause of the dark brown color of *L. canum* nectar. The concentration of (-)-DPBQ in the nectar of *L. canum* was found to be extremely high (up to 1.39 mg/mL). A bird visitor, Japanese White-eye (*Zosterops japonicus*), was used for testing its behavioral responses to the nectar, nectar sugar, (-)-DPBQ and (+)-DPBQ. The results clearly indicated that (-)-DPBQ mainly functioned as a color attractant to bird pollinators in *L. canum* nectar (Luo *et al*, *Org Lett*, 2012, 14: 4146-4149). In addition, (-)-DPBQ exhibits selective cytotoxic, antioxidant, and NO inhibitory activities, suggesting it to be a highly functional natural pigment (ZL201210109715.1).This research was financially supported by the National Natural Science Foundation of China (31070320).

Stoichiometric characteristics of four submersed macrophytes in three plateau lakes with contrasting trophic statuses

Wei Li[1]*, Te Cao*[2]*, Jiayou Zhong*[3]*, Leyi Ni*[2]*, Houbao Fan*[1]
1. Nanchang Institute of Technology
2. Institute of Hydrobiology, The Chinese Academy of Sciences
3. Jiangxi Institute of Water Sciences

Plant nutrient concentrations and their stoichiometric characteristics are often used to predict nutrient availability and nutrient limitation. However, there is still debate because plants, especially submersed macrophytes, can store excess nutrients and exhibit different survival strategies. To determine the extent to which the trophic status of lakes affect nutrient concentrations of submersed macrophytes and to estimate the relative contribution of lake and interspecific differences to variation of plant nutrient concentrations, we investigated four common submersed macrophytes, *Potamogeton maackianus*, *Potamogeton pectinatus*, *Potamogeton malaianus* and *Myriophyllum spicatum*, in three plateau lakes with contrasting trophic statuses (i.e. oligotrophic: Fuxian Lake; mesotrophic: Erhai Lake; eutrophic: Dianchi Lake) in Yungui Plateau in southwest China. The results indicated that the average C:N ratios were not different among the three lakes. However, the C:P and N:P ratios in Erhai Lake and Dianchi Lake were significantly lower than those in Fuxian Lake. The N:P ratios of *P. maackianus* and *P. pectinatus* did not significantly differ among the lakes. By contrast, the N:P ratios of *P. malaianus* and *M. spicatum* indicated different levels of interspecific stoichiometric homeostasis. The C and N concentrations and C:N ratios were mainly determined by the species, while the P concentrations and C:P ratios were mainly determined by the trophic status of lakes. Our study suggested that the C:N:P stoichiometric characteristics of submersed macrophytes exhibit high interspecific differences but substantial homoeostasis in response to different trophic conditions in plateau lakes.

Effects of simulated acid rain on physiological characteristics and active ingredient content of *Asparagus cochinchinensis* (Lour.). Merr.

Juan Liang

College of Biological and Food Engineering, Huaihua University

The effects of simulated acid rain at pH 2.0, 3.0, 4.0, 5.6 and 6.8 (control), respectively, on the agronomic traits, chlorophyll content, resistance physiology and active ingredient content of *A. cochinchinensis* cultured in pots were studied to explore the sensitivity and tolerability of *A. cochinchinensis* to acid rain with the hope to provide the theoretical basis for the cultivation of *A. cochinchinensis*. The results showed that 1) compared to the control with pH 6.8, acid rain with pH 5.6 did not significantly affect the shape and color of leaves as well as the contents of amino acid and soluble sugar in tuber roots of *A. cochinchinensis*, but significantly enhanced the activities of superoxide dismutase (SOD) and peroxidase (POD) and 2) with the increase of acid rain stress (pH≤3), the damage degree of leaves and the content of malondialdehyde (MDA) in leaves gradually increased, but the content of photosynthetic pigment, the increment of stem length and fresh weight, the activities of POD and SOD and the content of amino acid, soluble sugar and saponin in the tuber roots all decreased. The experiments indicated that 1) acid rain significantly affected the physiological characteristics and active ingredients accumulation of *A. cochinchinensis*, 2) *A. cochinchinensis* showed a certain resistance to acid rain, 3) pH ≤ 3 is the critical point (threshold) for acid rain to damage *A. cochinchinensis*, and 4) artificial cultivation of *A. cochinchinensis* should avoid medium and strong acid rain pollution.

Spatial variation of absorptive root traits and nutrient foraging strategies of Chinese fir (*Cunninghamia lanceolata*) from different locations across Subtropical China

Yingchun Liao[1], *Houbao Fan*[1], *Huimin Wang*[2]

1. Research Institute of Ecology & Environmental Science, Nanchang Institute of Technology

2. Qianyanzhou Ecological Research Station, Key Laboratory of Ecosystem Network Observation and Modeling, Institute of Geographic Sciences and Natural Resources Research

Absorptive roots and their related mycorrhizal fungi are mainly responsible for soil resource acquisition. Understanding of the spatial variation of absorptive root traits is crucial to predict the adaptation of tree absorptive roots and their nutrient foraging strategies in different environmental conditions. A study was conducted to measure the absorptive root traits related to nutrient foraging (root morphology, architecture and arbuscular mycorrhizal (AM) colonization) of Chinese fir (*Cunninghamia lanceolata*) across six areas in subtropicalChinathat differed markedly in their environmental conditions. The six Chinese fir populations were selected from the central (Shaxian, Taihe and Huitong) to the marginal portions (Tongling, Nayong and Pingxiang) of the geographic range in subtropical China. Absorptive root diameter differed significantly with root order and study sites ($P < 0.05$), while special root length (SRL) and special surface area (SSA) only showed significant difference with root order. Higher root C/N was found in marginal distribution areas except Tongling, but generally kept at lower levels in central distribution areas. Absorptive root AM colonization varied with root orders and study sites, with the 1st order roots significantly higher than the 2nd order roots ($P < 0.05$). The AM colonization of absorptive roots tended to be higher in areas with high annual mean precipitation (MAP), but to be suppressed by low soil pH. Branch ratios and AM colonization were negatively correlated ($P < 0.05$) and were at high levels in areas with low soil pH. The absorptive roots within species varied across geographic range with different climates were supposed to follow different economic strategies for nutrient acquisition. Our findings suggest root proliferation and AM colonization are the main strategies and can make complementarities in nutrient foraging.

T3

A233

Complementarity in nutrient foraging strategies of absorptive fine roots and arbuscular mycorrhizal fungi across 14 coexisting subtropical tree species

Bitao Liu

Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences

In most cases, both roots and mycorrhizal fungi are needed for plant nutrient foraging. Frequently, colonization of roots by arbuscular mycorrhizal (AM) fungi seems to be higher in species with thick and sparsely branched roots than in species with thin and densely branched roots. Yet whether a complementarity exists between roots and mycorrhizal fungi across these two types of root systems remains unclear. We measured traits related to nutrient foraging (root morphology, architecture and proliferation, AM colonization and extramatrical hyphal length) across 14 coexisting AM subtropical tree species following root pruning and nutrient addition treatments. After root pruning, species with thinner roots showed more root growth but lower mycorrhizal colonization than species with thicker roots. Under multi-nutrient (NPK) addition, root growth increased but mycorrhizal colonization decreased significantly whereas no significant changes were found under nitrogen or phosphate additions. Moreover, root length proliferation was mainly achieved by altering root architecture but not root morphology. Thin-root species seem to forage nutrients mainly via roots whereas thick-root species rely more on mycorrhizal fungi. Additionally, the reliance on mycorrhizal fungi was reduced by nutrient additions across all species. These findings highlight complementary strategies for nutrient foraging across coexisting species with contrasting root traits.

A234

Ecophysiological responses of *Camellia japonica* (Naidong) to different water and light conditions

***Cuiju Liu**, Xiao Guo, Qinghua Liu*
Qingdao Agricultural University

Camellia japonica (Naidong) living in Qingdao, China, is a special ecotype of *Camellia japonica* and was selected as research materials in present study. The *Camellia japonica* (Naidong) saplings were subjected to two light regimes L1, L2 (65%, 15% of full sunlight), and three water supply regimes W1, W2, W3 [75%, 50%, 25% of field capacity (FC)]. The ecophysiological and morphological responses of *Camellia japonica* (Naidong) were studied. The results showed that height (H), basal diameter (BD) and crown area (CA) of *Camellia japonica* (Naidong) were increased with the treatment time under L1 and L2, the morphological index was higher with the L1 treatment as compared to the L2, and the relative growth rate of each index increased rapidly. But with the extending of stress time, the relative growth rate increased slowly; SLA and LWC under L2 was significantly higher than L1. With the decreasing of water regimes, the Photosynthetic Rate (A), Ranspiration Rate (E), Stomatal Conductance (Gs) and Water Use Efficiency (WUE) decreased, Intercellular CO_2 Concentration (Ci) increased gradually, and Vapour Pressure Deficit (VPD) increased firstly and then decreased. The value of Maximal Fluorescence in the dark (F_m) Variable Fluorescence (F_v) and Maximal Quantum Yield (F_v/F_m) under the L1 conditions were higher than L2 conditions, and the Initial Fluorescence in the dark (F_0) showed the opposite trend. With the decreasing of moisture gradient, the F_0 increased gradually under L1, while showed the opposite trend under L2. Significant differences were found in photosynthetic pigment contents of leaves among various light and water treatments. Under high irradiation, chlorophyll a, chlorophyll b and total chlorophyll were higher than low irradiation, and the Chla/Chlb value showed the opposite trend. The contents of Superoxide Dismutase (SOD), Peroxidase (POD), Catalase (CAT), Malondialdehyde (MDA) and Proline (Pro) were significantly difference at every level of light and water treatment. And the contents of POD, SOD increased firstly and decreased later with the water gradient decreasing. The content of CAT decreased with the decreasing of water content under L2 conditions, and the contents of MDA and Pro increased gradually with the water gradient decreasing. Drought or shade has some restrictive effect to the growth of *Camellia japonica* (Naidong), certain moisture and light were favorable for plant growing. *Camellia japonica* (Naidong) could tolerate a certain degree of drought resistance and adapt the larger amplitude of light intensity. At the same time, it can change the enzyme activity and osmotic adjustment substances to against damage.

Latitudinal defense pattern of woody species is mainly dominated by heritability

***Jian-Feng Liu**[1], Xiao-Fei Wang[1], Yan-Yan Ni[1], Ze-Ping Jiang[1], Feng-Feng Kang[2], Yi-Hua Xiao[3], Yuan-Wen Kuang[4], Yong-Biao Lin[4], Zhi-Feng Guo[5]*
1. Research Institute of Forestry, Chinese Academy of Forestry
2. College of Forestry, Beijing Forestry University
3. Research Institute of Tropical Forestry, Chinese Academy of Forestry
4. South China Botanical Garden, Chinese Academy of Sciences
5. Heshan Institute of

Recent studies have called the latitudinal herbivory-defense hypothesis (LHDH) into question (e.g., Moles *et al.,* 2011). However, our previous field investigation conducted on natural Chinese cork oak (*Quercus variabilis* Blume) stands supported this hypothesis (Wang *et al.,* 2016), and found that climate (e.g., annual precipitation, minimum temperature of the coldest month) and herbivory, rather than edaphic factors, contributed more to the species' latitudinal defense pattern. To further test whether climate or soil or genetic factors dominate latitudinal defense pattern of oaks, two common garden experiments were designed. The seeds of five oak provenances across the north-south transect with spanning ~14° latitude (~40.2 ° N, ~37.5 ° N, ~33.5 ° N, ~30.7 ° N, ~26.3 ° N) were collected in September, 2014. Then one part of the seeds were germinated and cultivated beyond the south distribution edge of the species (~22° N, Heshan, Guangdong Provenance, South China). The other part of the seeds for seedlings were cultivated with sandy substrate in the greenhouse of CAF (~40° N, Beijing), and were treated with four soil nutrient conditions: low nitrogen with low phosphorus (LNLP), low nitrogen with optimum phosphorus (LNOP), optimum nitrogen with low phosphorus (ONLP), optimum nitrogen and phosphorus (ONOP). After one growing season (September, 2015), chemical defense substances across the seedlings' tissues (the concentrations of total phenolics, total condensed tannins and flavonoids), as well as herbivory rates in the south common garden experiment, were examined and analyzed. Our results showed that even the seedlings were grown beyond the species' south distribution edge, the latitudinal pattern of chemical defensive traits was still consistent with our previous field results, namely, compared to the north provenances, the south provenances had higher concentrations of chemical defense substances.

Consequently, the south provenances suffered less leaf loss though all provenances were under the same herbivory pressure. Under nutrient treatments, the abundance degree of N or P did not alter the geographical patterns of chemical defense substances across latitudes, as the concentrations of chemical substances decreased with the increase of the latitudes of the five provenances. Our results suggest that edaphic or climatic factors may contribute, to some extent, to latitudinal defense pattern of woody plants, but the genetic factor is paramount, which reflects long-term adaptation and coevolution of wood plants with natural enemies. Our results are enormously important to elucidate the controversies of latitudinal defensive hypothesizes, and also have practical significances on human-assisted migration of valuable woody species in the context of climate change. This work was funded by the National Natural Science Foundation of China (No. 41371075).

A236

Species abundance distribution of woody plants on islands in a fragmented landscape

Jinliang Liu[1], *Fangliang He*[2,5], *Thomas J. Matthews*[3,4], *Mingjian Yu*[1]
1. College of Life Sciences, Zhejiang University
2. Sun Yat-sen University-Alberta Joint Lab for Biodiversity Conservation, State Key Laboratory of Biocontrol, School of Life Sciences, Sun Yat-sen University
3. GEES (School of Geography, Earth and Environmental Sciences), The University of Birmingham
4. Conservation Biogeography and Macroecology Programme, School of Geography and the Environment, University of Oxford
5. Department of Renewable Resources, University of Alberta

Species abundance distribution (SAD), which describes the commonness and rarity of species sampled within a community, has important applications in community assembly and biodiversity conservation. Habitat fragmentation is a main threat to the biodiversity. However, the effects of habitat fragmentation on the change of SAD have little been developed. Generally, the shapes of SAD, such as logseries model and lognormal model, are affected by the trade-off between successful colonization and extinction in fragmented ecological communities. In this study, we used the Gambin's alpha index, which reflects the shape of SAD, and nestedness analysis to study the forest community assembly in the Thousand Island Lake (TIL), eastern China. TIL is a large man-made hydroelectric reservoir formed by the construction of Xin'anjiang Dam on the Xin'an River in 1959, with more than 1,000 land-bridge islands. On 24 study islands with secondary Masson pine forests, all woody plants with diameter at breast height (DBH) ≥ 1 cm were tagged, measured, identified and stem-mapped on the entire island of small islands (area < 1 ha) and 0.5-1 ha plots on large islands (> 1 ha) during 2009-2010. We found that the SADs of 22 islands in all 24 islands were fitted for logseries model better than lognormal model, and Gambin's alpha index significantly decreased when islands area increased, which indicate that the shape of SAD changed from lognormal to logseries with the increase of island area. All islands were dominated by similarly common species, and the species spatial turnover of different islands mainly occurred among rare species. Moreover, with the increase of difference between the area of two islands, the nestedness (i.e. species richness loss) became higher and species spatial turnover became lower. These results suggested that island area determined the shape of SAD, and the successful colonization on large islands with the selective extinction of rare species on small islands caused the change of SADs shape in this fragmented landscape. The study results have substantial implications for conservation: a logseries distribution implies that a large fraction of species is committee to extinction and the rare species showed easier to extinction on small islands, we should focus on the rare species in the continuous habitat before fragmentation.

Role of indehiscent pericarp in formation of soil seed bank in five cold desert Brassicaceae species

Juan J. Lu[1], *Dun Y. Tan*[1], *Carol C. Baskin*[1,2], *Jerry M. Baskin*[1,2]
1. Xinjiang Agricultural University
2. University of Kentucky

The dispersal and germination unit of some Brassicaceae species is the fruit, but few studies have tested effects of the pericarp on formation of a soil seed bank in this family. We determined the effects of the indehiscent pericarp on germination and longevity of buried seeds of five Brassicaceae species native to cold deserts of central Asia. Germination phenology (seedling emergence) was monitored for intact dispersal units and isolated seeds of *Chorispora sibirica*, *Goldbachia laevigata*, *Spirorrhynchus sabulosus*, *Tauscheria lasiocarpa* (annuals) and *Sterigmostemum fuhaiense* (perennial) at natural temperatures in watered and nonwatered (natural precipitation) soil. Intact dispersal units and isolated seeds were buried under natural conditions and exhumed at regular intervals for 35 months to monitor germination, viability and moisture content of isolated seeds, seeds in dispersal units and seeds removed from dispersal units after burial. Isolated seeds of *Goldbachia*, *Spirorrhynchus* and *Tauscheria* germinated only the first autumn and those of *Chorispora* and *Sterigmostemum* the first autumn and first spring, with higher germination percentages in all species in watered than in nonwatered soil. A high percentage of seeds in buried dispersal units of *Chorispora*, *Goldbachia* and *Sterigmostemum* was viable after 35 months, and seeds exhibited a 6-month dormancy cycle, being nondormant only in autumn and spring. Seeds in buried dispersal units of *Spirorrhynchus* and *Tauscheria* germinated when exhumed the first spring, but all non-germinated seeds were dead after 1 year. Presence of the pericarp allows *Chorispora*, *Goldbachia* and *Sterigmostemum* to form a persistent seed bank but not *Spirorrhynchus* and *Tauscheria.*

Mutualism between star anise (*Illicium verum* Hook. f., Schisandraceae) and its pollinator: Larvae and adult gall midges exploit rotten floral organs for food

Zhonghui Ma[1,2], *Shixiao Luo*[1], *Dianxiang Zhang*[1]
1. South China Botanical Garden, CAS
2. Guangxi Uniersity

An understanding of the reproductive ecology of tree species is crucial for their effective conservation and management, yet such information is often lacking. In this study, the pollination system involving *Illicium verum* (star anise) was studied in southern China. Gall midges (*Anabremia* sp., Cecidomyiidae), frequently visit and oviposit in the flowers of *I. verum*, and their eggs stay dormant in the flowers untill intensively hatch into larvae after the end of the sexual phase. The fungus *Choanephora* sp. (Choanephoraceae) and *Rhizopus* sp. (Mucoraceae) infect the flowers during the post-sexual phase as the floral organs gradually becoming rotten and succulent. Adult midges feed on the mycelia and their larvae suck secretions of rotten tissues to obtain additional nutrition. Different from post-sexual phase heating found in other Asian *Illicium* species, stable lower than ambient temperature in the flower chambers during the sexual phase, and abundant mycelia of fungi growing in the post-sexual phase are among the factors maintaining the pollination mutualism between *I. verum* and the gall midges in the summer season. A similar tripartite mutualistic mode occurring in unrelated tropical species provided vivid demonstration of plasticity and parallel evolution in pollination mechanisms. The difference of frequency of adult midges visiting and ovipositing in flowers of *I. verum* reasonably explained the significant difference in the natural fruit set ratio and seed abortion rate between the origin and introduced populations. To resolve the high incidence of pollination limitations due to a pollinator-shortage in the introduced site, a series of management strategies are suggested.

Plant community structure responses to addition of water extracts of litter in the alpine meadow of Qinghai-Tibetan Plateau

*Zhouwen Ma, **Fujiang Hou**, Zhaofeng Wang, Saman Bowatte*
College of Pastoral Agriculture Science and Technology, Lanzhou University, Lanzhou, China.

Plant litter is a key component of grassland ecosystems that link plant productivity and soil functions. In this study, we determined the effects of litter quality on plant growth and community characteristics in alpine meadow grassland at Qinghai-Tibetan Plateau, China. We added four concentrations of water extracts of litter (0, 5, 10 and 20%) of *Kobresia setchwanensis*, *Elymus nutans* and *Saussurea hieracioides* and measured their effects on plant community species composition, height, diversity and above-ground biomass. We found addition of water extracts of litter significantly affected the plant community height, above-ground biomass plant community species diversity and plant functional groups (PFG) important value ($P < 0.05$), while plant richness and density were not affected ($P > 0.05$). The responses to addition of water extracts of litter were different depending on the litter type. Both plant community height and above-ground biomass showed a negative linear relationship with litter concentration. In contrast, plant community species diversity indices (Simpon dominance index, Shannon-Wiener Diversity index and Pielou evenness index) were positively related to litter concentration. The status and functional of Gramineae and Sedge PFGs could be decreased, but Legumes and Forbs PFGs could be increased with litter concentration. Our results indicate that litter is an important control of plant growth and community structure in alpine meadow grasslands.

Some biomorphological features of the northern hemiparasites (Orobanchaceae) from Eastern Europe

Svetlana Petrova
Lomonosov Moscow State University

We try to work out the problem whether the transition to parasitism in hemiparasitic Orobanchaceae occurs on the basis of different life forms, or there is a certain trend, leading to the formation of only few specific biomorphotypes. We studied the life forms and the early stages of development in 5 northern hemiparasites from Eastern Europe: *Bartsia alpina*, *Castilleja lapponica*, *Pedicularis lapponica*, *P. sceptrum-carolinum*, *Rhinanthus minor* subsp. *groenlandicus*. Three biomorphological types was distinguished: hemicryptophytes – short-rhizomatous (*P. sceptrum-carolinum*, *C. lapponica*, *B. alpina*) and long-rhizomatous (*P. lapponica*) herbaceous perennial polycarpics with adventive roots and assimilating shoots, and terophyte – an annual monocarpic with a tap root and assimilating shoots (*R. minor*). All analyzed species form lateral haustoria. We studied the early stages of development to reveal the type of hemiparasitic dependence on the host plant. Our experiments showed that all the studied perennial hemiparasites were able to germinate without a host, but their further development depended on the presence of a suitable host plant. Different experiments to stimulate a germination of *R. minor* subsp. *groenlandicus* seeds, failed. Nevertheless, some authors considered *R. minor* as the facultative hemiparasites that does not require any special factors for germination. The seedlings of studied species have much in common in their structure: they have an embryonic root with a ring of absorption hairs at the root neck, a relatively long hypocotyl, a terminal bud and two green cotyledons. The root hairs at the absorption zone occur only in *C. lapponica*; *B. alpina* and both *Pedicularis* species are lack of normal root hairs. However, in *B. alpina* we observed long haustorial hairs at the central area of the embryonic root that can be regarded as an indicator of the earliest attempt to establish a contact with a host, though without special external signals. If we assume that the main features marked the process of structural transformation to parasitism are the reduction of root hairs and increasing of specialization to chemical factors that trigger the formation of haustoria, it can be concluded that the studied species are at different stages of transition to the parasitism. The least specialized species is *C. lapponica*, more specialized taxa are *B. alpina* and then *Pedicularis* species. However, in any case, all the perennial species are obligate hemiparasites. It is believed that annuals are the final step in the process of reductional evolution of life forms, and it can be supposed that for annual hemiparasites it is easier to keep a contact with the host plants, because this contact is needed for a short time of no more than one vegetative season. Perennial hemiparasites, especially obligate, have to form more complex structures and physiological mechanisms to maintain the normal development for years. In reality, as show our results and some literature data the hemiparasites of different taxa may have different biomorphological types, and the transition to a parasitic lifestyle may occur on the basis of different life forms.

Overexpression of *Chorispora Bungeana ABF1 G*ene in tobacco enhances cold and drought tolerance by modulating ROS scavenging

***Xiaohong Pu**, Guoyan Zhang, Lizhe An, Xiule Yue*
School of Life Sciences, Lanzhou University

Plants show sensitively response to the changing external environment and biotic stress during plant life history. Among these environmental factors, drought and low temperature obviously affect the growth, reproduction and survival of plants. Our previous study demonstrated that *CbABF1*, a bZIP transcription factor from an alpine subnival plant *Chorispora bungeana*, can greatly increase the survival rate of transgenic tobacco (*Nicotiana benthamiana*) under cold and drought stresses. To further reveal the adaptive mechanisms of *CbABF1* transgenic tobacco, physiological characteristics were analyzed. In contrast with WT, *CbABF1* transgenic tobacco showed decreased relative conductivity, H_2O_2 and MDA content, but significantly increased soluble sugar content under cold and drought stress. In addition, it was found that the activities of superoxide dismutase (SOD), catalase (CAT) and peroxidase (POD) of transgenic tobacco were significantly elevated under cold and drought stresses. Together, these findings indicated that CbABF1 enhanced cold and drought tolerance through maintaining the integrity of the membrane system by weakening ROS toxic effects on cells in tobacco, which will provide theoretical support for the further study on the function of *CbABF1* gene.

Necromass stocks in Brazilian Atlantic Forests

***Luis Carlos Quimbayo Guzmán**, Simone Aparecida Vieira*
University of Campinas

Forests have a capacity of storing carbon (C) in the form of vegetal tissues, mainly as wood. When a tree dies, an important portion of its C biomass gets stored as dead wood (DW) and litter. Eventually, most of that C is released to the atmosphere, as DW and litter are decomposed. Understanding the dynamic of death and decomposition allows to quantify the role of necromass (DW + litter) in C cycle in tropical forests and its influence in their function as C sink or source. To understand these dynamics, litter stocks and DW stocks, production and decomposition are being measured in a Brazilian Atlantic Forest along two different gradients: (1) altitudinal and (2) successional. 18 forestry inventory plots (1 ha each) are being monitored, all snags (ø > 4.8 cm) are being measured, litter stocks are being sampled with circular collectors (0.32 m^2), line intersect method is being used to measure fallen DW (ø > 2 cm) stocks and production, DW heterotrophic respiration is being measured as a proxy of decomposition with an infrared gas analyzer (EGM-4). All plots are distributed in nucleus Picinguaba, Santa Virginia and Cunha of "Serra do Mar State Park" (São Paulo, Brazil) in altitudes that range from 10 to 1,200 m. The 6 successional gradient forest plots were located between 1,000 and 1,200 m.a.s.l. and were classified as Old-growth, Selectively Logged, Late Succession and Early Succession forests. DW stocks showed a positive relation with altitude, which was determined mainly by the decrease in soil temperature with altitude and its effect in wood decomposition. Litter presented high water content in all places (> 60%), these areas have low forests fire risk. Early successional forest presented a 65% increase in litter stock after a freeze (2016 winter), other successional stages did not present such pattern, which suggests higher susceptibility to extreme weather events in early stages. Along the successional gradient, the early stage presented the lowest DW stocks because it still is a growing forest, with low DW production. DW stocks were similar among other successional stages, so in these tropical Atlantic Forests the DW component might recover its original dynamics only a few decades after disturbance.

Study on antioxidant activity of the extracts from *Solidago canadensis* L.

***Xiao Shen**[1,2], Zhenxing Wang[1,3], Zhengrong Zou[1,2]*
1. College of life science, Jiangxi Normal University
2. Key Laboratory of Protection and Utilization of Subtropic Plant Resources of Jiangxi Province
3. Southwest Forestry University

Solidago canadensis L. is one of the major invasive species, which has caused the significant environmental and economic influence around in China. In order to utilize and prevent the *Solidago canadensis* L., the total flavonoids and phenolic contents in its ethanol extract (70%), petroleum ether, ethyl acetate, *n*-butanol, water extracts were investigated by $AlCl_3$ assay and Folin-Ciocalteu assay, respectively, and the in vitro antioxidant activities of them were also studied by several methods including ABTS (agreement of basic telecommunications services) assay, DPPH (1,1-diphenyl-2-picrylhydrazyl) assay, FRAP (ferric reduction ability) assay and ORAC (oxygen radical absorbance capacity) assay, with Vc (vitamin c) and BHT (butylated hydroxytoluene) as positive control. The results showed as follows: (1) The ethyl acetate extract possessed the highest amount of total flavonoids (10.12 mg/g) and phenolic (814.77 mg/g) than other extracts. (2) The ethyl acetate extract had the strongest antioxidant activity among other extracts. (3) The antioxidant activity of ethyl acetate extract was higher than Vc ($P < 0.05$). Thus, the ethyl acetate extract of *Solidago canadensis* L. can be regarded as a kind of potential resource of high-efficiency and natural antioxidants. This will provide some foundations and references for further exploiting and utilizing the *Solidago canadensis* L.

Biofertilizer as an ecological pathway to decrease chemical fertilizer in Maize

*Safar Nasrolahzadeh[2], **Ali Shirkhani**[1], Saeed Zehtab Salmasi[2]*
1. Seed and Plant Improvement Institute (SPII), Kermanshah Agricultural and Natural Resources Research and Education Center. AREEO, Kermanshah, Iran
2. Department of Eco-physiology, Faculty of Agriculture, University of Tabriz, Tabriz, Iran

Iran is a major importer of Maize in the world. Maize is one of the most important crops in the western Iran. Maize production in this region has two major problems: water shortage and low percentage of organic matter in soil. In this research, effects of vermicompost and azotobacter as a boifertilizers and chemical fertilizers levels on yield and some traits of leaves of maize under normal and deficit irrigation was investigated in two years (2014 and 2015). Results showed that grain yield, leaf area index, leaf chlorophyll contents, the normalized difference vegetation index (NDVI) and leaf relative water content (RWC) were decreased by deficient irrigation. Use of azotobacter and vermicompost significantly increased these traits in normal and deficit irrigation. Results also showed that using 6 ton/ha of vermicompost and azotobacter, 50% of the maize fertilizer supplied. The results showed that combined use of biofertilizers with chemical fertilizers increased the yield and other traits. Therefore the uses of biological fertilizers significantly reduce the consumption of chemical fertilizers and reduce the adverse environmental effects. So biofertilizers could be considered as a suitable substitute for chemical fertilizer in organic agricultural systems. On the other hand from this experiment, application of vermicompost in combination with chemical fertilizers showed better performance than only chemical fertilizers, even in 100% recommendation based on soil test treatments. As a general conclusion these results suggest that integrating organic sources with 50% of recommended NPK fertilizers are appropriate for sustainable crop production in normal and deficient irrigation.

Quantitative classification of forest vegetation on Hainan Island

Lin Siliang[1]*, Kong Fanmao*[2]*, He Jiekun*[1]*, Yu Jiehua*[1]*, Zhu Hua*[3]*,* ***Jiang Haisheng***[1]

1. School of Life Science, South China Normal University, Guangzhou, Guangdong

2. Guangzhou Qimao Ecological Technology Co., Ltd., Guangzhou, Guangdong,

3. Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Mengla, Yunnan

Vegetation classification is the foundation and a complex problem of vegetation research. Due to the rich plant diversity and complex community struction, making it more difficult to explore and study the vegetation classification in tropical forest. As a typical tropical island of China, vegetation classification on Hainan Island has been the concern of researchers. Although most previous studies of forest vegetation classifications on Hainan Island had followed the classification system of "*Vegetation of China*", but the disputation are still exists. This paper bases on 870 forest plant plot data, adopting the quantitative classification approach, combining the environmental factors (including climate, topography and soil) to classify, analyze and explore the forest vegetation on Hainan Island. We found that forest on Hainan Island could divide into 2 Vegetation Type Groups (Evergreen forest and Deciduous forest), 6 Vegetation Types (Tropical rainforest, Tropical seasonal moist forest, Tropical montane evergreen broad-leaved forest, Tropical coniferous forest and Other evergreen forest, which are belong to Evergreen forest; Tropical monsoon forest are belongs to Deciduous forest) and 4 Vegetation Sub-Types (Tropical seasonal rainforest and Tropical montane rainforest that are belong to Tropical rainforest, Deciduous monsoon forest and Semi-deciduous monsoon forest that are belong to Tropical monsoon forest), and 32 main Formations. Our result show that forest of Hainan split into Deciduous forest group and Evergreen forest group in the high classification level. Although this result is unlike previous classifications studies, but it reflect the actual precipitation gradiant between eastern and western part of Hainan Island is the key cause in forest vegetation differentiation. The differentia of this two vegetation types is the dominance of evergreen and deciduous tree species in community. The Evergreen forest districts on the easten Hainan Island, whose climate is obvious wet; and the Deciduous forest districts on the westen Hainan Island, whose climate is obvious drought. This conclusion is similar to the other study in the tropical region. We also identified a Vegetation Types: tropical seasonal moist forest by cluster and ordination, which is an interesting vegetation community. It sharing the same climatic conditions with Tropical rainforest, and also maintaining some identification species of Tropical rainforest. But due to the limestone and sandy soil, the soil moisture content is low, which making more deciduous species growth in those community than the Tropical forest. Furthermore, the ecological physiognomy and floristic composition of community show significant different with Tropical rainforest. In addtion, it is improper to classify those community into Tropical monsoon forest only according to the ecological physiognomy. It also show significant differences in floristic composition and climatic condition with Tropical monsoon forest.

Nuclear AFLP loci drive adaptive population genetic differentiation in the old rare conifer *Pseudotaxus chienii* (Taxaceae): Effects of climate, soil, and their interactions

Qi Deng[1]*, Zhen Wang*[2]*, Ting Wang*[3]*,* ***Yingjuan Su***[1]

1. Sun Yat-sen University

2. Nanjing Agricultural University

3. South China Agricultural University

Respective roles of climate, soil, and their interactions on the adaptive genetic differentiation in plants remain to be elucidated. In this study, we selected an old rare conifer *Pseudotaxus chienii* as a model species to explore the association between adaptive genetic variation and climate and soil variables. We measured soil and extracted climate data. We performed genome scans for 11 natural populations of *P. chienii* across its entire distributional range to detect adaptive genetic loci by using amplified fragment length polymorphism (AFLP), nuclear simple sequence repeat (nSSR), and chloroplast simple sequence repeat (cpSSR) markers. Then the spatial analysis method (SAM) was applied to evaluate the correlation between adaptive genetic loci and environmental variables. Moreover, the neutral genetic variation pattern, spatial genetic structure, linkage disequilibrium (LD), and the potential geographic distribution based on ecological niche modellings were also examined. We identified 26 AFLP but no nSSR and cpSSR adaptive loci in *P. chienii*. We found 22 of the AFLP adaptive loci significantly associated with climate (precipitation and temperature) and/or soil (K, Ca, Mg, Zn, pH, and electrical conductivity) variables, of which 17 solely linked to climate, three related to both climate and soil, whereas only two specific to soil. The ongoing global warming was predicted to induce population shrinkage in southern China and shift to Central China. *Pseudotaxus chienii* was found to possess a moderate to high level of genetic variation and differentiation, a significant fine-scale spatial genetic structure within the distance of 2 km, and an extremely low proportion of LD between genetic loci. The adaptive response to environmental changes of *P. chienii* might be predominantly driven by nuclear rather than chloroplast genome. Climate is of relatively greater importance than soil in shaping the adaptive genetic differentiation, wherein the synergistic effects of climate and climate-soil variables were also validated. The identified climate and soil variables should be taken into account when applying ex-situ conservation. This work was supported by the National Natural Science Foundation of China (31570652).

A247

Species diversity and population dynamics of endangered plant *Disanthus cercidifolius* var. *longipes* in China

Yunong Tian, *Xiaodong Jin, Guowen Xie, Xueyin Guo*
School of Life science, University of Guangzhou

Disanthus cercidifolius var. *longipes* is a rare and endangered species of China, and only distributs in a few counties in Guangdong, Hunan, Jiangxi and Zhejiang provinces. the community characteristics and population dynamic of this species were studied by using typical sample method, including species diversity, age structure and population distribution pattern *etc*. The results are as follows: 1). There are rich plant resources in *D. cercidifolius* var. *longipes* community, including 331 species of vascular plants, belonging to 204 genera, 93 families. The type of the pantropical distribution is the most common type in the areal types of families, accounting for 47.56% in total, which shows this community originated from tropics. In the areal types of genera, the proportion of the tropical distribution is similar to that of the temperate one, indicating the transitional floristic characteristics from tropic to temperate. Based on cluster analysis, the type of the temperate distribution is the highest in the areal types of non-Chinese endemic species, while the type of the tropical distribution is the highest in the areal types of species endemic to China. 2). The species diversity of *D. cercidifolius* var. *longipes* community. The variation tendency in species richness index, Simpson index, Shannon-Wiener index and Pielou evenness index in different sample plots is basically consistent. The species richness index and Shannon-Wiener index of the shrub layer are higher than those of the tree layer, while Simpson index and evenness index of the tree layer are higher than those of the shrub layer. 3). The population distribution pattern of *D. cercidifolius* var. *longipes* population belongs to cluster type. The size structure is rendered as the typical pyramid, indicating that this population is in a growth period. The static life table analysis showed that the life expectancy of the population decreased with the increase of size structure. The survival curve of this population is approximately linear, indicating its growth is relatively stable. 4). The endangered causes of *D. cercidifolius* var. *longipes* were analyzed and the results showed that the internal causes include: some barriers of its seeds germination in natural conditions; forced dormancy and physiological dormancy; poor pollen competitiveness, shortage of pollinators and low pollination efficiency. The external causes include: the high seedling mortality rates due to the illumination conditions; geographical isolation and less communication between populations; the human disturbance. In order to better protect the *D. cercidifolius* var. *longipes*, in situ and ex situ conservation should be combined.

Higher plant as biomonitors of metal contamination in abandoned karst bauxite, Southwestern China

Dengfu Wang[1,2], *Zhaohui Zhang*[2]
1. Institute of Karst Science, Guizhou Normal University
2. Key Laboratory for information System of Mountainous Area and Protection of Ecological Environment of Guizhou Province, Guizhou Normal University

Bauxite mining on karst results in several ecological and environmental issues including metal pollution, water and soil erosion and the destruction of vegetation. However, untreated abandoned karst bauxite may result in hazards to ecosystems and human health. In general, higher plants are commonly used as biomonitors to estimate the pollution of metals in the soil. The plant specimens and soils were collected on Shangdong abandoned karst bauxite near the County of Xiuwen in the Guizhou Province of southwestern China. Higher plants containing *Pteris vittata*, *Miscanthus floridulus*, *Coriaria nepalensis*, *Pinus massoniana*, *Artemisia argyi and Senecio scandens*. The levels of six metal elements (Al, Mg, Ca, Fe, K, Ti) in the plants and soils were determined. The metal contents in soil substrates: aluminum, 9,827-57,000 mg/kg; magnesium, 612.1-8,343 mg/kg; calcium, 12,650-84,290 mg/kg; iron, 3,274-63,900 mg/kg; kalium, 5,673-19,550 mg/kg; and titanium, 158.9-8,840 mg/kg. The metal concentrations in plants tissues: root, 4.304-24,750 mg/kg; stem, 10.04-7,758 mg/kg; and leaf, 6.545-31,310 mg/kg. Compared and analyzed the concentrations of metals in plants and soils. The results showed that *Pteris vittata* plant root content of aluminum the highest, *Artemisia argyi* the lowest; *Senecio scandens* plant stem content of kalium the highest, *Artemisia argyi* the lowest, *Coriaria nepalensis* plant leaf content of calcium the highest, *Miscanthus floridulus* the lowest and different plants contained varied concentrations of metals, the same plant contained varied concentrations of metals in plants tissues, thereinto, the levels of metals in *Pteris vittata* plant and *Miscanthus floridulus* plant, root > leaf > stem, the indicated that the metal elements may have transport and transformation process in plants tissues. Correlation analysis showed that Mg, Ca and K contents were extremely significant positive correlation in soils ($p < 0.01$); Mg, Ca and Al contents were extremely significant positive correlation in plant roots ($p < 0.01$); Mg and K contents were significant positive correlation in plant stems ($p < 0.05$); Al and Ti contents were extremely significant positive correlation in plant leaves ($p < 0.01$). Through the research, we found that *Pteris vittata* plant contents of metals (Al, Ca, Fe, K) were highest in the soils, *Pteris vittata* plant root contents of six metal elements were highest and *Pteris vittata* > *Miscanthus floridulus* > *Coriaria nep-*

alensis. Therefore, *Pteris vittata* plant had strong accumulation ability to the metals contents, which its can be used as biomonitor indicator of metals contamination and provided materials for ecological monitoring and restoration in abandoned karst bauxite.

Effects of exclosure on community interspecific relationships in Hulunbuir Meadow Steppe

Guoqing Wang

Heilongjiang Bayi Agricultural University

We selected 17 species according to important values in each plot, using variance ratio to analyze the overall association. The χ^2 test with 2 × 2 contingency table, Ochiai index and PC were applied to analyze the inter-specific associations of dominant and companion species. The results indicated that the community was insignificantly negative correlation inside exclosure, the community was insignificantly negative correlation outside exclosure. The χ^2 test that the proportion of positive and negative correlation in the inside exclosure is below the outside exclosure, and the community is not stable inside exclosure. The Ochiai index is consistent with the PC trend in the inside exclosure and outside exclosure. The maximum value of Ochiai index and PC appears in the *Cleistogenes squarrosa* and *Leymus chinensis, Cleistogenes squarrosa* and *Poa sphondylodes, Leymus chinensis and Poa sphondylodes.* The advantage of dominant species is obvious in the inside exclosure. The Ochiai index and PC of dominant species inside exclosure is lager outside exclosure.

Study on plant niche of Hulunbuir meadow steppe under enclosure

Guoqing Wang

Heilongjiang Bayi Agricultural University

To study the niche characteristics of meadow steppe, The meadow steppe were monitored using the method of sampling in field investigation. The plant height, coverage, density and aboveground biomass were measured. The calculation of the niche breadth of Levins and Pianka's niche overlap is used. The results showed that the niche breadth of *Leymus chinensis, Poa sphondylodes* Trin, *Cleistogenes squarrosa* (Trin.) Keng were the largest in enclosure. The maximum of niche overlap was between *Cleistogenes squarrosa* (Trin.) Keng and *Poa sphondylodes* Trin. The niche overlap of *Cleistogenes squarrosa* (Trin.) Keng, *Poa sphondylodes* Trin, *Bupleurum chinense* DC. were the largest outside enclosure. The maximum of niche overlap was between *Galium verum* L. and *Potentilla acaulis* L. The forage of *Gramineae* was the adequatest in enclosure.

A251

Niche dynamics of dominant species during restoration process of meadow steppe in enclosure

Guoqing Wang, *Guangming Du*

College of Animal Science & Veterinary Medicaine, Heilongjiang Bayi Agricultural University

The niche dynamics during restoration process of dominant in enclosure meadow steppe of Hunlunbuir were analyzed by means of niche breadth index and niche overlap index. The results showed that the total breadth of niche of *Leymus chinensis, Poa sphondylodes, Cleistogenes squarrosa* were higher other species. *Poa sphondylodes, Leymus chinensis, Allium neriniflorum, Leymus chinensis* were the species with the largest niche breadth for the restoration stage of 1, 3, 5 and 7 years respectively. The niche breadth of *Leymus chinensis* has been higher. The niche breadth of *Poa sphondylodes, Cleistogenes squarrosa* was gradually decreased. There was a trend that the niche breadth of *Allium neriniflorum, Serratula centauroides, Caragana microphylla* increasing with increasing degree of community restoration. The dominant position of Gramineae decreased. There were linear relationships of between niche breadth and niche overlap. The interspecific competition was increased with enclosure. Then, the interspecific generated niche differentiation and competition was decreased. The develop of community towards stable state.

Anatomy stem of species of moss from the source area of Urumqi river

Hong Wang, *Abuduaini Aifeire, Zhen Yan Yuan, Yong Man Lu*

Xinjiang University

The moss plants belong to 13 families, 19 genera and 37 species were gathered from the source area of Urumqi river. The stem structure treated paraffin sectioning was observed by scanning electron microscopy (SEM). It exits the obvious differences among the different families and genera, The stem of most species has a cellular layer with different length epidemic cell, but there are a little significant differences among the same genera different species, For example, *Ditrichum flexicaule., Distichium capillaceum* and *Distichium inclinatum* belong to the same family, although there are many similarities on their stems. But, there are a lot of differences of their stems, the epidermal stem cell wall of *Ditrichum flexicaule* is smooth and the different levels of depression, which has a variety of irregular decorations on surface, the cell walls of outside and inside cortex are thickened strongly, the small parenchyma cells which crowded into a small ball form the axis. For *Distichium capillaceum*, the outer wall of the epidermis is thin and inward concave strongly, there are a large number of particles and the small pores on the surface, the endothelial cell wall is relatively thin. Compared with the former two species, *Distichium inclinatum* has different characters on stem: epidermal stem cells studded a small amount of grain arrange irregularly, axis cells are much bigger, arrange mosaic. Thus, these micromorphological structure as one of the classification basis, and characteristics of cold and arid resistant. For example, stem epidermis cell walls are strong, the cell wall is rough, When the weather was dry the cuticle layer wrinkled, cortex cell is large, axis the cell wall corner is thickened *etc.*, and it is better to understand how these mosses to adaption the extreme environment, it can provide some reference to study the structure of the stem cells in the extreme cold environment. Therefore, it is helpful to the further research on the cell genetic and physiological ecology.

Leucospora multifida—A new invasion species in China

Ying Wang, *Ruifang Gao, Daojian Yu, Dongmei Chen, Caiyu Xiang, Heqing Huang, Jun Wang*

ShenZhen Entry-Exit Inspection and Quarantine Burea

In 2014, a new invasion species that had never been recorded in China, *Leucospora multifida* (Michx.) Nutt. (Narrow-leaf paleseed, cleft conobea), was found in the gap on wharf hardened cement ground used for the import of bulk raw grains in Shenzhen. *Leucospora multifida* (Scrophulariaceae) is the only specie of Genus *Leucospora*. The probability of entry is high. The plant of *Leucospora multifida* is native to southwest of United States. It is now found in the central and eastern states of US, including Florida. It was also been recorded in southeast of Canada. This plant is suitable for the shade, sufficient sunlight and the moist environment. The muddy, sandy, gravel and rock soil are also prefer to growing. The plant is annual herbaceous, short, erect, with the height of 5.0~21 cm and much branches. There are full of sticky glandular pubescent on stem, leaf, flower stalk and sepal. Terete, green or purple tinged with green of the stems. Although the plant is short, the root system is flourishing with as far as over 30 roots of a well growing individual. Each root plunged into the ground and then a number of radicular grow. The roots range cover an area of more than 1 m^2, which are firmly into the soil or cement cracks in the ground. A plant could produce lots of seeds. Each blade (opposite or juniors) has two flower leaf axils or two capsules, each capsule containing 60~90 seeds. The probability of establishment is high. This plant reproduce mainly by seeds, the seeds are as small as dust. The surface of the seed is sticky so as to be attached to waterfowl and poultry (such as duck, goose) wet feathers, which could be also mixed in bulk grain or with soil during long-distance communication of plantlet. The seed could spread by wind and rain, or in the mud with the movement of person, vehicles and animals. The probability of spead is high. According to the pest risk assessment, the pest introduction risk of the invasive species is concluded as a high level.

A unique method to trace the dynamic expansions of *Spartina alterniflora*

Yaqian Wu[1], *Xiangming Xiao*[1,2], *Bangqian Chen*[1]

1. Institute of Biodiversity Science, Fudan University, Shanghai, China

2. Department of Microbiology and Plant Biology, Center for Spatial Analysis, University of Oklahoma, Norman, USA

Biological invasion seriously affects the local ecosystem balance, causes a certain threat to ecological security. Three types of Landsat images were embedded in MODIS pixels which were selected by three observation points. Combined with history and field survey data, there were all beaches in each MODIS pixel in 1984 until *Spartina alterniflora* was naturally expanded. *Phragmites australis* and *Suaeda salsa* also live in this wetland. Comparing with spectral indices, *Spartina alterniflora* has a longer growth cycle and higher productivity than *Suaeda* and Reed. This is one reason why it has spread so fast here. From 1990-2000, *Spartina* showed a quick invasion trend, the rate is ranging from 15.5% to 44.4%. After that, two inland MODIS pixels have changed to pure *Spartina* pixels, while the other one which is near the coast completely was expanded in 6 year ago.

Phylogeography and evolution of *Quercus delavayi* from subtropical evergreen broad-leaved forest in Yunnan Plateau

Jin Xu, *Min Deng*

Shanghai Chenshan Botanical Garden/Shanghai Chenshan Plant Science Research Center, Chinese Academy of Sciences

Quercus delavayi is a character/dominant element of subtropical evergreen forests in Yunnan Plateau. This species provides an ideal model system to examine Late Tertiary/Quaternary phylogeography in relation to ancient geological and climatic events in Yunnan Plateau. In this study, we selected 33 populations of *Q. delavayi*, 314 individuals, using three chloroplast DNA (cpDNA) intergenic spacer regions (*psb*A-*trn*H, *pet*G-*trn*P and *trn*T-*trn*L) to do phylogeographic analyses, discussing the population genetic structure and genetic diversity level of this species. The results show that *Q. delavayi* has high genetic diversity (H_T = 0.907) and high genetic differentiation (G_{ST} = 0.782, N_{ST} = 0.912, $P<0.05$). The phylogenetic analysis revealed two major haplotype lineages (North-central Yunnan vs. Northwest Yunnan and South Yunnan). The fossil-constrained BEAST analysis revealed that haplotype divergence began at late Miocene. The topographic changes related to the uplift of Yunnan Plateau might play a significant role on intraspecific divergence of *Q. delavayi*. This species occupied multiple refugia during the Pleistocene glacial periods. The combined effects of paleogeomorphological and climatic changes of the Cenozoic have had profound impacts that shaped the extant distribution of *Q. delavayi*.

Super absorbent polymer seed coatings promote seed germination and seedling growth of *Caragana korshinskii* in drought

Liqiang Su, Jiaguo Li, ***Hua Xue****, *Xiaofeng Wang**

National Engineering Laboratory for Tree Breeding, College of Biological Sciences and Biotechnology, Beijing Forestry University, Beijing, PR China

Coating the seeds with water absorbent materials could improve their survival, especially for those planted in drought or barren area. In this study, effects of five kinds of super absorbent polymers (SAPs) on seed germination and seedling growth of *Caragana korshinskii* under drought condition were investigated. Our results showed that SAP coatings could significantly improve the percentage and energy of seed germination, as well as reduce relative electrical conductivity (REC), proline, MDA, H_2O_2 content and POD activity during germination. These results implied that seeds could uptake moisture from SAP coatings to alleviate drought-induced oxidative stress and membrane damages, thus exhibit a better vigor and germination performance. Meanwhile, after coating *C. korshinskii* seeds with SAPs, more seedlings emerged and grew better. Under the combined influence of water absorption capacity of SAP and other factors, the efficiency of five SAP coatings are in the sequence of D > E > B > A > C. Moreover, the function of SAP coating on promoting seedling survival was confirmed in Mu Us Sandy Land. The average seedling number of SAP D coated seeds increased to two folds of that of naked seeds. Our results are expected to be helpful on understanding and utilizing SAP seed coatings in improving plant survival under drought conditions.

Effect of mulching on root-zone soil environment and physiological traits of young apple trees

Ping Huang, Ruixue Zhang, Hui Cao, ***Hongqiang Yang***
College of Horticulture Science and Engineering, Shangdong Agricultural University

Soil surface mulching was one of important method to promote sustainable production in orchard system by stabilizing the soil environment. The experiment explored the variation of the moisture, temperature and available nutrients in root-zone, root architecture and nitrate metabolism transformation, leaf photosynthesis and transpiration, leaf water use efficiency (WUE) and plant growth using three-year old potted apple trees (*Malus domestica* cv. *Starkrimson*) mulched with straw mat, agricultural carpet, transparent-plastic film and horticultural fabric. The results showed that soil moisture, temperature, new root volume, root fractal dimension and root activity increased significantly by mulching the above 4 materials. The increment of relative water content in the soil mulched with straw mat and horticultural fabric was largest. Straw mat and agricultural carpet made the soil temperature more stabilized. Four treatments all enhanced the stability of soil pH and increased the content of soil organic matter, alkali-hydrolyzable N, available P and available K. The root fractal dimension was the highest and root structure was more complex after mulching straw mat, the root diameter, root volume and surface-area were the largest and the roots were thick and strong after mulching agricultural carpet; the total root length and root activity the highest after mulching transparent-plastic film; the number of root tips was the most after mulching horticultural fabric. There were significant seasonal differences in the effects of four treatments on root nitrate metabolism transformation. The activity of root nitrate reductase (NR) and nitric oxide synthase (NOS) and the production rate of nitric oxide (NO) were significantly increased in the late summer and the early winter; and the effect of straw mat was the most significant on them, while the transparent plastic film decreased them significantly in late summer. In the Mid-autumn, all the four mulching treatments increased the activity of root NR and NOS, while horticultural fabric increased root NO production. During the whole treatment, the four mulching treatments promoted the new shoots growth and stem diameter enlargement, in which the straw mat and the horticultural fabric were more effective in promoting plant growth, while transparent plastic film with minimal effect. For the comprehensive effect of the 4 mulching materials on soil, root and leaf, the order of beneficial degree was straw mat, agricultural carpet, horticultural fabric and transparent-plastic film from high to low.

Camellia japonica (Naidong) under different illumination and nitrogen deposition of physiological ecology response

Jikai Yang
Qingdao Agricultural University

Global climate change, including the change of illumination and nitrogen deposition, *etc.*, are growing, this paper studies different illumination and nitrogen deposition on *Camellia japonica* (Naidong) of the morphological index, chlorophyll content and chlorophyll fluorescence characteristic, the influence of the gas exchange characteristics and physiological ecology characteristics. Will help to understand and predict the impact of climate change on winter resistance camellia, to better adapt to the environment and provide a theoretical basis for protection. The research results show that the plant height (H), base diameter (BD), the crown (CA), specific leaf area (SLA) and water content (LWC) is not affected by nitrogen and nitrogen and light interaction effects, under the light and the interaction of the nitrogen morphological indicators of winter *Camellia* resistance with the increase of number of days on the rise, the same with fewer illumination, under the condition of nitrogen morphological indicators of winter camellia resistance drops, also showed the low light to its growth has certain inhibitory effect, but the L1 morphological indexes were higher than in L2. Part of the gas exchange parameters affected by illumination, nitrogen deposition, and the interaction was significant. Winter resistance of camellia vapor pressure deficit (VPD) by nitrogen deposition, illumination and the effects of the interaction of the two significant, net photosynthetic rate (A), transpiration rate (E) significant difference under nitrogen deposition and lighting effects, but no significant difference under the two interaction, water use efficiency (WUE) in significant difference under the influence of nitrogen deposition, no significant difference under the light and the interaction between the two. L2 winter resistance under low illumination camellia chlorophyll than L1 illumination condition, but Chla/Chlb above L2, chlorophyll, the only significant difference under the light conditions, under nitrogen deposition and the interaction between the difference was not significant. L2 winter camellia resistance under variable fluorescence (Fv), maximum fluorescence (Fm), PS II photochemical efficiency (Fv/Fm) and PS II potential active (Fv/F0) values are higher than that of L1, and initial fluorescence (F0) value, on the other hand, all the chlorophyll fluorescence parameters of the plants were very significant differences only under the effect of light, and under the light and the interaction between the two was not significant.

Differential effects of plant identities on soil nematode community in a coal gangue mountain

Zaichao Yang*, Fei Xie, Jinghui Zuo, Hong Xiang, Xuying Wang, Wen Liao, Shiming Han*
Liupanshui Institute of Biology, Department of Life Science, Liupanshui Normal University

Coal gangue is a low combustion value and commercially worthless rock during mining. Some different plant mosaics have grown in surface soil of the accumulative coal gangue, however, few studies about how soil community respond to these plant mosaics. Here, we investigated if plant mosaics effect on soil nematode community are mediated by plant or other soil factors. We showed that nematode diversity was maximal at both legume (*Trifolium repens*) and grass (*Setaria viridis*), and nematode diversity was minimal at ruderals (*Plantago asiatica* and *Taraxacum mongolicum*). In addition, nematode diversity was positively related to litter biomass and soil moisture and was negatively related to pH. In functional groups of nematode community, the amount of bacterial-feeder, carnivores and omnivores was most abundant at legume, and that of plant-feeder was most abundant at grass, and that of fungal-feeding nematodes was most abundant at ruderals. Using a structural equation model, we explained 62% of the variance in soil nematode community, identified direct and indirect effect paths, and showed that the different groups of plant accounted for approximately three-fifths of the explained variance. We conclude that plant identity may be a key mediator in regulating soil community diversity.

Re-analysis of transcriptome data reveals effects of salt and drought stress on regulatory gene expression in xerophyte *Zygophyllum xanthoxylum*

Meng-Zhan Li, Qing Ma, Wei Li, Suo-Min Wang, ***Hong-Ju Yin***

Lanzhou University

Zygophyllum xanthoxylum is a succulent xerophyte species with remarkable tolerance to diverse abiotic stresses. Previous studies have preliminarily revealed physiological mechanisms of *Z. xanthoxylum* in response to abiotic stresses. Furthermore, our transcriptomics study has identified many potential functional genes which may directly involve in salt and drought tolerance in *Z. xanthoxylum*. However, the upstream regulators of these functional genes and the molecular mechanisms are still elusive. In the current study, we re-analyzed the transcriptome and digital gene expression profiling data of *Z. xanthoxylum* roots during 50 mM NaCl (salt) and -0.5 MPa osmotic (drought) treatments. Among the total 6,258 and 6,063 differentially transcribed genes, a lot of regulatory genes were up- or down-regulated in response to salt and drought respectively, including those encoding transcription factors (TFs) in various classes (Such as NAC, WRKY, AR2/ERF, MYB and bHLH), protein kinases and phosphatases, and genes associated with protein turnover (such as ubiquitination and sumoylation enzymes encoding genes). To further extend functional characterization, we identified the orthologs of differentially expressed genes in the model species *Arabidopsis thaliana*, which then allowed us to perform in silico functional inference, including gene network analysis for protein function, protein subcellular localization and gene co-expression. The data reported here indicated the extensive potential regulatory events of salt and drought tolerance in *Z. xanthoxylum*, and will shed new light on the molecular mechanisms of stress tolerance of the xerophyte plant species.

Salt accumulation of vegetative organs and ecological stoichiomery characteristics in typical halophytes in Xinjing, China

Yanhua Yong*, Xia Zhang, Shaoming Wang, Meilin Ren, Meilin Yang, Yuan Liu, Zhiyong Zhang*

Shihezi University

Aims: Study on the salt accumulation in vegetative organs and C, N, P stoichiometry in halophytes contributes to understanding the adaptive strategy to the saline environment and the distribution mechanism of nutrients and salinity of the halophytes. *Methods:* Four typical dominant species, including three perennial shrubs (*Halocnemum strobilaceum*, *Suaeda microphylla* and *Kalidium foliatum* and an annual herb (*Salicornia europaea*) were selected for analyzing the salt accumulation and C, N, P stoichiometry, as well as their relationships. *Important findings:* 1) The salt accumulation appeared "salt island" effect at vigorous stage, because Na$^+$, Cl$^-$ and EC showed significant positive trends, when salt ions transported from the root to the top of 4 halophytes. 2) P was growth restrictive element of perennial shrubs during their growth and development, while both N and P were restrictive factors for annual herb. 3) Organs, species and their interactions affected C, N, P stoichiometry and salt icons except Mg^{2+}. 4) C was negatively correlated with N and P, but there was a significant positive correlation between N and P. 5) EC, Na$^+$ and K$^+$ were positively correlated with N, N:P and negatively correlated with C, C:N and C:P, and yet K$^+$, CO$_3^{2-}$ had significant positive correlation with P. These results implied that there was some kind of mutual promoting relationship between nutrients and salinity in halophytes dealing with the saline environment, and fertilizing with N can promotes sodium chloride saline soil desalted.

De novo assembled and characterization of the transcriptome response to cadmium in Cosmos (*Cosmos bipinnatu*s cav.) roots

Xiaofang Yu*, Yi Wang, Yujing Liu, Jian Zeng, Xing Fan, Lina Sha, Houyang Kang, Haiqin Zhang, Yonghong Zhou*

Sichuan Agricultural University

Cadmium (Cd) causes damages to various plants, while some plants have unique detoxification and metal transport mechanism to reduce Cd toxicity. In present study, *Cosmos bipinnatus* cav. could be regard as "Cd accumulation plant" and have potential for phytoextraction. Therefore, physiological and transcriptome analyses were carried out. In this study, *C. bipinnatus* accumulated 60.36 ± 1.67 μg g^{-1} Cd in leaves, 321.15 ± 16.04 μg g^{-1} Cd in stems, and 576 ± 41.48 μg g^{-1} Cd in roots under 40 μM Cd treatment, but showed no obvious symptom response to Cd. Subcellular distribution analysis indicated that vacuole is the predominant sink for Cd sequestration in roots while cell wall can be another large part of Cd accumulation at high concentration of Cd exposure (120 μM). In addition, the result of transcriptome showed that 66,407 unigenes was assembled and 41,674 (62.75%) of the unigenes were annotated in at least one database, 40.16%

of total annotated unigenes were longer than 1,000 bp. Moreover, compared with CK, the total of 3,814 unigenes including 2,067 up-regulated unigenes and 1,747 regulated unigenes were regulated by Cd. RT-qPCR showed that the expression profiles of differentially expressed genes (DEGs) were in consistent with results from RNA-Seq analysis. Among these DEGs, we found several candidate genes encoding *ZIPs*, *ABC transporters*, *HMA2*, *HMA3*, *NRAMP2*, *NARMP3*, *GST*, *Grx* and peroxidase were response for Cd influx, accumulation, transportation and detoxification in *C. bipinnatus*. These results provide a novel insight into characterization of the transcriptome response to Cd in *C. bipinnatus*.

Methane uptake dependent on biotic factors rather than precipitation, warming and nitrogen deposition in a temperate desert

Ping Yue[1], *Xiaoqing Cui*[2], *Fengzhan Geng*[1], *Wenchao Wu*[1], *Kaihui Li*[1], *Yanming Gong*[1], *Xuejun Liu*[2]
1. Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences
2. China Agricultural University

Climate change and elevated nitrogen (N) deposition play vital roles in the balance of the atmospheric methane (CH_4). However, information on the response of CH_4 uptake to elevated precipitation, temperature and N deposition in temperate deserts is still scarce. An *in situ* field experiment was conducted to investigate the effect of simulated precipitation, warming and N deposition on CH_4 uptake in the Gurbantunggut Desert, northwest China, from September 2014 to October 2016. The results showed that the Gurbantunggut Desert was a weak sink for CH_4 (0.92 kg C ha^{-1} yr^{-1}) and non-growing season accounted for 28.04% of annual CH_4 uptake. Our research was different from some previous studies which reported a strong sink for CH_4 in desert soil. Treatments with increased precipitation (30% or 60 mm yr^{-1}) increase and low N deposition elevation (30 kg N ha^{-1} yr^{-1}) significantly enhanced soil CH_4 uptake, while no significant impact on CH_4 uptake by warming and higher N deposition (60 kg N ha^{-1} yr^{-1}). Therefore, the sink of CH_4 in temperate desert was not significantly impacted by warming, increased precipitation and N deposition. However, we found that biotic factors could explain CH_4 uptake by 48.8%, while only 10.4% contribution was by environmental factors. The results indicate that CH_4 uptake was mainly controlled by biotic factors (such as plant biomass, microbial biomass carbon and microbial biomass N) and was not sensitive to elevated N deposition and precipitation and warming in this temperate desert.

Energy flows and biodiversity in a model ecosystem

Fanqi Zeng, *Wenxu Wang, Jiang Zhang*
School of Systems Science, Beijing Normal University

Climate change has been caught great attention. Ecological systems coevolve with climate systems. Thus, understanding the intrinsic dynamics of ecological systems is of paramount importance for exploring and predicting climate change. Food chains, as a systematic and simplistic model, have been a paradigm for investigating the long term evolution of ecological systems in virtue of the dynamical analysis on the inter-play between the topology and the dynamical processes occurring on a food chain. We build a food chain model by considering energy exchanges among species, which is characterized by using population dynamical equations. We will compare our model with existent food chain models based on sufficiently empirical data. Our work is expected to be able to quantitatively capture and describe the interactions among species with respect to energy exchange, then deepen the understanding of ecological systems and their coevolution with climate change.

The elevational gradient of mountain deciduous forests, patterns and reasons

Chao Zhao[1,2], *Baiping Zhang*[1,2], *Jing Wang*[1], *Jing Wang*[1], *Yonghui Yao*[1]
1. State Key Laboratory of Resource and Environmental Information System, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing
2. Jiangsu Center for Collaborative Innovation in Geographical Information Resource Development and Application, Nanjing

The thermal gradient along elevational are more compact than the latitudinal, together with the variety of topography, inclination, aspect, and the diverse precipitation conditions, making the mountain vegetation patterns more complex. Vegetation zonation is an easy way to assess the pattern of vegetation along elevational gradient. Most of the previous studies took a zonal belt as homogeneous one, neglecting the gradient inside. Some researchers found that the distribution range along elevation of one species can be divided into the upper zone, core zone and lower zone through detailed investigation, the upper and lower zone are pioneer communities, while the core zone is climax communities. A vegetation belt is zoned by the dominant species, thus it can be divided into three zones likewise. Typical ecological parameters (dominant species, tree heights, diameters at breast height (DBHs), coverage) of deciduous forests (800-1,600 m a.s.l) on Mt. Baotianman (1,820 m a.s.l, 33°25’~33°33’N, 111°53’~112°E), Henan Province, China was studied to understand the gradient inside of deciduous broad leaf forest. Both the tree heights and species richness showed a hump-shaped cure as altitude increases, which reached the highest height of 15-16 m at the elevation of around 1400 m. The core zone of mountain deciduous forests turn out to be the elevation between 1300-1400 m. Mass effect (or Source–Sink effect), Mid-Domain Effect (MDE), may be applied to explain the distribution pattern inside a zonal belt. This research promoted our understanding of the distribution patterns of vegetation along elevational gradient.

The photosynthetic characteristics and growth response of *Photinia frasery* ‘Rubens’ seedlings to municipal sewage sludge application

Guangqizhao Zhao

Shanghai Botanical Garden

A potted experiment was conducted to study the effects of municipal sewage sludge application on *Photinia frasery* ‘Rubens’ growth and photosynthetic characteristic. The results showed plant height, stem basal diameter, and biomass of the *Ph. frasery* seeding significantly increased with sewage sludge application, with 5.0% sludge treatment the maximum. All of the contents of chlorophyll a and chlorophyll b in leaves of *Ph. frasery* ‘Rubens’ tended to increase with the increase of sewage sludge dosage, and the contents of chl a increased faster than that of chl b. The chl a/b showed an increase tendency, whereas the net photosynthesis rate (*Pn*) and transpiration rate (*Tr*) in leaves showed a decrease. Compared with control, the 7.5% sludge treatment led to a decrease in *Pn* by 49.13%, and the *Tr* treatments of 2.5%, 5.0% and 7.5% decreased by 15.67%, 5.07%, and 21.20%, respectively. The stomatic conductance (*Gs*) reached an increase by 17.98% at 5.0% treatment compared with control. The intercellular CO_2 concentration (*Ci*) came to a climax at 7.5% treatment, increased by 28.96% compared with control and by 11.28% compared with 5.0% treatment. Basically intercellular CO_2 concentration (*Ci*) increased with the increase of sewage sludge dosage. The average and maximal value of net photosynthesis rate (*Pn*) in August increased to the maximum in different seasons after sewage sludge land application. The maximal value of stomatic conductance (*Gs*) and transpiration rate (*Tr*) decreased with the season.

Biomass increment and mortality losses in tropical secondary forests of Hainan, China

Jun-Fu Zhao
Hainan University

Secondary forests after severe logging are important part of China’s forests. We investigated the forest biomass and its accumulation rate of a tropical secondary forest through 38 plots in Hainan Ialand, China. These secondary forests are moderate carbon sink with averaging on 1.96~2.17 tC ha^{-1} yr^{-1}. Biomass increment is majorly contributed by medium size (10~35 m) trees which differ from selective logged forest in Amazon. Tree morality account near 30% of the biomass increment and plays an negligible role in biomass accumulation estimation. Tree mortality rate is highly dependent on tree size. High mortality rate in small trees and seedlings might be related to enforced competition due to elevated irradiance after logging. In the perspective biomass and its accumulation, tropical forest is fragile to logging campaign and need careful forest management.

Separate and combined effect of UV-B radiation and drought on the growth and physiology in *Artemisia sphaerocephala*

Yuanyuan Zhao*, Lijing Zhang, Xiumei Miao, Xiaolong Chen, Xiaowei Hu, Shuzhen Nan, Pengfang Yang, Guoqin Duan, Hua Fu*
College of Pastoral Agriculture Science and Technology, Lanzhou University

In natural world, plants are often affected by synthetic effect of various abiotic stresses. In this study, using *Artemisia sphaerocephala* as material, the effect of compound treatment of UV-B radiation and different level of drought stress was investigated. Results showed that plant height and biomass decreased, relative conductivity (REC) and malondialdehyde (MDA) increased when compared with CK in all treatments, except for the compound treatment of light drought stress and UV-B stress (LD + U). Under individual treatment, severe drought stress (SD) possessed less value on plant height and biomass as compared with light drought stress (LD) and UV-B stress (U), while value of REC and MDA exceeded LD and U. These results suggested that SD had the most remarkable effect of inhibiting growth in *A. sphaerocephala*. Under compound stress, plant height and biomass were significantly increased, whereas the value of REC and MDA were obviously decreased in both LD + U and the compound treatment of severe drought stress and UV-B stress (SD + U). This result indicated that additive UV-B would remit the damage which caused by drought in *A. sphaerocephala*. In addition, U had the significantly relaxative effects whether in LD or SD, and could lay the foundation of further study in the interaction mechanisms of these two environment factors.

Response of biological soil crust coverage to wind-blown sand burial during the succession of artificial sand-fixing vegetation in the Tengger Desert, Northern China

Yun Zhao[1,2]*, Rongliang Jia*[1]*, Jialing Teng*[1,2]*, Wenxiong Jia*[3]
1. Shapotou Desert Research and Experiment Station, Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences
3. Northwest Normal University

In artificially constructed desert ecosystems, the formation and development of a biological soil crust (hereafter crust) is one of the key indicators of successful construction of artificial sand-fixing vegetation. Importantly, with the successional progression of sand-fixing vegetation, the crust coverage undergoes substantial changes related to surface stabilities. Furthermore, surface stabilities crucially influence both the succession of sand-fixing vegetation and changes in crust coverage. Therefore, crust coverage is commonly used as a visual indicator to assess surface stability in a desert ecosystem. However, crust coverage is susceptible to sand burial (one of the common natural disturbances in desert areas) due to both its soil surface inhabitation and small stature. In order to study the characteristics and mechanisms of the response of crust coverage to sand burial during the succession of artificial sand-fixing vegetation, we used a space-replacing-time method to measure the roughness, heights, and coverage of four dominant crust types following sand burial. Furthermore, based on this, we computed the D1 value [the initial sand burial depth at which crust coverage (from 99.99%) begins to decline] and the D2 value (the threshold sand burial depth at which crust coverage declines to 0%). These crusts consist of *Bryum argenteum* crust, *Didymodon vinealis* crust, *Syntrichia caninervis* crust, and cyanobacteria-lichen-moss mixed crust in revegetated areas established in 1956, 1973, 1981 and 1987 at Shapotou, on the southeastern edge of the Tengger Desert. Our results show the following patterns. (1) With increasing sand depth, crust coverage declined along a logistic curve. (2) The mixed crust showed the lowest D1 value and the highest D2 value. Among the three moss-dominated crusts, the lowest D1 and D2 values were found in *B. argenteum* crust, whereas the D1 and D2 values of *D. vinealis* crust and *S. caninervis* crust differed depending on the history of the artificial revegetation: *D. vinealis* crust < *S. caninervis* crust at revegetated area established in 1956, and *S. caninervis* crust < *D. vinealis* crust at revegetated areas established in 1973 and 1981. (3) With successional progression of the artificial sand-fixing vegetation, the lowering rate of crust coverage gradually declined with increasing sand depth, whereas D1 and D2 values gradually increased. (4) With the development of the artificial sand-fixing vegetation, the lowering rate of crust total coverage gradually declined with increasing burial depth, indicating the increasing surface stabilities and ability to resist sand burial. (5) With successional progression of the artificial sand-fixing vegetation, the crust heights and roughness increased, significantly influencing the lowering rates of coverage and D1 and D2 values. In conclusion, our findings should provide strong support for future evaluation of the influence of sand burial on the structure and functions of crust, as well as the stability of artificial sand-fixing vegetation.

Impact of different vegetation on the emission of soil greenhouse gas and soil microbial activity

Jihai Zhou[1], *Jiyong Zheng*[2], *Fengpeng Han*[2], *Houbao Fan*[1]

1. Nanchang Institute of Technology

2. North West Agriculture and Forestry University

Different vegetation types change the soil environment to different extents, influencing the biogeochemical cycles. At present, many researchers are investigating the relationship between vegetation and microbial activity in natural ecological systems to provide a theoretical basis for ecological restoration in the area. Here, the effect of vegetation types on soil greenhouse gas emission and soil microbial activity was investigated in Guyuan, Ninxia Hui Autonomous Region. Soil samples were collected from different layers of soil (0-10, 10-20, 20-30 and 30-40 cm) for each of five typical vegetation types, including four artificial vegetations: *Medicago sativa*, *Prunus sibirica*, *Hongmei apricot*, *Caragana microphylla*, and one natural grassland. The results showed that soil greenhouse gas emission and microbial activity were varied in the five types of vegetations. Overall, the emission of soil CO_2, N_2O and the adsorption of CH_4 all decreased with the depths of soil. The maximal CO_2 emission occurred in natural grassland, while the minimum in *Caragana microphylla* land; the maximal N_2O emission occurred in *Hongmei apricot* land, while the minimum in *Medicago sativa* land; the maximal CH_4 adsorption occurred in natural grassland, while the minimum in *Medicago sativa* land. Compared with the natural grassland, the soil CO_2, N_2O emission in the four artificial vegetations were about 43.2%-74.9% and 82.5%-138.6%, the soil CH_4 adsorption in the four artificial vegetations decreased by 42.5%-71.1%, and the activity of soil flourescein diacetate (FDA) hydrolysis, alkaline phosphatase, urease and invertase in the four artificial plantation recovered by 50.0%-67.1%, 50.9%-91.2%, 61.9%-80.2% and 35.0%-92.6%. Further research is still required to explore soil greenhouse gas emission and its microbial mechanism in the processes of vegetation change.

Modeling the geographical distribution pattern and dominant climatic factors of *Cerasus schneideriana*

Hong Zhu, *Yong-Fu Li, Hua-Chen Wang, Yi-Fan Duan, Xian-Rong Wang*

Nanjing Forestry University

Cerasus schneideriana is an endemic species of cherry tree in East China, whereas its natural habitats were threatened and fragmented under climate change scenario as well as many other reasons. To understand the relationship between geographical distribution pattern of *C. schneideriana* and its dominant climatic factors on the regional scale, the DIVA-GIS software and the BIOCLIM model were jointly applied to predict the present and future potential spatial areas on the basis of actual distribution points. The results showed that *C. schneideriana*'s actual distributions covering 6 provinces of East China, including Zhejiang, Fujian, Anhui, Jiangxi, Guangxi and Hunan. The natural distribution center was located in mountainous areas of Zhejiang-Fujian border, and the north boundary was arrived at Zhejiang-Anhui border. Under future climate change situation (CCM3), the probability of potential areas of *C. schneideriana* were increased, and had a tendency to the north expansion. The principal component analysis (PCA) reveled the annual precipitation (bio12), precipitation of the driest quarter (bio6), precipitation of the warmest quarter (bio18) and temperature seasonality (bio4) were the dominant factors for geographical distribution of *C. schneideriana*. The frequency histograms further showed the factor's optimum range were 1,503~2,003 mm, 604~951 mm, 528~791 mm and 601~872 (SD*100) respectively. Evaluation by the ROC curve proved the BIOCLIM model predicted the distribution accurately (AUC = 0.998) and reliably. Therefore, our research revealed that *C. schneideriana* were suited to live in north subtropical region of China, with warm and humid condition, water and heat were the two key climatic factors to the distribution pattern.

Decomposition of phenolics in *Polygonum viviparum* litter on an alpine meadow

Wenzhen Zong, ***Jing Wang***, *Jing Gao, Yongsheng He*

College of Pastoral Agriculture Science and Technology, Lanzhou University

Phenolic compounds are widely distributed in higher plants as secondary metabolites, and they play an important role in nutrient cycling through litter decomposition. Most of the studies on phenolic decompositions in litter were conducted in forest ecosystem, whereas how the characteristics of alpine ecosystems affect phenolic decomposition is barely known. In addition, the report on the structural change of condensed tannins during litter decomposition is very limited. In this study, a phenolic-rich plant, *Polygonum Viviparum*, on an alpine meadow in the Qinghai-Tibetan Plateau in China was selected as the research object. Phenolics and condensed tannins in litter during different decomposition stages were extracted, purified and identified to answer the two major questions: (1) Is the decomposition pattern of phenolics in litter in alpine ecosystems different from that in forest ecosystems? (2) Do low-molecular-weight phenolics and condensed tannins show dynamic structural changes during decomposition? A one-year litter bag experiment was conducted to investigate the decomposition dynamics of phenolics in *P.viviparum* litter. The content of total phenolics and condensed tannins in litter at different decomposition stages was analyzed. Low-molecular-weight phenolics and condensed tannins in litter were characterized with high performance liquid chromatography and mass spectrometer. The results showed that the content of total phenolics and condensed tannins displayed an overall decreasing trend during the decomposition process. During the early stage of decomposition, the loss of phenolic compounds could be attributed to degradation by soil microbes, which were protected by the snow cover in winter. During the middle stage of decomposition, however, the rapid loss of phenolics was mainly due to leaching, as the temperature and precipitation was elevated in the alpine growing season. This decomposition pattern was different from that in forest ecosystems, where leaching usually accounts for the loss of phenolics in the initial stage. The low-molecular-weight phenolics identified in litter included gallic acid, protocatechuic acid, chlorogenic acid, trans-ferulic acid and (+)–rutin. The monomer units of condensed tannins identified in litter included (–)–epicatechingallate, (–)–epicatechin and (–)–epigallocatechin as the extender units, and (+)–catechin, (–)–gallocatechin and (–)–epigallocatechin gallate as the terminal units. All of these phenolic compounds and monomer units of condensed tannins disappeared gradually from the litter and the emergence of new compounds was not observed. The decomposition pattern of litter phenolics in the alpine ecosystem was different from that in forest ecosystem, and the loss of phenolics during decomposition was mainly due to microbial degradation and leaching instead of chemical oxidation and polymerization. The results could help us to understand the role of phenolics in nutrient cycling in alpine meadows.

The modular nature of intraspecific trait variability: An experimental demonstration using a broad-niched herbaceous perennial species

Lauri Laanisto, *Tiit Hallikma*
Estonian University of Life Sciences

Although it’s commonly assumed that interspecific trait variation (ITV) contributes more to functional variability in plant communities than intraspecific variation, recent studies have shown that the latter can be as high or even higher under some circumstances. Several factors related to ITV are known to have significant effects on community assembly and species interactions. Yet, despite the significance of ITV having been emphasized in reviews, and its magnitude comprehensively analyzed in studies, general patterns of ITV are yet to emerge. Further research is necessary to systematically search for the mechanisms how ITV affects community and ecosystem processes. Majority of ITV-studies with plants have so far focused on measuring key functional traits for many species in conjunction, and in just one or few locations (typically communities). Our study examined ITV from a hitherto unexplored angle, proposing that ITV dynamics in plants could be explained by modularity concept. We propose that phenotypic plasticity in plants, which is the main source of ITV is usually expressed in subindividual level, which creates complex interplay between local responses and systemic control. In order to test the modular nature of ITV, our study focused only on one species: *Phacelia secunda*–widely-distributed common herbaceous perennial plant endemic to Chile. We measured a large number of traits throughout the whole bioclimatic range of its distribution. Both generative and vegetative traits were measured, and both abiotic and biotic environmental factors potentially governing the ITV of different traits were recorded. The species studied has a wide climatic niche, and occurs in habitats ranging from sandy beaches to mountain forests. It′s also known to be morphologically variable along climatic gradients. ITV responses of *Phacelia secunda* to abiotic and biotic factors showed differentiating patterns. Whereas abiotic factors (climatic factors) predominantly influenced vegetative traits of the structures that are responsible for resource gathering, biotic factors (diversity and abundance of surrounding vegetation) influenced generative organs, which translate acquired resources into fitness. These results strongly indicate that ITV has modular nature and different abiotic and biotic variables affect different plant organs differently. In our case climatic factors affected predominately the vegetative traits of *Phacelia secunda*, but biotic interactions from surrounding vegetation affected the generative traits. It remains to be tested whether this contrasting pattern is to be found with other species as well. Our study widens the perspective of ITV studies in several ways: Firstly, it′s based on measurements taken from populations from the entire distribution range of one broad-niched species, which gives the opportunity to assess ITV dynamics throughout a species’ full bioclimatic amplitude. Secondly, our approach was to measure as many functionally meaningful traits as possible. Thus, instead of trying to relate a specific functional trait and its variability to a specific environmental gradient, we were able to seek more general patterns in ITV. Thirdly, we measured both generative and vegetative traits, and tested ITV separately against abiotic and biotic factors.

A novel cotton WRKY gene, *GhWRKY6-like* improves salt tolerance by activating ABA signaling pathway and scavenging of reactive oxygen species

Abid Ullah, *Chen Lin, Heng Sun, Yang Xiyan, Zhang Xianlong*
National Key Laboratory of Crop Genetic Improvement, Huazhong Agricultural University

WRKY transcription factors are transcriptional regulators of signaling pathways involved in response to biotic and abiotic stresses. Hereby, we reported that ectopic expression of *GhWRKY6-like* gene significantly improved salt and osmotic stress tolerance in *Arabidopsis* while, silencing of *GhWRKY6-like* increased sensitivity to abiotic stresses in cotton. Expression of *GhWRKY6-like* was remarkably induced by abscisic acid (ABA), poly ethylene glycol

(PEG) and salt stresses. The *GhWRKY6-like* gene was cloned and transformed into *Arabidopsis* for further characterization. Our results showed that germination rate and root length was significantly improved in overexpressing *GhWRKY6-like* plants as compared to wild type (WT) plants under salt, mannitol and ABA treatments. And overexpressing plants showed higher salt tolerance than WT plants in soil. In addition, overexpressing plants accumulated less H_2O_2 and malondialdehyde (MDA), while higher proline content, superoxide dismutase (SOD) and peroxide dismutase (POD) activities were detected under drought and salt stresses. In contrast, virus-induced gene silencing (VIGS) of *GhWRKY6-like* in cotton showed enhanced sensitivity as compared to WT plants during salt and drought stresses. Moreover, expression analysis revealed that *GhWRKY6-like* enhance drought and salt tolerance by activating ABA signaling pathway genes. Our results revealed that *GhWRKY6-like* enhanced osmotic, drought and salt tolerance in *Arabidopsis* by scavenging of reactive oxygen species and regulating ABA signaling pathway. We suggest that overexpression of *GhWRKY6-like* gene in cotton will enhance tolerance against salt and osmotic stresses.

Floral nectary morphology and proteomic analysis of nectar of *Liriodendron tulipifera* Linn.

Yanwei Zhou[1,2*]*, Meiping Li*[1,2]*, Fangfang Zhao*[1,2]*, Hongguang Zha*[3]*, Liming Yang*[4]*, Ye Lu*[1,2]*, Guangping Wang*[1,2]*, Jisen Shi*[1,2]*, Jinhui Chen*[1,2]
1. Key Laboratory of Forest Genetics and Biotechnology, Ministry of Education, Nanjing Forestry University, Nanjing, China
2. Co-Innovation Center of Sustainable Forestry in Southern China, College of Forestry, Nanjing Forestry University, Nanjing, China
3. College of life and environment science, Huangshan University, Huangshan, Anhui, China
4. School of life science, Huaiyin Normal University, Huai'an, Jiangsu, China

Nectar is a primary nutrient reward for a variety of pollinators. Recent studies have demonstrated that nectar also has defensive functions against microbial invasion. In this study, the *Liriodendron tulipifera* nectary was first examined by scanning electron microscopy, and then the nectar was analysed by two-dimensional gel electrophoresis and liquid chromatography–tandem mass spectrometry, which led to identification of 42 nectar proteins involved in various biological functions. Bioinformatic analysis was then performed on an identified novel rubber elongation factor (REF) protein in *L. tulipifera* nectar. The protein was particularly abundant, representing ~60% of the major bands of 31 to 43 kDa, and showed high, stage-specific expression in nectary tissue. The REF family proteins are the major allergens in latex. We propose that REF in *L. tulipifera* nectar has defensive characteristics against microorganisms.

A531
Selfing species exhibit diminished niche breadth over time despite larger geographic ranges

Daniel Park*, Charles Davis*
Harvard University

A recent study demonstrated that self-pollinating plants ("selfers") have larger geographic ranges and inhabit higher latitudes than their outcrossing relatives. The authors hypothesized that for selfers, the increased likelihood of successful colonization in new areas and initial purging of deleterious mutations offset their associated inability to adapt to new environments due to low heterozygosity. They also raised the possibility that selfers may exhibit broader environmental tolerances. Here we demonstrate that selfers do not have wider climatic niche breadths than their outcrossing sisters. Selfing sister pairs exhibited greater niche overlap than outcrossing sisters as well, implying their niches are slower to diverge. Furthermore, the niche breadth of selfers is predicted to decrease significantly faster than closely-related outcrossers even as their range sizes increase. Finally, selfers displayed higher rates of mutation accumulation than their outcrossing sisters. These results collectively indicate the long-term cost of selfing despite their initial geographic range expansion.

Physiological responses of *Stevia rebaudiana* to PEG-induced drought stress in greenhouse culture

Shokoofeh Hajihashemi[1]*, Jan Geuns*[2]
1. Plant Biology Department, Faculty of Science, Behbahan Khatam Alanbia University of Technology, Khuzestan
2. Laboratory of Functional Biology, KULeuven, Heverlee-Leuven, Belgium

Plants frequently encounter unfavorable growth conditions. Drought is one of the major abiotic stresses that can disrupt cellular structures and impair key physiological functions. This study evaluated the physiological, antioxidant and growth responses of sweet medical herb of *Stevia rebaudiana* to drought stress-induced by polyethylene glycol (PEG 6,000, 0% to 15% w/v) treatment in greenhouse cultivation. Drought stress significantly decreased plants growth which was the consequence of a reduction in water content, photosynthesis pigments and carbohydrates biosynthesis. H_2O_2 generation increased in response to drought stress which subsequently resulted in lipid peroxidation and increase in malondialdehyde and electrolyte leakage. The ROS accumulation leaded to an increase in some non-enzymatic antioxidants (e.g. phenols, flavonoids, total amino acids, proline, α-tocopherol, glycine betaine, ascorbate pool) and the activity of some key antioxidant enzyme (e.g., catalase, ascorbate peroxidase, polyphenol oxidase, superoxide dismutase and peroxidase) to scavenge free radicals. The reduction of DPPH, $NO^{\bullet}$, $O_2^{\bullet -}$ and $OH^{\bullet}$ in the leaf extract of drought-stressed plants confirms the strong ROS scavenging properties of *Stevia*. Also, a significant increase in total antioxidant capacity (FRAP) of drought-stressed plants provide a hint at its antioxidant capacity. Collectively, our results demonstrated that reduction of *Stevia* growth and yield is the consequence of drought-induced oxidative stress, reduction of photosynthesis and carbohydrates biosynthesis, and membranes damage which lead to cell death. Hence more leaf biomass production with higher steviol glycosides is the major criterion for *Stevia* crop, sufficient irrigation is recommended to obtain higher yield.

Non-botanical approaches can fail to predict and classify wetland biological condition

Suneeti Jog[1], *Jason Bried*[2], *Xiao Feng*[3]
1. Northeastern State University
2. University of Arkansas
3. Oklahoma State University

Wetland biological integrity is continuously threatened by human activity. Impacts to biological health may be inferred directly (i.e. bioassessment), or estimated indirectly using rapid assessment or computer-based data layer analysis. Rapid buffer assessment is often used in lieu of intensive vegetation surveys which require considerable time and expertise. This study tests if rapid buffer assessment and surrounding land use can predict and classify wetland biological health as represented by floristic quality (FQ) and taxonomic distinctness (TD). Floristic quality is computed based on sensitivity of plants to human disturbance, while taxonomic distinctness takes species relatedness into account. From surveys of 106 non-forested wetlands in Oklahoma, we found a limited ability for land use and buffer quality to estimate site-specific FQ values. Similarly, land use was not a reliable predictor of site-specific TD values. However, limited land use had potential to identify higher levels of FQ, and more intensive land use showed potential to identify lower average TD. This suggests that both measures (FQ and average TD) are needed for a more complete classification of wetland biological response to anthropogenic disturbance. Despite growing interest in relatively rapid or low-cost methods of wetland assessment, our results do not support using such methods in lieu of direct bioassessment.

The effect of different water treatments on the photosynthetic characters and chromosomal control in wheat (*Triticum aestivum* L) seeding

Zhiying Bai[1], *Bin Lu*[1], *Cundong Li*[1], *Chunji Liu*[2]
1. Hebei Agricultural University
2. CSIRO Plant Industry

Wheat is one of the most important food crops in the world and water shortage is the most significant factor affecting its yield. Drought is becoming more prevalent and how to breed varieties for water-stressed environments is becoming an urgent task for all scientific disciplines related to food production. As photosynthesis is the foundation of plant production, chromosomal controls of characteristics related to photosynthesis and biomass of wheat seedlings were investigated using a set of inter-varietal chromosome substitution lines between Chinese Spring and Synthetic 6X (Syn) under a well-watered and a water-stressed treatment. The experiments were conducted in growth rooms with the controlled environment facilities (CEF) at Queensland Bioscience Precinct, Brisbane. The relative water content of pots were maintained at 75%±5% (well-watered, control) and 45%.±5% (water-stressed) respectively by weighting method. Results from this study showed that, as expected, water stress resulted in reduction in net photosynthesis rate, chlorophyll content, stomatal conductance, seedling dry mass, but promoted water use efficiency. As substitution lines with the best performance for each of the characteristics assessed were often different, different genes may have to be targeted in breeding varieties for water-stressed and non-water-stressed environments. Under well-watered condition, compared to CS, two substitution lines (5A and 5B) showed significantly increased photosynthesis rate, substitution 1A showed significant positive effect on stomatal conductance, three substitution lines (5A, 7A and 5B) were found to be significantly increased chlorophyll content, substitution 5B showed the highest water-use efficiency (WUE) among all substitution lines. It suggested that main gene responsible for regulating high photosynthesis and chlorophyll content might be located on chromosomes 5A, 5B and 5A, 5B, 7A of Syn respectively. It also suggested that chromosomes 5B and 1A of Syn might regulate high WUE and stomatal conductance respectively. Under water-stressed condition, five substitution lines (1A, 3A, 7B, 4D and 6D) showed significantly higher net photosynthetic rate than CS, four substitution lines (1A, 2A, 3A and 4D) showed higher stomatal conductance than CS, substitution 2D showed significantly higher dry mass than CS, five substitution lines (1A, 3A, 2D, 3D and 4D) showed higher WUE than CS, three substitution lines (1A, 2A and 7A) showed significantly higher dry mass. It indicated that main gene regulating high photosynthesis might be located on chromosomes 1A, 3A, 7B, 4D and 6D of Syn. The main gene regulating high stomatal conductance might be located on the chromosomes 1A, 2A, 3A and 4D of Syn. The main gene regulating high WUE and dry mass might be located on chromosomes 1A, 3A, 2D, 3D, 4D and 1A, 2A, 7A of Syn respectively. It is concluded that substitution line 1A was outstanding in that it contributed positively to each of the characteristics measured under the water-stressed treatment. Thus targeting gene (s) on this Syn chromosome in breeding varieties for water-stressed environments could be productive.

Diversity in wood functional traits in the hyper-diverse mangrove communities in new guinea

Lawong Balun
University of Papua New Guinea

Mangrove is a taxonomically diverse interface vegetation community between terrestrial and marine ecosystem with species of wide phylogenetic affinities exhibiting morphological and functional convergence. It is speculated that wood traits among the hyper-diverse mangrove community display narrow functional performance. This study set out to test the hypothesis that the hyper-diverse mangrove communities in New Guinea exhibit a narrow functional performance despite their wide phylogenetic affinities. I investigated the variation in wood and hydraulic functional traits of 31 mangrove species across zonations and among different growth forms from six hyper-diverse mangrove communities in New Guinea. Wood anatomical traits (wood density, vessel diameter, vessel density, hydraulic mean vessel diameter) of 31 co-existing mangrove species in six hyper-diverse mangrove communities in New Guinea varied markedly across different zonation bands. Wood density (P$_{wood}$) varied significantly among different zones ($F_3,2_1 = 40.96$, $P < 0.0001$). P_{wood} varied by over 30% among different growth forms, but the differences were not significant ($P > 0.05$). Maximum P_{wood} (0.94 ± 0.03 g m-3) was observed in the mean low tide (MLT) zone and decreased in the landward direction. P_{wood} varied significantly among different rooting system types ($F_4,2_7 = 6.33$, $P < 0.001$). Vessel density (V_d) varied significantly among different zones ($F_3,1_6 = 5.01$, $P < 0.01$) but variation was not significant among different growth forms ($F_2,1_5 = 1.66$, $P > 0.22$). Vessel diameter (d_V) varied significantly among different growth forms ($F_2,1_5 = 4.57$, $P < 0.03$) but did not significantly differ among the zones ($F_2,1_7 = 0.33$, $P > 0.72$). A linear correlation of $P_W$ood and leaf mass area showed no significant correlation ($r = 0.10$, $P > 0.08$). A linear correlation of vessel density and vessel diameter showed an inverse relationship ($r = 0.18$, $P < 0.02$). Vessel density was also inversely correlated to weighted hydraulic mean diameter ($r = 0.22$, $P < 0.01$). A linear correlation of potential hydraulic conductivity (K_P) and vein density showed no significant correlation ($r = 0.0005$, $P > 0.05$). K_P was inversely correlated to: V_d ($r^2 = 0.21$, $P < 0.01$), strongly correlated to d_V ($r^2 = 0.95$, $P < 0.0001$), and strongly correlated to d_h (mean hydraulic diameter, pm) ($r = 0.78$, $P < 0.0001$). A linear correlation of calculated leaf area specific hydraulic conductivity (K_L) and vein density showed a significant relationship ($r = 0.47$, $P < 0.05$). K_L was correlated to A_{max} ($r^2 = 0.56$, $P < 0.05$).

Study on the regulation mechanism of AM fungi on the content of effective components in *Clematis intricate* with different levels of nitrogen and phosphorus

Ting Liu, Hongjiao Li, Xingjiao Sun, Xiao Li, ***Tebuqin Borjigin***
Inner Mongolia medical university

Clematis intricata (*Clematis intricata* Bunge) is a kind of Mongolian medicinal plants, and one of its effective components are flavonoids. The aim of this study was to investigate the effect of AM fungi on the content of effective components in clematis. The experiment was set up with 0N, 10%N, 20%N, 50%N, 100%N, 200%N six levels (KNO_3 and NH_4NO_3) and 0P, 5%P, 10%P, 20%P, 50%P, 100%P 6 P level (KH_2PO_4), and N, P levels were inoculated with AMF (*Glomus mosseae, G.m*) and without inoculation (CK) 2 treatments, each treatment was repeated 3 times, and 6 month old seedlings were used. The content of total flavonoids in plants was significantly increased by inoculation with *G.m* at different N levels. Under the condition of 0 N -20% N, the content of total flavonoids was significantly higher than that of non-inoculated ones. Under the condition of 50% N-200% N, the content of total flavonoids has no significant difference between inoculated ones. The content of total flavonoids was highest at 10% N, and the content was about 29.4 mg/g. The expression of key enzymes of flavonoid biosynthesis genes (*CiPAL, CiCHS, CiCHI, CiF3H, CiFLS* and *CiDFR*) were determined by qRT-PCR. Under different nitrogen levels, inoculated the expression of *CiPAL* in 10% N and 20% N level increased, others down regulated; *CiCHS* and *CiCHI* expression was down regulated at 50% N, others were increased, whereas the expression of *CiFLS* in 20% N increased, others were down regulated. The content of total flavonoids in plants was significantly increased by inoculation with *G.m* at different P levels. With the increase of P concentration, the content of total flavonoids increased first and then decreased in the range of 0 P to 50% P, and reached the highest at the level of 5% P and 10% P, which was 17.4 mg/g and 17.3 mg/g, respectively. Under different phosphorus levels, the content of total flavonoids was highest at 100% P, and about 20.2 mg/g, and was significantly higher than that of 5% P and 10% P. The expression of key enzymes of flavonoid biosynthesis genes (*CiPAL, CiCHS, CiCHI, CiF3H, CiFLS* and *CiDFR*) were determined by qRT-PCR and found that under different P levels, the expression of *CiPAL* was significantly up-regulated in inoculated ones except 50%P level, the expression of *CiCHS* significantly up-regulated in all P levels, while the expression of *CiFLS* in 20% P up-regulated, in other P levels were down regulated. At different nutritional conditions of nitrogen and phosphorus under the inoculation of AM fungi can significantly improve the total flavonoids content of *Clematis intricate*. The nitrogen and phosphorus may have different and complex mechanisms to influence the content of effective components.

Research on the dynamics of plant carbon content and nitrogen content at different successional stages in Deglaciated Terrain on Mt. Yulong

Li Chang
1. State Key Laboratory Breeding Base of Desertification and Aeolian Sand Disaster Combating, Gansu Desert Control Research Institute, Lanzhou, China
2. State Key Laboratory of Cryosphere Sciences, Cold and Arid Regions Environmental and Engineering Research Institute, Lanzhou 730000, China
3. College of Earth and Environmental Sciences, Lanzhou University, Lanzhou 730000, China

With global climate warming, deglaciated terrain, which is 1250m in length, surrounding Baishui No. 1 Glacier on Mt.Yulong was formed since the late 19th century. It provides an ideal place for plant succession in nature. In view of frequent fires and the need to restore ecosystem in Mt. Yulong, as well as fewer reported studies, it has very important theoretic and practical significance in researching ecological succession in this region. We selecting Mt. Yulong in China's alpine-monsoonal temperate glacier region as the study area, a chronosequence method (substituting space for time) was used to study the chang of physiological characteristics of dominant species. According to plant nutrient content, its overall trend of plant C or N content was Arenaria delavayi (SUC1) < Polygonum macrophyllum (SUC2) and Arenaria delavayi (SUC3) < Carex capilliformis (SUC4) and Kobresia fragilis (SUC5). While the overall trend of plant C:N was Arenaria delavayi (SUC1), Polygonum macrophyllum (SUC2), Arenaria delavayi (SUC3) and Carex capilliformis (SUC4) < Kobresia fragilis (SUC5). According to the results of regression analysis, among the 4 dominant plants, the nutrition content of Arenaria delavayi had not remarkable response to soil nutrition, while Polygonum macrophyllum has the remarkable response to soil nutrition. In the 4 soil nutrition indicators, many dominant plants have remarkable response to soil Total nitrogen content, soil Total carbon content comes second. With the succession went on, the overall trend of plant C or N content and plant C:N, which have been influenced most by the soil total nitrogen content, increased significantly.

Study on traits segregation of F_1 generation of Phalaenopsis-type *Dendrobium*

He-Ming Chen[1,2], *Fu-Bing Lv*[1,2], *Wen-Fang Xiao*[1,2], *Zuo Li*[1,2]
1. Environmental Horticulture Research Institute of Guangdong Academy of Agricultural Sciences
2. Guangdong Provincial Key Laboratory of Ornamental Plant Germplasm Innovation and Utilization

In recent years, the study of Phalaenopsis-type *Dendrobium* mainly focused on tissue culture, cultivation management and factory nursery, but there was almost no reported about traits separation of hybrids and genetic performance. F_1 generation and its parents were compared in this experiment and researched the rules of its genetic performance for superior individual selection of breeding progeny and matching of the parents. In October 2006, we selected the varieties of D104, D105, D106, D107, D108 for the six artificial crosses in Guangdong Ornamental Plant Germplasm nursery, and hybridization seeds were obtained after four months and sowed sterilely, one year later F_1 hybrid plants had 2100 and planted. F_1 generation was first flowering in 2009, and 100 plants were taked randomly from every combinations to investigate the following nine ornamental traits: plant height, plant width, leaf length, leaf width, pedicel length, flower diameter, flower number, flower color and the beginning of flowering. The results showed that: (1) The averages of the four quantitative traits of plant width, leaf width, pedicel length, flower diameter were relatively decreased with mid-parent value and showed the recession phenomenon in a certain degree which had a similar phenomenon such as gerbera, azaleas and lily, the reason might be that advantage was reduced after the sexual process and the average of the traits of hybrid population declined, but the variation ranges in combination were larger, the individuals of breeding larger plants and flowers larger or pedicel longer were possible mainly by improving the cultivation conditions and the level of management. (2) There were super-parent advantages in plant height, leaf length, flower number, flower color and the beginning of flowering, especially flower number and flower color, the average of number of flowers was 106.22% which was more than 37.08% with mid-parent value, and the colors of calyx and petal segregated the other 7 kinds by the 4 kinds of parents, the lip colors segregated the other 5 kinds by the 4 kinds of parents. (3) F_1 generation showed red series and segregated widely in the flower color whether with white flowers as maternal or red series, that was to say, the genetic ability of red series was stronger.

Study on hybridization compatibility of Nobile-type *Dendrobium* and phalaenopsis-type *Dendrobium*

He-Ming Chen[1,2], *Fu-Bing Lv*[1,2], *Zuo Li*[1,2], *Wen-Fang Xiao*[1,2]
1. Environmental Horticulture Research Institute of Guangdong Academy of Agricultural Sciences
2. Guangdong Provincial Key Laboratory of Ornamental Plant Germplasm Innovation and Utilization

In horticulture, *Dendrobium* is divided into Nobile-type *Dendrobium* and Phalaenopsis -type *Dendrobium*. Among them, Nobile-type *Dendrobium* is also known as deciduous *Dendrobium*, natural flowering is commonly March to May in the spring, Phalaenopsis-type *Dendrobium* is called evergreen *Dendrobium*, the flowering is longer, usually blossoming is August to December in autumn and winter. But the research on hybridization compatibility of Nobile-type *Dendrobium* and Phalaenopsis-type *Dendrobium* is very little. The hybridization compatibility of Nobile-type *Dendrobium* and Phalaenopsis-type *Dendrobium* has been reseached since 2008 in Environmental Horticulture Research Institute of Guangdong Academy of Agricultural Sciences. 11 varieties of Nobile-type *Dendrobium* and 7 varieties of Phalaenopsis-type *Dendrobium* were positive and negative hybridization, 12 capsules were gained from 154 hybrid combinations, and the success rate of cross was 7.79% which Phalaenopsis-type *Dendrobium* was successful as female parent, but Nobile-type *Dendrobium* was not to succeed as female parent. The result of the reseach was consistent with Wilfret and Kamenoto thinking the cross compatibility between 5% to 24% of Nobile-type *Dendrobium* and Phalaenopsis-type *Dendrobium*. But the seeds of most capsules showed no sign of germination after sterile sow, only the seeds of 2 capsules germinated and turned green after sterile sow, one was transplanted to seedlings, the other was germinating. Therefore, the histologic study will carryed out to reseach about pollen morphology, germination features on the stigma after pollination, in order to determine the stages and locations for hybrid incompatibility, and provide the basis to overcome the hybrid incompatibility in the next step.

Virus-induced gene sliencing as a tool for *TT12* gene functional study in strawberry

Siyu Chen, Yueming Tang, Yueyang Hu, Xiaowei Liu, Xunju Liu, Haoru Tang, ***Qing Chen***
Sichuan Agricultural University

In this study, cv. ‘toyonoka’ strawberry was used as materials. On the basis of cloning strawberry *transparent testa 12* (*TT12*) gene, we carried out bioinformatic and temporal expression analysis of strawberry *TT12* gene. By constructing the carrier of virus-induced gene silencing (VIGS), we silenced the *TT12* gene in the strawberry fruit and then we tested the changes of anthocyanin and proanthocyanidin content. In addition, we studied the subcellular localization expression of *TT12* gene by transient expression in Arabidopsis protoplast. Strawberry *TT12* gene contained 12 transmembrane domain structures, and *TT12* gene mainly expressed on the vacuole membrane. *TT12* gene down-regulated-expression by VIGS could significantly decrease proanthocyanidin content but no obvious change of anthocyanin content in fruit. These results revealed that *TT12* gene’s role in flavonoids compounds metabolic pathways mainly by imparting in the proanthocyanidin branch and could highlight the special transportation mechanisms of different secondary metabolites.

Identification of 46 *MYB* transcription factor genes and analysis of their expression during abiotic stress in maize (*Zea mays*)

Yanhong Chen
Nantong University

The *MYB* transcription factor superfamily is a large gene family that plays central roles in developmental processes and defense responses in plants. Unlike in *Arabidopsis*, few members of the *R2R3-MYB* gene family have been functionally well characterized in maize, especially in abiotic stress-response pathways. Subgroup-specific conserved motifs outside the MYB domain may reflect functional conservation. A comparative genomics study using *Arabidopsis* abiotic stress-responsive MYB protein sequences identified 46 *ZmMYB* genes that may be involve in abiotic stress responses. An expression pattern analysis of the 46 *ZmMYB* genes under abiotic stress treatments was used to identify 22 *MYB* genes that were induced by one or more of the stress treatments. *ZmMYB30* was highly upregulated under the four stress treatments. The overexpression of *ZmMYB30* in transgenic *Arabidopsis* promoted salt-stress tolerance and also increased the expression levels of a number of abiotic stress-related genes, allowing the plants to overcome adverse conditions. This is the first comprehensive study of the roles of the *MYB* gene family in abiotic stress responses in maize.

Effects of drought stress on the growth, physiology and secondary metabolite production of *Pinellia ternata* Thunb.

Yuhang Chen[1], *Yun Chen*[2], *Qiaosheng Guo*[2], *Guosheng Zhu*[3], *Changlin Wang*[2], *Zuoyi Liu*[3]
1. Key Laboratory of Small Molecule Special Structure Drugs, Sichuan Institution of Higher Education&Chengdu Medical College, Chengdu, 610500, China
2. Institute of Chinese Medicinal Materials, Nanjing Agricultural University, Nanjing, 210095, China
3. Institute of Morden Chinese Medical Materials, Guizhou Provincial Academy of Agricaltural Sciences, Guiyang, 550006, China

Dried tuber of *Pinellia ternata* is one of the most important ingredients in many traditional medicinal preparations. Drought stress can affect the growth, physiology and secondary metabolites of plants. This study was conducted to determine the changes in terms of these variables over 35 days in *P. ternata* under four water regimes: 75% of field capacity (FC) (Control), slight drought stress (60% FC; LD), moderate drought stress (45% FC; MD), and severe drought stress (30% FC; SD). The results showed that the fresh and dry tuber weights, plant height, leaf area, number of tubers, tuber propagation index, and photosynthetic pigment content were highest in *P. ternata* plants grown under the well-watered treatment (75% field capacity). The peroxidase (POD) and catalase (CAT) activities and malondialdehyde (MDA) content were significantly higher in leaves of *P. ternata* under drought stress. The soluble protein content of *P. ternata* tubers was significantly higher under moderate drought stress, but the soluble sugar content of *P. ternata* tubers was significantly lower under severe and moderate drought stress. Additionally, the total alkaloid content of *P. ternata* tubers showed the highest increase under severe drought stress, but the guanosine and succinic acid contents of *P. ternata* tubers were significantly lower under drought stress. The maximum yield of total alkaloid, guanosine and succinic acid of *P. ternata* tubers were obtained under the well-watered regime. The results suggest that a well-watered regime (75% FC) can be an effective means of promoting tuber production and improving secondary metabolites production in *P. ternata*.

Proteomic analysis of alfalfa seeds response to heat stress during storage

Lingling Chen[1,2], ***Hang Cheng***[1], *Peisheng Mao*[1]
1. China Agricultural University
2. Chifeng Academy of Agricultural and Animal Sciences

Seed germination is a critical process in the life cycle of higher plants. The climate changes and global warming have affected all aspects of both our life and the biodiversity around us. The seeds also face the threat of a sharp decline in seed vigor resistance to heat stress during storage. However, knowledge about the molecular and physiological mechanisms underlying the heat stress of seeds has been lacking. The experiment was designed for alfalfa (*Medicago sativa* L.) seeds with 10% moisture content stored at 35,40,45 and 50°C for 8 d to compare the changing of seed vigour and proteomic processes. The objective was to determine the difference of protein expression level under heat stress in alfalfa seeds and to identify proteins associated with heat stress. 24 differentially expressed proteins were successfully identified by 2-DE coupled with LC-MS/MS. Among these expressed proteins, 1 were down-regulated at 40°C, 4 were down-regulated at 45°C, 17 were down-regulated at 50°C, and 2 were up-regulated at 50°C. The identified proteins were grouped into different categories of biological process according to GO and KEGG pathway enrichment analyses. Most of them were functionally categorized as cellular process, metabolic process and stress tolerance. 17.6 kDa class I heat shock protein, glyceraldehyde-3-phosphate dehydrogenase, and ubiquitin-conjugating enzyme E2 were mapped to two statistically remarkable categories in KEGG ($P<0.05$). In order to investigate the transcript level of the identified proteins in response to heat stress, quantitative RT-PCR assays were conducted. Among all the identified proteins, eight gene products were selected to investigate the expression patterns of their transcriptional levels and 75% of them had detectable expression at the mRNA level. The proteins identified in the present study provide a basis to elucidate further the molecular mechanisms underlying the adaptation of alfalfa seeds to high temperature stress. We will further study the metabolic pathways, and confirm the association of correlated proteins, which may provide a better understanding of the molecular mechanism for heat tolerance.

Effect of two nitrogen sources on the morphology and bio-

mass of foxtail millet

***Jihan Cui**, Shunguo Li, Xueyan Xia, Meng Liu, Yu Zhao, Shijia Song, Jing Zhao*
National Foxtail Millet Improvement Center Institude of Millet Crops, Hebei Academy of Agricultrual and Forestry Sciences Minor Cereal Crops Laboratory of Hebei Province

Nitrogen (N) is one of the essential elements of plant, which plays an important role in plant growth and development. The main source of N absorbed by plant is nitrate N and ammonium N. Some plant tends to absorb ammonium N, such as rice. Some plant tends to absorb nitrate N, such as tomato. Some plant tends to absorb a mixture of ammonium N and nitrate N, such as licorice. Because there is a great difference in absorption, transportation, storage and assimilation of the two N sources, which will inevitably affect the growth and development of plant, as well as other physiological processes. At present, most of the studies on foxtail millet are focused on relationship of N application rate (or period) and yield, the effect of N forms on the morphology and biomass of foxtail millet have not been reported. In order to study ammonium N and nitrate N on morphology and biomass of foxtail millet (*Setaria italic* L.) and to give some reference evidences for preferential absorption N source of foxtail miller, vermiculite cultivation method was using with nutrient solution including two nitrogen forms. The result showed that the two N sources significantly affected the morphology and biomass of foxtail millet, and there was no significant difference in root morphology and spike length. There were significant differences in plant height, biomass, leaf area and leaf chlorophyll content which effected by two N sources: compared with ammonium N, nitrate N increased root biomass by 17%, stem biomass by 32%, leaf biomass by 39%, total biomass by 40%, height by 38%, leaf area by 40%. Compared with nitrate N, ammonium N increased chlorophyll content by 173%, and spike biomass by 12%. There were significant differences in root/shoot ratio and spike proportion: compared with nitrate N, ammonium N increased root/shoot ratio 8% and 44% spike proportion. This study showed that nitrate N played an important role in body construction by promoting plant height, leaf area and biomass, while, ammonium N played an important role in the functional structure by increasing the chlorophyll content and sex organ construction.

The *Reaumuria trigyna* transcription factor RtWRKY1 confers tolerance to salt stress in transgenic *Arabidopsis*

*Chao Du, Lei Song, Xue Wang, **Yingchun Wang***
Key Laboratory of Herbage & Endemic Crop Biotechnology, College of Life Sciences, Inner Mongolia University, Hohhot

Reaumuria trigyna (*Reaumuria* Linn genus, family *Tamaricaceae*) is an endangered dicotyledonous shrub with the features of a recretohalophyte, and it is endemic to the Eastern Alxa-Western Ordos area of China. It is regarded as a living fossil owing to its Tethys Ocean origin and is considered a key protected plant in Inner Mongolia. Recent studies demonstrated that *R. trigyna* shows outstanding performance because of its highly efficient antioxidant system, salt glands with secretion function, and strong osmoregulatory ability. *R.trigyna* transcriptome data analysis showed that the expression levels of 67 WRKY genes changed significantly under salt stress. A total of 171 differentially expressed genes (DEGs), and 155 DEGs were enriched in the “oxidoreductase activity” and “response to stress” GO categories, respectively. Thus, WRKY TFs may play a positive role in the response of *R.trigyna* to salt stress by regulating the expression of genes related to plant growth and homeostasis. Here, to explore the molecular mechanism underlying the response of *R.trigyna* to salt stress, the Group I WRKY transcription factor gene *RtWRKY1* was cloned from *R.trigyna* based on *R.trigyna* transcriptome data, and the expression pattern and function of *RtWRKY1* had been studied. The full-length *RtWRKY1* gene was 2100 bp, including a 1261 bp open reading frame (ORF) encoding 573 amino acids. *RtWRKY1* was mainly expressed in the stem and was induced by salt, cold stress, and ABA treatment. Overexpression of *RtWRKY1* in *Arabidopsis* significantly enhanced the chlorophyll content, root length, and fresh weight of the transgenic lines. *RtWRKY1* transgenic *Arabidopsis* exhibited higher proline content, GSH-PX, POD, SOD, and CAT activities, and lower MDA content, Na^+ content, and Na^+/K^+ ratio than wild-type *Arabidopsis* under salt stress conditions. Salt stress induced the expression of ion transport, proline biosynthesis, and antioxidant related genes, including *AtAPX1*, *AtCAT1*, *AtSOD1*, *AtP5CS1*, *AtP5CS2*, and *AtSOS1* in transgenic lines. These results suggest that *RtWRKY1* confers tolerance to salt stress in transgenic *Arabidopsis* by regulating plant growth, osmotic balance, Na^+/K^+ homeostasis, and the antioxidant system.

Cloning and bioinformatic analysis of three genes encoding terpenoid metabolic enzymes in tobacco

*Jian Du, Yingying Huang, Yanjie Zhang, Jinyong Huang, Jia Guo, Weixin Tian, Hui Wang, **Caipeng Yue***
School of Life Sciences, Zhengzhou University

Solanesol is a 45-carbon, unsaturated, all-trans-nonaprenol isoprenoid, widely found in higher plants, mammals and microbial organisms as natural product, and first isolated from flue-cured tobacco in 1956 by Rowland *et al.,* In the tobacco, solanesol content ranged from 0.3% to 3%. At the process of solanesol synthesis, there are three key enzymes, including 1-deoxy-xylulose 5-phosphate synthase (DXS), Farnesyl diphosphate synthase (FPS) and Solanesyl diphosphate synthase (SPS). In this study, we explore the genes function and verified them via PCR, transgenic, tissue culture, subcellular localization, phylogenetic analysis and so on. According to bioinformatics analysis, K326-*dxs* contained a 2142 bp open reading frame and encoded a hydrophilic protein which contained 713 amino acids. K326-*dxs* located in the chloroplast, do not contain signal peptide and transmembrane structure, but has transit peptides. The full length of K326- *fps* gene is 1029 bp and the gene encodes 342 amino acids. The FPS protein is a hydrophilic protein and did not contain signal peptide and transmembrane structure. The *solanesyl diphosphate synthase* gene *(sps)* has been obtained, the further research will be put into practice.

Effects of shift part of nitrogen fertilizer from basal to storage

root formation on growth and yield of sweetpotato (*Ipomoea batatas* L.)

Xiangbei Du*, Min Xi, Xiaoping Liu*
Anhui Academy of Agricultural Sciences

Appropriate nitrogen (N) fertilizer management is beneficial for improving growth, yield and yield components of field crops. Field experiments were conducted to determine the effects of application methods [basal application and split application levels (35 d after transplanting)] and N rates (80 and 100 kg ha^{-1}) on the sweetpotao (*Ipomoea batatas* L.) yield during summer 2015 and 2016. The experiments were carried out at the Agronomy Research Farm of Agricultural Sciences of Anhui Academy in Hefei City, China. It was concluded from the results that split application of N were more beneficial in terms of better growth, higher yield and yield components of sweetpotato under reduced N condition. More N application at later growth stage resulted in better growth and higher yield. The results further demonstrated that reducing the rate of soil applied N up to 80 kg N ha^{-1} in two splits (25% at basal and 75% at 35 d after transplanting) improve growth and sweetpotato productivity. Outcomes of this research will help producers schedule fertilization to maximize yield and nutrition use efficiency.

An application of hemispherical photography to analysis maize canopy structural parameters under natural light

Jiangchuan Fan*, Xinyu Guo*
Beijing Research Center for Information Technology in Agriculture/National Engineering Research Center for Information Technology in Agriculture/Beijing Key Lab of Digital Plant

Hemispherical photography (HP) has already proven to be a powerful indirect method for measuring various components of canopy structure. One of the main problems of hemispherical photography for determination of canopy structure such as leaf area index (LAI) and mean leaf inclination angle (MLA), is the selection of the optimal brightness threshold in order to distinguish leaf area from sky area thus producing a binary image. In this process, one of the challenges is how to overcome various natural light conditions which sometimes strongly affect the profile of the crop images taken outdoor. In this paper an illumination invariant multiple exposure images fusion and mapping method was proposed in order to squash negative impact of variant illumination. Firstly, a series of multiple exposure maize canopy hemispherical images was captured under natural light condition. The camera (Canon EOS 5D Mark III) with aperture (sigma 8mm f3.5 ex DG FISHEYE) was placed in the bottom of canopy towards to the sky provided vertical 360 degree horizontal 180 degree canopy images. Which were captured at different exposure times such as 1/800s, 1/400s, 1/200s, 1/125s, 1/30s, 1s. Secondly, the multiple photographs fused into a single radiance map whose pixel truncated in shadowed and lighted parts of original images expended to higher range. We were able to determine the irradiance value at each pixel, we could plot it against the measured pixel value discretized according to the 256 pixel values commonly observed in 8-bit images for each exposure time. The pixel values are proportional to the true irradiance values in the scene. The pixel values, exposure times, and irradiance values form a least squares problem. Finally, we also employed a histogram equalisation method to map irradiance values to RGB color space. After mapping processing, brightness of image have a more properly distribution, dark regions were lit more brightly and saturated regions were depressed to normal brightness condition, moreover, histograms of images share the similar distribution, which make the brightness and color of image more or less have the same values. The comparison results show that canopy gaps fraction of HP acquired at 14:00 and 17:00 with threshold value 180 has difference of 15.4% percent, and our method reduces the difference up to 2.8% percent. In canopy structure parameters analysis phase, canopy gaps were extracted from those photos, and then leaf area index (LAI) and mean leaf inclination angle (MLA) could be inversed by Beer-Lambert theory, based on the quantitative relationship between the radiation condition and the canopy structure. The experiment was conducted in 2013, density was 60000 plants/ha, normal water and fertilizer management. The hemispherical images were obtained in 8/06,8/13,8/19,8/22,8/26,9/12, the distribution of LAI and MLA was consistent with rules of growth and development of maize canopy. Moreover, a performance comparison of direct surveying method and our method was carried out, LAI and MLA values of 13 samples were collected with two methods, results of regression analysis shows that our method have a high consistency with canopy structure parameter direct surveying method, the correlation coefficient between two methods hit 0.94. The line slope was 1.463, our method measurement values were lower than direct surveying method. Our method expands the HP canopy structure parameters acquire timing, provides an automatic monitoring solution.

Cloning of cDNAs of flowering time genes from different flowering periods of *Camellia* plants

Shuguo Fan
School of Chemistry and Life Sciences, Chuxiong Normal University

The optimal timing of transition from vegetative to reproductive growth, known as the floral transition, is crucial for successful sexual reproduction of flowering plants. This developmental transition is precisely regulated by various environmental stimuli and endogenous signals, such as light, temperature, nutrients, and plant age. In plants, the transition from vegetative growth to flowering is regulated by a complex combination of environmental and internal signals. This developmental transition is controlled by environmental cues, such as seasonal changes in day length (photoperiod) or winter cold (vernalization) as well as ambient conditions including light intensity and spectral quality. It has been reported that floral integrator gene expression is repressed by the MADS box transcription factor SHORT VEGETATIVE PHASE (SVP), an inhibitor of flowering. Mutations in *SVP* cause early flowering under noninductive short days (SD) and under long days (LDs). SVP plays a similar role in response to vernalization where it forms a heterodimer with the MADS box transcription factor FLOWERING LOCUS C (FLC) to strongly repress flowering before exposure to cold. In *Arabidopsis*, the floral transition and floral organ identity are controlled by a subset of MADS-box transcription factors such as AGL24 and SHORT VEGETATIVE PHASE (SVP). These two closely related MADS-box genes have been shown to be important for various stages of reproductive development. No related results have been reported in *Camellia japonica*. In order to elucidate the function of *SVP*-, *FLC*- and *AG*-like genes in camellia, related primers have been designed for *CjSVP* (F: 5′- ATGGCGAGAGAAAAGATTCAG-3′; R: 5′- CTAACCACCATACGGTAAGCC-3′), *CjFLC* (F: 5′- TGACATAGAAAGCTACCACC-3′; R: 5′-CTCCCTTCACTATTCTTCATC-3′) and *CjAG* (F: 5′- CACCGGATCGGTGGCAGAAATTAATGC-3′; R: 5′-GGATCGGATTCGGGTAATACTTCTCTC-3′), respectively. RNAs were extracted from the leaves and flowers from different camellia varieties with different flowering periods (17 Camellia varieties were used, flowering from December to March), followed by measuring the purity and quality of RNAs, respectively. The total RNA was used as a template for reverse transcription to obtain cDNA first strand, and then for gene cloning. The results showed that the total RNA could be extracted from flowers than that in leaves of *Camellia japonica*. RT-PCR was performed and cDNA was cloned by using primers mentioned above. RT-PCR results showed that some specific bands could be clearly visualized, which were to be sequenced, and sequence alignments were to be performed.

Preliminary observations on plant morphology and morphological and anatomical characteristics of the flower bud differentiation on *Camellia japonica*

Shuguo Fan

School of Chemistry and Life Sciences, Chuxiong Normal University

The morphological characteristics of different flowering periods of *Camellia japonica* varieties were primarily investigated, which are trees, up to 13 m, or shrubs; young branchlets glabrous; leaves leathery, elliptic, 5~10 cm long, apex blunt or sharp mucronate, base broadly cuneate, glabrous on both surfaces, lateral veins 7~8 pairs, obtusely toothed; petiole 0.8~1.5 cm long; single flowers terminal and axillary, red; flowers sessile; bracts and sepals 10, semi orbicular or orbicular, 0.4~2 cm long, sericeous, glabrescent; petals 6~7, outer 2 suborbicular, free, 2 cm long, more than 5 pieces of hair, obovate, 3~4.5 cm long, connate 8 mm, glabrous; stamens 3 round; outer filament tube 2.5~3 cm long, 1.5 cm long; ovary glabrous, style 2.5 cm long, apex 3 crack; capsule globose, 3~5 cm in diameter, March cracked, woody mericarps, thickness of 6~8 mm, 1~2 seeds per locule; seed glabrous; flowering in December to March of the following year. Morphological and anatomical characteristics and external morphology of *C. japonica* flower bud during differentiation were investigated for nearly four years from January 2013 to October 2016. The results show that (1) Solitary flower bud was axillary or terminal; (2) The differentiation of flower bud started at the beginning of May and ended at the middle and later September; (3) The process of flower bud differentiation can be divided into six periods: pre-differentiation of flower bud, sepal formation, petal formation, stamen and pistil formation, anther and ovule formation, as well as stamen and pistil maturity, stamen and pistil primordium differentiated almost simultaneously, and stamen and pistil nearly synchronized development during stamen and pistil formation. Development of pistil was slightly earlier than that of stamen during anther and ovule formation in almost all the camellia varieties, firstly the lower part of pistil enlarged, then extended upward and closure up, forming ovary, locule, ovule and stigma. Subsequently stamen elongated quickly and formed anther. Meanwhile ovule was also elongated, when stamen and pistil maturity. At the period of stamen and pistil maturity, all the organs were becoming mature; (4) Correspondingly, external morphology changed at different differentiation stages. The above results lay a solid foundation on the research of flowering mechanism of Camellia.

A291

Separation of cDNA of the *FT* flowering gene from *Paeonia rockii*

Shuguo Fan

School of Chemistry and Life Sciences, Chuxiong Normal University

Plants integrate day length and ambient temperature to determine the optimal timing for developmental transitions. In *Arabidopsis* (*Arabidopsis thaliana*), the floral integrator FLOWERING LOCUS T (FT) and its closest homolog TWIN SISTER OF FT promote flowering in response to their activator CONSTANS under long-day inductive conditions. Low ambient temperature (16°C) delays flowering, even under inductive photoperiods, through repression of FT, revealing the importance of floral repressors acting at low temperatures. *FT* gene is an important factor of integration into flowering; it plays an important role in the regulation of flowering time aspect. DNA and RNA were extracted from the leaves and flowers from ornamental plants *Paeonia rockii*, followed by measuring the purity and quality of DNA and RNA, respectively. The total RNA was used as a template for reverse transcription to obtain cDNA first strand, and then for *FT* gene cloning. The results showed that the total RNA was easier to be extracted from flowers than that in leaves of *P. rockii*. RT-PCR was performed and *FT* cDNA was cloned by using primers (F:5’-ATGCCTAGAAATAGGGATCCACTA-3’, R:5’- TTATCTTCTTCCGCCTGACC-3’), a 1000-bp single band was clearly visualized, which was to be sequenced, and sequence alignment was to be performed.

De Novo transcriptome analysis of polysacchides biosynthesis and metabolic pathways involving nucleotide-sugar interconversion enzymes in *Codonopsis pilosula*

Jianping Gao[1], *Lingya Cao*[2], *Jing Li*[1], *Xiaolin Wang*[1], *Xiaoxiao Li*[1], *Zhong Cheng*[2]

1. College of Pharmacy, Shanxi Medical University

2. College of Basic Medicine, Shanxi Medical University

Codonopsis genus has been extensively used in China as a therapeutic agent, and *Codonopsis Radix* one of the valuable herbs among the 42 species of the *Codonopsis* genus used for replenishing qi deficiency, strengthening the immune system, improving poor gastrointestinal function, *etc*. Codonopsis polysaccharides (CPPs) are of the key pharmacologically active components in *C. pilosula*. However, the regulation of synthetic pathways of CPPs has not been fully investigated. To explore the genes of cluster related with CPPs biosynthesis, we performed *de novo* transcriptome analysis of *C. pilosula*, and established the plant culture system in vitro for the purpose of understanding the regulation of metabolic pathways involving nucleotide-sugar interconversion enzymes. An EST collection was created from a transcriptome library prepared from different parts of *C. pilosula* (Franch.) Nannf. We constructed the metabolic pathways related to biosynthesis of CPPs, which is divided into three main steps. The first step is the formation of UDP-Glu and GDP-Man from Glu-6-P and Fru-6-P, which are then converted in the second step into other NDP-sugars. Finally, the active monosaccharide units, NDP-sugars, are added to the sugar residues of various polysaccharides and glycoconjugates by the action of various glycosyltransferases (GTs). The large number of genes were found to encode enzymes that catalyze the formation of the CPPs, a total of 723 GT unique sequences containing 170 UGTs were obtained. The stable prokaryotic expression systems of four genes, such as UDP-glucose pyrophosphorylase (*UGPase*), sucrose transporter (*SUC*), phosphomannose isomerase (*PMI*) and phosphomannomutase (*PMM*), were constructed and confirmed by PCR, TA cloning and sequencing, sequence analysis were also performed. UGPase is a key enzyme that functions upstream of the biosynthesis pathway of Astragalus polysaccharides, and is responsible for the conversion of glucose-1-phosphate to UDP-Glu. PMI, on one hand, allows plants carrying it to convert mannose-6-phosphate, on the other hand, PMI-based selection system is harmless and highly versatile in plants, which means that PMI could be used to monitor transgenic events and visually separate transgenic material from non-transformed material. The cloning and expression of genes involved in polysaccharides biosynthesis would discover the regulation of polysaccharides metabolism and understand the related pathways. To achieve the purpose of exploring the functions of genes, the adventitious root and cluster bud induction and culture system of *C. pilosula* (Franch.) Nannf. were established. Seeds from HuGuan were treated with 400 mg/L gibberellin for 8 h, 25℃ light culture. Then the adventitious roots and cluster buds were obtained through tissue culture by manipulation of NAA and 6-BA concentration, respectively. Our results provide understanding of the biosynthesis of CPPs at the molecular level in *C. pilosula* inferred by RT-qPCR analysis of candidate genes functioning at key separate branches of biosynthesis pathway of CPPs. Therefore, the plant signaling molecules were discovered to enhance the efficient and sustainable production of CPPs and related bioactive natural products. The tissue culture system would be applied to understand the metabolic mechanism related with the production of CPPs *in vitro*.

Sucrose plays a crucial role in response to heat and chilling stress by reducing oxidative damage in potato

*Qiao-Qiao Chen, Zai-Ping Feng, Hui-Jun Yuan, **Hui-Ling Gong***
School of Life Science and Engineering, Lanzhou University of Technology

Abiotic stress is strongly detrimental to plant growth and development. Heat and chilling stress is the primary abiotic stresses that limit plant biomass production and productivity. Sucrose represents the major transport form of photosynthetically assimilated carbohydrates and plays versatile roles in plants. On the other hand, sugars function directly as protective agents at higher concentrations, and they serve as substrates or signals for stress-induced alterations at low concentrations, while the mechanism of the protective function seems to be unclear.To determine the alleviative effects of exogenous sucrose on chilling and heart stress, potato seedlings were pretreated with sucrose for 1 day and exposed to heat and chilling, respectively. The results showed that: 1) Pretreatment with sucrose led to a significantly increase in survival rate in potato seedlings suffering from heat and chilling stress. 2) Pretreatment with sucrose increased the activities of superoxide dismutase, ascorbate peroxidase, hydrogen peroxidase and peroxidase under heat and chilling stress. 3) Sucrose pretreatment reduced the production of reactive oxygen species, the superoxide anion (O_2^-) and the hydrogen peroxide (H_2O_2) were at a lower level than control. At the same time, the content of malonaldehyde was also reduced. In summary, we propose pretreatment with sucrose enhances chilling and heat tolerance in potato by activating antioxidant enzymes, and sucrose may act as a signal molecule interacting with antioxidant pathway.

High phenotypic plasticity does not imply high salt stress tolerance: A case study of two pioneer species from the Yellow River Delta

Xiao Guo[1,2]*, Xiao-Huang Ren*[2]*, Franziska Eller*[3]*, Ming-Yan Li*[2]*, Ren-Qing Wang*[2]*, Ning Du*[2]*, Wei-Hua Guo*[2]
1. Qingdao Agricultural University
2. Shandong University
3. Aarhus University

A greenhouse experiment was conducted in which two leguminous species commonly used in the Yellow River Delta for vegetation restoration, Robinia pseudoacacia and Amorpha fruticosa, were subjected to the five salt treatments: 0, 50, 100, 150 and 200 mmol L-1. We aimed at investigating which of the two species would be better suited for growth in a saline environment, and whether the acclimation capacity to salinity resulted from an inherently higher phenotypic plasticity of the species. The results showed that salinity affected most growth parameters and biomass parameters but had no effects on most leaf traits and physiological parameters of the two species. Height, relative growth rate of crown area, root biomass and leaf mass ratio of R. pseudoacacia were reduced by higher salinity while A. fruticosa was not affected. Chlorophyll a to chlorophyll b ratio and total antioxidative capacity of A. fruticosa increased with higher salinity while those of R. pseudoacacia remained unchanged. Root mass ratio and vitamin C concentration of both species were not affected by salinity, whereas vitamin C concentration of A. fruticosa overall was higher than that of R. pseudoacacia. Methane dicarboxylic aldehyde concentration of R. pseudoacacia increased with the increase of salinity while that of A. fruticosa was not affected. Root to shoot ratio of A. fruticosa was higher than of R. pseudoacacia at most salt treatments. Of all leaf traits, only leaf area differed among the different salinities. Robinia pseudoacacia generally exhibited a greater plasticity than A. fruticosa in response to salinity, but A. fruticosa was more resistant to the higher salinities, compared to R. pseudoacacia, and is thus a better candidate for vegetation restoration in saline areas.

Differences of photosynthetic characters among the typical geographic populations in the *Houttuynia* of China

Anna He, *Xianjin Wu*

Department of Life Science, Huaihua University

Houttuynia cordata is a perennial herb in genus *Houttuynia* of family Saururaceae. It is a functional food with enriched nutrition and a herbal medicine with long history for treatment of pneumonia, acute and chronic bronchitis, urinary tract infections and other diseases. In this paper, morphology of six typical geographical *Houttuynia* taxa and their differences in photosynthesis at normal temperature and adverse conditions such as high and low temperatures and drought were studied. The results showed that the morphological differences of the six taxa mainly manifested as plant color, main stem height, internode length of aerial stems, leaf length and leaf width. Under normal conditions, EM and HH (from Hunan Huaihua) had similar values and diurnal variation trends of Pn, Tr, Gs and Ci. Moreover, Pn was not significantly different among the six taxa and Tr, Gs and WUE differ significantly only among a few taxa. By contrast, adverse treatment such as heat (40°C), cold (5°C) and drought (70% soil water holding capacity) could substantially decrease Pn, Tr and Gs, but increase WUE. The differences in Pn, Tr and Gs were significant only among multiple taxa, while the difference in WUE was significant among all taxa. In addition, the alteration trends of chlorophyll fluorescence parameters in EM and HH after adverse treatments were very similar. Comprehensive analysis of the changes in gas exchange and chlorophyll fluorescence parameters after adverse treatments found besides *Houttuynia* taxon from high latitude Rugao, Jiangsu had high tolerance to cold, all other *Houttuynia* taxa with strong tolerance to heat and cold were from Southwest and South-central China. Photosynthetic stress resistance of all *Houttuynia* taxa was inheritable and closely related to the eco-climatic conditions of their provenance. EM may be considered a taxonomical variant of *Houttuynia cordata*.

The role of H_2O_2 in the regulation of cyclic electron flow in the salt tolerance of soybean

Yi He, *Junliang Fu, Dean Jiang*

State Key Laboratory of Plant Physiology and Biochemistry, College of Life Sciences, Zhejiang University, Hangzhou, China

NDH (NAD (P)H dehydrogenase complex)-dependent cyclic electron flow (CEF) plays an important role when plant was exposed to stress environments. Meanwhile, stress environments induced the production of reaction oxygen species (ROS). H_2O_2 as one of ROS might play a critical role in the regulation of CEF. However, under stress conditions, the relationship between H_2O_2 and CEF is not yet clear. In this study, to further elucidate how H_2O_2 as a signal molecule induced the activation of CEF, we monitored the localization and content of H_2O_2 in soybean's leaf, petiole and stem, as well as related CEF activity in three different soybean varieties. The results showed that the CEF of the 3rd compound leaves could be upregulated in about 5-10 min by exogenous H_2O_2 treated in the 2nd leaves, especially in the salt-tolerant S111-9. In addition, the H_2O_2 signal could transfer from leaves to petioles, stems and adjacent leaves via apoplastic pathways and this signal could initiate the CEF of the 3rd compound leaf and regulate the activation of its CEF. Meanwhile, the speed of transmission was related to the salt tolerance of soybean varieties. Furthermore, Salt stress and H_2O_2 could increase the CEF and ATP content of leaves, but no longer increased the H_2O_2 signal. Therefore, these results suggested that the H_2O_2 signal was also strongly interconnected with CEF in the response to salt stress. This study was not only helpful to our understanding for the defense signal transduction under stress conditions, but also had an important theoretical significance and application value for the improvement of crop salt tolerance.

Embryonic factor 10 encodes a DEAD-box RNA helicase that regulates embryo development and meristem homeostasis in *Arabidopsis*

Xiu-Li Hou[1,2]*, Hua-Qin Gong*[1]*,* ***Chun-Ming Liu***[1]

1. Institute of Botany, Chinese Academy of Sciences

2. University of Chinese Academy of Sciences

Embryogenesis is a critical process for the life cycle of flowering plants. Shoot and root meristems formed during embryogenesis establish the above- and below-ground tissues, respectively, after seed germination. Factors linking embryogenesis and post-embryonic development are still unknown. By screening of ethyl methanesulfonate (EMS)-mutagenized populations of *Arabidopsis,* we identified the *embryonic factor 10-1* (*fac10-1*) mutant that showed zygote-lethal phenotype. *FAC10* gene was cloned through map-based cloning and confirmed by a genetic complementation test against a T-DNA insertion allele *fac10-2*. *FAC10* encodes a putative DEAD-box RNA helicase highly conserved in prokaryotes and eukaryotes. Expression studies using *pFAC10:FAC10-sYFP* and *pFAC10:FAC10-GUS* transgenic plants revealed that *FAC10* is highly expressed in actively dividing cells in root and shoot meristems. Homozygous *fac10-2* displayed short root with reduced meristematic cells in roots, variable sized and multiple shoot apical meristems, delayed germination and slow growth phenotypes. Expression patterns of RAM- and SAM-specific marker genes such as *pWOX5:erGFP*, *pSCR:erGFP*, *pSHR:SHR-GPF*, *pWUS:-GUS* and *pCLV3:GUS* were altered greatly in 5-day old *fac10-2* seedlings. Quantitative RT-PCR and northern blot results showed miR164 reduced significantly in *fac10-2*. These results suggest that the DEAD-box RNA helicase *FAC10* plays a critical role in embryo development and meristem homeostasis in *Arabidopsis*.

Cytosolic and nucleosolic calcium signaling are mutually ex-

cluded in *Arabidopsis*

Feifei Huang
Beijing Key Laboratory of Gene Resource and Molecular Development, College of Life Sciences, Beijing Normal University, Beijing.

Calcium acts as a universal second messenger to be involved in responses to environmental stresses and developmental processes. Previous reseaches showed that a number of stimuli induced the [Ca^{2+}] increases both in the cytoplasm and nucleus in plants. However, the relationship between cytosolic and nucleosolic calcium signaling is still obscure. Here, we have generated the transgenic plants containing the fusion protein of human parvabumin (PV) with nuclear export signal sequence (NES-PV) or nuclear localized signal sequence (NLS-PV) in order to selectively block cytoplasmic calcium or nuclear calcium. Firstly, we find that osmotic-stress induced [Ca^{2+}]$_{cyt}$ increase (OICI$_{cyt}$) and salt-stress induced [Ca^{2+}]$_{cyt}$ increase (SICI$_{cyt}$) were impaired in *NES-PV* lines as compared with *Arabidopsis* wild type (WT). Similarly, osmotic-stress induced [Ca^{2+}]$_{nuc}$ increase (OICI$_{nuc}$) and salt-stress induced [Ca^{2+}]$_{nuc}$ increase (SICI$_{nuc}$) were also disrupted in *NLS-PV* lines. These results indicated that PV can effectively block the increase of [Ca^{2+}] in response to various stimuli in plants. However, OICI$_{cyt}$ and SICI$_{cyt}$ were similar in *NLS-PV* plants as WT, and vice versa. Furthermore, we found that osmotic-stress and salt-stress induced stomatal closure were reduced dramatically both in *NES-PV* and *NLS-PV* lines. Interestingly, the phytohormone abscisic acid and Methyl jasmonate induced stomatal closure were abolished only in NES-PV lines, but not in NLS-PV lines as compared with WT. These results implied that cytosolic and nucleosolic calcium signaling are independent and coexistent to play the pivotal roles in plant growth and development.

GsCHX19.3, a member of cation/H$^+$ exchanger superfamily from wild soybean contributes to high salinity and carbonate alkaline tolerance

Bowei Jia[1,2], Mingzhe Sun[1,2], Junkai Yang[1], Jianwei Li[1], ***Xiaoli Sun***[1]
1. Heilongjiang Bayi Agricultural University
2. Northeast Agricultural University

Cation/H$^+$ exchangers (CHX) are characterized to be involved in plant growth, development and stress responses. Although soybean genome sequencing has been completed, the GmCHX family hasn't yet been systematically analyzed. Here, a total of 40 *GmCHXs* were identified and phylogenetically clustered into five groups. Members within each group showed high conservation in the exon-intron organization and motif architecture. Interestingly, only Group IVa members exhibited high expression in different tissues, as well as induced expression under carbonate stress. Among them, *GsCHX19.3* displayed the greatest up-regulation in response to carbonate alkaline stress, which was further confirmed by quantitative real-time PCR analysis. We also observed the ubiquitous expression of *GsCHX19.3* in different tissues and its localization on plasma membrane. Moreover, we found that *GsCHX19.3* expression in AXT4K, a yeast mutant lacking four ion transporters conferred resistance to low K^+ at alkali pH, as well as carbonate stress. In *Arabidopsis*, *GsCHX19.3* overexpression increased plant tolerance to high salt and carbonate alkaline stresses. Furthermore, *GsCHX19.3* transgenic lines showed lower Na^+ concentration and higher K^+/Na^+ values under salt-alkaline stress. Whereas *atchx19* knockout mutant displayed decreased stress tolerance, higher Na^+ concentration and lower K^+/Na^+ values. Taken together, our findings indicated that *GsCHX19.3* contributed to high salinity and carbonate alkaline tolerance.

Nutrient status of nipa (*Nypa fruticans* Wurmb.) from semi-wild stands in selected areas of Mindanao, the Philippines

Junaldo Mantiquilla, *Reynaldo Abad, Sandy Faye Salmasan*
University of the Philippines Mindanao

Nipa (*Nypa fruticans* Wurmb.) is a potential source of biofuel from its sap. Increasing sap yield requires understanding nutrient requirements of this palm necessary for cultural management practices. Hence, the nutrient status of nipa in its natural habitats in southern Philippines (Western, Northern, Eastern and Southern Mindanao) were determined to establish baseline data of essential elements using soil and leaf analyses. Results revealed that nipa palms thrived in a wide variety of soils from clayey, loamy to sandy clay loam types. Elemental variations were observed across sampling sites owing to their locations in the estuaries, human activities and soil pH. Exchangeable bases Na, Ca, Mg and K varied considerably across areas affecting leaf levels of nipa. However, leaf B levels were shown to be regulated even at toxicity levels of B in the soil. These growing conditions indicate that nipa palm can tolerate highly variable physico-chemical factors that exist in the estuaries. The essential elements had the following levels in the leaf tissue: 1.30±0.30% N, 0.13±0.03% P, 0.82±0.14% K, 0.12±0.29% Ca, 0.03±0.03% Mg, 0.16±0.13% Na, 0.53±0.10% S, 0.70±0.10 mg/kg Cu, 4.30±0.90 mg/kg Zn, 20.00±2.30 mg/kg Fe, 64.20±31.70 mg/kg Mn and 4.40±1.70% B. These leaf nutrient levels will serve as benchmark information for fertilizer research in the future.

Morpho-physiological indices for drought tolerance in pigeonpea (*Cajanus cajan* L. Millsp.) genotypes under rainfed and irrigated conditions

Satish Khadia, *Suresh Kanuri*
S. D. Agricultural University, S.K.Nagar

A field experiment was carried at Centre of Excellence for Research on Pulses, Sardar Krushinagar Dantiwada Agricultural University (S.D.A.U.), Sardarkrushinagar, Gujarat during Kharif 2013 to study the morpho-physiological indices for drought tolerance of different pigeonpea genotypes under rainfed and irrigated conditions. Significant differences exhibited amongst the genotypes for initial and final plant stand, days to flowering, days to maturity, 100 seed weight, harvest index. The genotypes SKNP 1004, SKNP 1005 and SKNP 0805 recorded minimum percent reduction in yield due to moisture stress. Relative Water Content (RWC), Drought Tolerance Efficiency (DTE) were found to be the most useful parameters while selecting genotypes for drought tolerance. The genotypes SKNP 1004, SKNP 1005, SKNP 0805 and BANAS were promising for yield and yield contributing characters in both rainfed and irrigated conditions.

Arabidopsis acyl-CoA-binding protein ACBP3 participates inplant response to hypoxia by modulating very-long-chain-fatty acid metabolism

***Lijuan Xie**, Yong Xia Lai, Shi Xiao*
Sun Yat-sen University

In *Arabidopsis thaliana*, acyl-CoA-binding proteins (ACBPs) are encoded by a family of six genes (*ACBP1* to *ACBP6*), and are essential for diverse cellular activities. Recent investigations suggest that the membranean chored ACBPs are involved in oxygen sensing by sequestration of group VII ethylene-responsive factor sunder normoxia. Here, we demonstrate the involvement of *Arabidopsis* ACBP3 in hypoxic tolerance. *ACBP3* transcription was remarkably induced following submergence under both dark (DS) and light (LS) conditions. *ACBP3*-overexpressors (*ACBP3*-OEs) showed hypersensitivity to DS, LS and ethanolic stresses, with reduced transcription of hypoxia-responsive genes as well as accumulation of hydrogen peroxide in the rosettes. In contrast, suppression of ACBP3 in ACBP3-KOs enhanced plant tolerance to DS, LS and ethanol treatments. Byanalyses of double combinations of OE-1 with *npr1-5*, *coi1-2*, *ein3-1* as well as *ctr1-1* mutants, we observed that the attenuated hypoxic tolerance in *ACBP3*-OEs was dependent on NPR1- and CTR1-mediated signalling pathways. Lipid profiling revealed that both the total amounts and very-long-chain species of phosphatidylserine (C42:2- and C42:3-PS) and glucosylinositol phosphorylceramides (C22:0-, C22:1-, C24:0-, C24:1-, and C26:1-GIPC) were significantly lower in ACBP3-OEs but increased in ACBP3-KOs upon LS exposure. By microscalethermophoresis analysis, the recombinant ACBP3 protein bound VLC acyl-CoA esters with high affinitiesin vitro. Further, a knockout mutant of *MYB30*, a master regulator of very-long-chain fatty acid (VLCFA) biosynthesis, exhibited enhanced sensitivities to LS and ethanolic stresses, phenotypes that were ameliorated by ACBP3-RNAi. Taken together, these findings suggest that *Arabidopsis* ACBP3 participates in plantresponse to hypoxia by modulating VLCFA metabolism.

Developing anti-stress sweet potato by over-expressing stress-tolerant genes

Ge Li
Jiangsu Normal University

Higher plants are usually more sensitive to environmental stresses, such as high salt, drought, high/low temperature and so on. Various environmental stresses are the main limiting factors for plant growth and distribution. And with the growing population and demand for food and energy, therefore, the cultivation of stress-tolerant crops is also increasingly important. To solve the problem, we need to develop new environmentally friendly industrial crop varieties to be grown on marginal land and desertification areas for sustainable development. My research is to improve the yield of sweetpotato, which is an attractive crop for coping with world food and energy problems, by transgenic. Screening the stress-tolerant genes based on the functional expression of studying genes (*IbMYB2*, *IBMYB3* and *IbMYB4*) and over-expressing them in the sweet potato via construction of over-expressing vector, and the gene with higher resistance have been screened out.

Expression of *cadR* enhances its specific activity for Cd detoxification and accumulation in *Arabidopsis*

Jingrui Li
Institute of Botany, the Chinese Academy of Sciences

Cadmium (Cd) is a transition metal that is highly toxic in biological systems. Anthropogenic emissions of Cd have increased biogeochemical cycling and the amount of Cd in the biosphere. Here we studied the utility of a bacterial Cd-binding protein CadR for the remediation of Cd contamination. CadR was successfully targeted to chloroplasts using a constitutive *CaMV35S* promoter or a shoot-specific chlorophyll a/b-binding protein 2 gene (*CAB2*) promoter and an RbcS (small subunit of the Rubisco complex) transit peptide. Under short-term (2-d) exposure to Cd, the *cadR* transgenic plants with showed up to 2.9-fold Cd accumulation in roots compared with the untransformed plants. Under mid-term (7-d) exposure to Cd, the concentrations of Cd in leaves began to increase but there were no differences between the WT and the *cadR* transgenic plants. Under long-term (16-d) exposure to Cd, the *cadR* transgenic plants accumulated greater amounts of Cd in leaves than the untransformed plants. Total Cd accumulation (μg per plant) in shoots and roots of the plants expressing *cadR* were significantly higher (up to 3.5-fold in shoots and 5.2-fold in roots) than those of the untransformed plants. We also found that targeting CadR to chloroplasts facilitated chloroplastic metal homeostasis and chlorophyll *b* accumulation. Our results demonstrate that manipulating chelating capacity in chloroplasts or in cytoplasm may be effective in modifying both the accumulation of and resistance to Cd.

Light affects salt stress-induced transcriptional memory of *P5CS1* in *Arabidopsis*

*Xuanjun Feng, **Jingrui Li***
Institute of Botany, the Chinese Academy of Sciences

To cope with environmental stresses, plants often adopt a memory response upon primary stress exposure to facilitate a quicker and stronger reaction to recurring stresses. However, it remains unknown whether light is involved in the manifestation of stress memory. Proline accumulation is a striking metabolic adaptation of higher plants during various environmental stresses. Here we show that salinity-induced proline accumulation is memorable and HY5-dependent light signaling is required for such a memory response. Primary salt stress induced the expression of Δ1-pyrroline-5-carboxylate synthetase 1 (*P5CS1*), encoding a proline biosynthetic enzyme and proline accumulation, which were reduced to basal level during the recovery stage. Reoccurring salt stress-induced stronger *P5CS1* expression and proline accumulation were dependent upon light exposure during the recovery stage. Further studies demonstrated that salt-induced transcriptional memory of *P5CS1* is associated with the retention of increased H3K4me3 level at *P5CS1* during the recovery stage. HY5 binds directly to light-responsive element, C/A-box, in the *P5CS1* promoter. Deletion of the C/A-box or *hy5* mutations caused rapid reduction of H3K4me3 level at *P5CS1* during the recovery stage, resulting in impairment of the stress memory response. These results unveil a previously unrecognized mechanism whereby light regulates salt-induced transcriptional memory via the function of HY5 in maintaining H3K4me3 level at the memory gene.

Identification of a regulatory element responsible for salt induction of rice *OsRAV2* through *ex situ* and *in situ* promoter analysis

Juan Li[1], *Yong-Bo Duan*[1,2], *Rong-Fang Xu*[1], *Rui-Ying Qin*[1], *Hao Li*[1], *Ya-Chun Yang*[1], *Hui Ma*[1], *Li Li*[1], *Peng-Cheng Wei*[1], *Jian-Bo Yang*[1]
1. Rice Research Institute, Anhui Academy of Agricultural Sciences
2. College of Life Sciences, Huaibei Normal University

Salt is a major environmental stress factor that can affect rice growth and yields. Recent studies suggested that members of the AP2/ERF domain-containing RAV (related to ABI3/VP1) TF family are involved in abiotic stress adaptation. However, the transcriptional response of rice *RAV* genes (*OsRAVs*) to salt has not yet been fully characterized. In this study, the expression patterns of all five *OsRAVs* were examined under salt stress. Only one gene, *OsRAV2*, was stably induced by high-salinity treatment. Further expression profile analyses indicated that *OsRAV2* is transcriptionally regulated by salt, but not KCl, osmotic stress, cold or ABA (abscisic acid) treatment. To elucidate the regulatory mechanism of the stress response at the transcriptional level, we isolated and characterized the promoter region of *OsRAV2* (P<em>$_{OsRAV2}$). Transgenic analysis indicated that P_{OsRAV2} is induced by salt stress but not osmotic stress or ABA treatment. Serial 5’ deletions and site-specific mutations in P_{OsRAV2} revealed that a GT-1 element located at position -664 relative to the putative translation start site is essential for the salt induction of P_{OsRAV2}. The regulatory function of the GT-1 element in the salt induction of *OsRAV2* was verified *in situ* in plants with targeted mutations generated using the CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats/CRISPR-associated protein 9) system. Taken together, our results indicate that the GT-1 element directly controls the salt response of *OsRAV2*. This study provides a better understanding of the putative functions of *OsRAVs* and the molecular regulatory mechanisms of plant genes under salt stress.

A307

Expression of a Na^+/H^+ antiporter *RtNHX1* from a recretohalophyte *Reaumuria trigyna* improved salt tolerance of transgenic *Arabidopsis thaliana*

Ningning Li, *Xue Wang, Linlin Zheng, Yingchun Wang*
Key Laboratory of Herbage and Endemic Crop Biotechnology, and College of Life Sciences, Inner Mongolia University, Hohhot, China

Reaumuria trigyna is an endangered recretohalophyte endemic to the Eastern Alxa-Western Ordos area of Inner Mongolia in china. Based on transcriptome data, a Na^+/H^+ antiporter gene, referred to as *RtNHX1*, was isolated from *R. trigyna*, which included a 1,662-bp open reading frame encoding a protein of 553 amino acids. *RtNHX1* was rapidly induced by NaCl and exogenous ABA treatment, and showed different tissue expression pattern before and after salt stress. Expression of the *RtNHX1* gene in yeast strain *AXT3* accumulated more Na^+ and K^+ of vacuolar, maintained relatively constant Na^+ concentration of the cytoplasm and lower Na^+/K^+ ratio of yeast cell, revealed that *R.trigyna* RtNHX1 are a functional antiporter capable of sequestering redundant Na^+ and K^+ into the vacuole. Transgenic *Arabidopsis* overexpressing *RtNHX1* accumulated more K^+ and less Na^+ in leaves, and exhibited lower Na^+/K^+ ratio than WT under salt stress, accordingly, the ions transport related genes, such as *AtAVP1*, *AtKUP6* and *AtKUP8,* were also up-regulated, indicating that over-expression of *RtNHX1* confers salt tolerance of transgenic *Arabidopsis* involving in maintaining Na^+/K^+ homeostasis. In addition, over-expression of *RtNHX1* significantly enhanced seed germination, biomass accumulation, contents of chlorophyll and root elongation of transgenic *Arabidopsis* under salinity stress, and dramatically rescued the salt-sensitive defects of the *nhx1* mutant. Transgenic *Arabidopsis* exhibited higher activities of POD and CAT, and contents of proline, relative water, and lower contents of MDA than that of WT under salt stress, moreover, the antioxidant and proline biosynthesis related genes, including *AtPOD1*, *AtCAT1*, *AtP5CS1*, *AtP5CS2*, were corresponding up-regulated, indicating that expressing *RtNHX1* confers salt tolerance of transgenic *Arabidopsis* through efficient capacity of osmotic adjustment and reactive oxygen scavenging, suggesting that *RtNHX1* may be a good candidate gene for improvement of salt tolerance in plants.

Terpenoids diversity in plant glandular trichomes and sesterterpenoid biosynthesis

Yan Liu[1], *Shi-Hong Luo*[2], *Chun-Huan Li*[1], *Ying Wang*[1], ***Sheng-Hong Li***[1]
1. Kunming Institute of Botany, Chinese Academy of Sciences
2. Shenyang Agricultural University

Plants glandular trichomes (GTs) are the adaptive defensive structures on the surfaces of aerial organs of most terrestrial plants. Plant GTs could produce, store and secrete a wide variety of secondary metabolites with defensive functions and important pharmaceutical value, and thus are regarded as phytochemical factories. To precisely investigate the bioactive compounds and their defensive functions in plant GTs, we have developed a new and precise approach, laser microdissection (LMD) coupled with NMR and UPLC-MS/MS. Two unique classes of C_{25} sesterterpenoids (named leucosceptroids and colquhounoids) with defensive functions against insect herbivores and pathogenic fungi were discovered in the GTs of the Himalayan Lamiaceae plants *Leucosceptrum canum* and *Colquhounia coccinea* var. *mollis*, respectively (Luo *et al*, 2010; Li *et al*, 2013). Leucosceptroids and colquhounoids are similar by their core structures, but are clearly distinct by their partially adverse stereochemistries and different post-modifications. Moreover, three new defensive clerodane diterpenoids (named seguiniilactones) with significant insect anti-feedant activity were found in the peltate GTs of *C. seguinii* (Li *et al*, 2014). In addition, four new phytotoxic labdane diterpenoids (named paraguhenryisins) were identified in the capitate GTs of *Paragutzlaffia henryi* (Acanthaceae) (Wang *et al*, 2015). The biosynthesis of leucosceptroids has been investigated. A plant geranylfarnesyl diphosphate synthase (GFDPS), the enzyme producing the C_{25} prenyl diphosphate precursor to all sesterterpenoids, was cloned and functionally characterized from the GTs of *L. canum*. GFDPS is localized to the plastids, and inhibitor studies indicated its use of isoprenyl diphosphate substrates supplied by 2-C-methyl-D-erythritol 4-phosphate pathway. Phylogenetic analysis suggested that GFDPS probably evolved from plant geranylgeranyl diphosphate synthase through gene duplication and neofunctionalization under the influence of positive selection (Liu *et al*, 2016). This research was financially supported by the National Natural Science Foundation of China (31525005, U1202263,31070320).

Effects of different water and nitrogen levels on starch synthesis enzymes in wheat grains during grain filling stage

Shuang Li, *Yang Gao, Xiaojun Shen, Zhuanyun Si, Aiwang Duan**

Ministry of Agriculture Farmland Irrigation Research Institute

Under the condition treated with three levels of irrigation and four levels of nitrogen fertilizer, the winter wheat cultivars of Aikang58 was planted in the field to investigate the effects of different water and nitrogen treatments on sucrose metabolism, starch content, the activities of enzymes of starch synthesis during the grain filling stage. Results showed that suitable irrigation and nitrogen fertilizer management could improve the ability of photosynthate supply and transformation, increase the activity of starch synthesis enzymes, promote grain filling proceeding and increase grain yield. Water stress could accelerate the rate of sucrose accumulation, shorten the peak time and accelerate wheat maturation process, while decrease the activities of ADPGPPase, SSS and GBSS in grains, and correspondingly reduce the starch content and amylopectin content in wheat grains. Nitrogen fertilization would mainly affect grain physiological metabolism at the late filling stage, while the impact was small at the early stage. Excessive nitrogen application did not improve the starch synthesis activity and grain yield, so reasonable management of water and nitrogen could generate positive interaction effects. Our experiment also indicated that under the field environment, the activity of SSS was mainly controlled by ambient temperature. Low temperature could decrease the activity of SSS and slow down the rate of starch accumulation.

The NAC transcription factor SIN1 influences the salinity tolerance of soybean by directly regulating ABA and ROS generation genes

Shuo Li, *Nan Wang, Dandan Ji, Fengning Xiang*

Shandong University

Soil salinity compromises the productivity of soybean, but the full nature of the plant's response and of its adaptation to the stresses still not understood. Here, the over-expression in soybean of a gene encoding GmSIN1, a salinity-induced NAC family transcription factor, was shown to enhance its productivity by up to 35% under non-stressed conditions and by 19% under conditions of salinity stress. The effect of the up-regulation was to maintain root elongation when the plants experienced salinity stress, effected by a simultaneous elevation of the level of both abscisic acid (ABA) and reactive oxygen species (ROS) to a more optimal level. GmSIN1 interacted with both *GmNCED3s* (ABA synthesis) and the *GmRbohBs* (ROS generation) genes and up-regulated their transcription by binding to their promoters at a novel site which has not been described previously. *GmSIN1*, *GmNCED3s* and *GmRbohBs* appear to establish a positive feedback system, which allowed for the rapid accumulation of ABA and H_2O_2, in turn amplifying the early salinity stress signal and improving the salinity tolerance. The suggestion is that the combined manipulation of ABA and ROS content should improve the salinity tolerance of soybean.

Functional analysis of maize silk specific gene *ZmSS1*

Wanying Li, *Jingjuan Yu, Qian Zhao*

China Agricultural University

Basic leucine zipper (bZIP) transcription factors regulate many processes including pathogen defence, seed maturation, flower development and stress signaling. The bZIP family in maize can be divided into 11 groups, Group D genes participate in two different processes: defence against pathogens and development. *ZmSS1*, which belongs to D group of bZIP transcription factor family, was cloned from maize silks. RNA-seq analysis revealed that the expression of *ZmSS1* was tissue-specific in maize silks, which was confirmed by qRT-PCR. *In situ* hybridization showed a specific accumulation of *ZmSS1* transcript in the xylem of silks. *ZmSS1* was not induced by the treatment of PEG, ABA, NaCl and SA in maize leaves. However, the expression of *ZmSS1* was increased in silk after treated with 100mM methyl jasmonate. The subcellular localization showed that the ZmSS1 protein is located in the nucleus of maize protoplasts. However, ZmSS1 don't have the ability of transcriptional activation in yeast and yeast-one hybrid assay showed that it could not bind to C-box or G-box, the predicted common binding core elements of bZIP D group. Heterologous expression of *ZmSS1* in *Arabidopsis thaliana* gave rise to a dwarf phenotype and the expression level of pathogenesis-related (PR) genes was up-regulated. The similar dramatic dwarfism phenotype was also shown in *ZmSS1* over-expression transgenic maize, but no obviously abnormality was observed in *ZmSS1* RNAi plants. Based on present results, we speculated that the *ZmSS1* is likely to involved in responses to pathogen challenge.

The role of *MSR1* in glutathione redox-dependent root development

Xin Yu[2,3], *Klaus Palme*[1,2], ***Xugang Li***[1,2]
1. State Key Laboratory of Crop Biology, College of Life Sciences, Shandong Agricultural University
2. Institute of Biology II/Molecular Plant Physiology, Faculty of Biology, the University of Freiburg
3. Citrus Research Institute, Chinese Academy of Agricultural Science/Southwest University

Glutathione is involved in thiol redox signaling and acts as a major redox buffer against reactive oxygen species, helping to maintain a reducing environment in planta. The crucial role of glutathione redox status in root growth has been revealed. We have previously shown that root apical meristem (RAM) and root stem cell niche were maintained by glutathione redox status in plastids, which was controlled by glutathione reductase 2 (GR2). The loss-of-function GR2 mutant *miao*, exhibited remarkable defects in root developmental. However, the downstream factors regulated by glutathione redox status in root development remains elusive. Here, we screened miao suppressors (*msr*) from a ethyl methanesulfonate -mutagenized miao population and isolated *msr1*, further identified *MSR1* gene. The aim of this study is to uncover the molecular mechanism how *MSR1* is involved in glutathione redox-dependent root development.

Dual phosphorylation of an ERF transcription factor by MPK3/MPK6 and CPK11 regulates pathogen resistance in *Arabidopsis*

Yihao Li
Beijing Key Laboratory of Gene Resource and Molecular Development, College of Life Sciences, Beijing Normal University

Plants have evolved an innate immune system to resist the pathogens during their lifespan. Recent studies have shown that pathogen-associated molecular patterns (PAMPs) can be recognized by the pattern recognition receptors (PPRs), which were located on the cell membrane, then activate the mitogen-activated protein kinase (MAPK) cascade and cytosolic calcium-dependent protein kinases (CPKs) signal transduction pathway to participate in pathogen resistance in plants. However, the cross-talk mechanism between these two signaling pathways remains unclear. Here, we found an *Arabidopsis* Ethylene Responsive Factor 72 (ERF72) can be phosphorylated in vitro by the kinases MPK3/6 and CPK11 which were all involved in plant immunity. Three CPK11 phosphorylation sites of ERF72 were identified by mass spectrometry. Overexpression of ERF72 enhanced the resistance to *Pseudomonas syringa*e pv. tomato DC3000. Transcriptome analysis of transgenic plants which overexpressed non-degrading form of ERF72 (MA-ERF72) have found that many genes associated with disease resistance are up-regulated. By analyzing the GCC box elements in these gene promoters, transcriptional activation assay, ChIP-qPCR and EMSA, we proved that ERF72 directly binds to the GCC box on the *WRKY33* promoter to activate its transcription. Phosphorylation of ERF72 by MPK3/6 and CPK11 stimulates its transcription activity. In summary, ERF72 is co-regulated by MAPK and CDPK signaling pathway and regulates the transcription of *WRKY33*, which is involved in the immune response in *Arabidopsis*.

The relationship between morphology of leaves and branches and hormone during individual development stage transition of *Populus euphratica*

Jiahao Li, Peipei Jiao, ***Zhijun Li***
College of life science, Tarim University

We choose *Populus euphratica* with different diameters on the same site as the research object, through the field investigation and laboratory analysis, the morphology characteristics and endogenous hormone contents variation of *Populus euphratica* branches and leaves, and the relationship among them were investigated. The results showed: (1) As the diameter class increased, the morphology of branches and hormone contents on the crown from base to top showed a stage, hierarchy variation, all the morphology parameter of branches and leaves tested, endogenous hormone contents, such as GA$_3$, IAA, and ZR, hormones ratio of IAA/ABA, ZR/IAA, GA$_3$/ABA, and ZR/ABA in leaves, IAA/ABA, GA$_3$/ABA ratio in branches, showed a significant or very significant positive or negative relationship with diameter classes and crown height. (2) Leaves number per branch, ZR/IAA of branches and leaves, ZR contents in leaves, and ZR/IAA ratio in branches can be used as an important indicator for *Populus euphratica* transition from juvenile to adult. leaf shape index, petiole length, diameter of branches, the flower bud numbers per branch and leaf IAA content, and IAA/ABA ratio can be used as important index for flower bud number increasing in adulthood trees; (3) The content of GA3, IAA and ZR in leaf, and the ratio of IAA/ABA, GA3/ABA, ZR/ABA showed a significant or highly significant positive or negative correlation with all leaf morphological indexes, and ZR/IAA ratio of leaves were very significant positively or negatively correlated with leaf index and petiole length, GA3/ABA ratio in branches was significant or very significant positively correlated with branch length and leaves number per branch. Preliminary results suggested that the leaf morphological variations of *Populus euphratica* leaves during individual development may influenced by the content of GA3, IAA, ZR and hormone ratio of IAA/ABA, GA3/ABA, and ZR/ABA. Leaf shape index and petiole length changes affected by leaf ZR/IAA ratio, while, the changes of GA3/ABA ratio on branches may result in the changes of shoot length and leaf numbers on per branch.

Relationship between morphology and nutrition characteristics of branches and leaves of *Populus euphratica* during transition of the individual developmental stages

Jiahao Li, Shuaifei Liu, ***Zhijun Li,*** *Peipei Jiao*
College of life science, Tarim University

Endangered tree *Populus euphratica* with different diameters on the same site was chosen as the research object, through the field investigation and laboratory analysis, variation of morphology and nutrition characteristics of *Populus euphratica* branches and leaves, and the relationship among them was investigated as the diameter increased. The results showed, as the diameter classes increased, leaf morphology and nutrition changes on the crown from the base to top showed a stage, hierarchy variation. All the morphology parameter tested, content of total nitrogen, total phosphorus, organic carbon of branches and leaves, and carbon nitrogen ratio of leaves were significantly or very significantly positive or negative correlated with diameter class and crown height; a comprehensive analysis showed that the shoot length, number of leaves per branch, the total nitrogen content of leaves and carbon nitrogen ratio of branches and leaves can be used as an important indicator for *Populus euphratica* transition from juvenile to adult, and leaf index, petiole length, diameter of branches, the number of flower buds per branch, organic carbon content can be used as important index for flower bud number increasing turning point in adulthood trees; leaf index can be used as an important index for transition *of Populus euphratica* from juvenile region to adult region on the crown, and leaf area, petiole length, organic carbon content of branches and leaves, total nitrogen content of leaves can be used as morphological index for flower buds increasing turning point in adulthood tress; meanwhile, total nitrogen, total phosphorus, total potassium and the content of organic carbon and carbon nitrogen ratio may play an important role in the regulation of leaf morphological changes during the stage transition.

Effects of *OsIAAGLU* on IAA content and plant architecture in rice

Xiao-Lu Yu[1]*, Hai-Yan Wang*[1]*, David W.M. Leung*[2]*, Xin-Xiang Peng*[1]*,* ***E-E Liu***[1]

1. South China Agricultural University

2. University of Canterbury

Plant architecture is an important agronomic trait that is closely related to yields. The distribution and levels of auxin or indole-3-acetic acid (IAA) within plant tissues are well known to be associated with plant architecture determination. An important mechanism of regulating free IAA levels in monocots is formation of IAA ester conjugates, which account for approximately 62-70% of the total IAA in rice seeds. In this study, the gene *OsIAAGLU* in the rice genome database was found to have 67% sequence similarity with IAA-glucose synthase of maize (ZmIAAGLU), which is known to catalyze the reaction of free IAA with glucose and generate IAA-glucose. Expression of *OsIAAGLU* was mainly in the leaf sheath of rice seedlings, and could be induced by IAA and NAA. OsIAAGLU was localized in the cytoplasm. The number of tillers and leaf angle were significantly increased in the transgenic rice lines over-expressing *OsIAAGLU* compared to the wild-type plants (WT), while plant height and panicle length as well as seed set percentage decreased. *OsIAAGLU* mutants constructed by CRISPR/Cas9 system exhibited increased height and a smaller leaf angle compared to WT. Overexpression of *OsIAAGLU* resulted in reduced sensitivity to NAA, while *OsIAAGLU* mutants were more sensitive to NAA than WT. Free IAA contents in the leaves of *OsIAAGLU*-overexpressing transgenic lines were lower and higher in *OsIAAGLU* mutants than that of WT. These results suggested that *OsIAAGLU* could play a regulatory role in IAA homeostasis and rice plant architecture.

Involvement of HbMC1-mediated programmed cell death in tapping panel dryness of rubber tree (*Hevea brasiliensis*)

Hui Liu*, Zhi Deng, Hong Yang, Longjun Dai, Dejun Li*

Key Laboratory of Biology and Genetic Resources of Rubber Tree, Ministry of Agriculture, Rubber Research Institute, Chinese Academy of Tropical Agricultural Sciences, Danzhou, China

Tapping panel dryness (TPD) in rubber tree (*Hevea brasiliensis*) is the key factor limiting the yield of natural rubber. Developing therapeutic targets and drugs to prevent and treat TPD has become a prominent problem required to be solved urgently for the sustainable and healthy development of natural rubber industry. It was reported that TPD was a programmed cell death (PCD) process, but lack further systematic study. Metacaspases, a family of cysteine proteases, are key regulators of PCD in plants. To reveal the role of metacaspase in TPD, we carried out genome-scale identification and expression analysis of metacaspase gene family in rubber tree. A total of nine *HbMC* genes were identified in rubber tree genome. Multiple sequence alignment and phylogenetic analyses suggested that these genes were divided into two types: type I (*HbMC1−HbMC7*) and type II (*HbMC8* and *HbMC9*). Gene structure analysis demonstrated that type I and type II *HbMCs* separately contained four and two introns, indicating the conserved exon–intron organization of *HbMCs*. Quantitative real-time PCR analysis revealed that *HbMCs* showed distinct expression patterns in different tissues, suggesting the functional diversity of *HbMCs* in various tissues during development. Most of the *HbMCs* were regulated by drought, cold, and salt stress, implying their possible functions in regulating abiotic stress-induced cell death. Of the nine *HbMCs*, *HbMC1* expression was found to positively correlate with TPD. In addition, it was up-regulated by TPD-inducing factors, such as wounding, ethephon, and H_2O_2 treatments. Ectopic expression of *HbMC1* in yeast and tobacco enhanced oxidative stress-induced PCD. We surmised that the up-regulation of *HbMC1* would trigger PCD, and then lead to TPD. *HbMC1* may act as a potential therapeutic target for TPD.

Mechansims of a DnaJ protein from the resurrection plant *Boea hygrometrica* to protect chloroplasts under severe drought stress

Jie Liu[1,2]*, Chunying Shen*[1]*, Zhenna Zhang*[1]

1. Insititue of Botany, the Chinese Academy of Sciences

2. Weifang University of Science and Technology

Plant development and growth are severely affected by drought stress. Photosynthesis, as one of the most sensitive physiological processes to such impact, results in damage to ultrastructure in chlorophylls, degradation of chloroplast pigment, enzymatic activity loss in photosystem and accumulation of reactive oxygen species. DnaJ is a heat shock protein considered involving in chloroplast development and stress protection. In this study, a gene of DnaJ protein localized in chloroplast from the resurrection plant *Boea hygrometrica* (BhDnaJ) was inducible expressed by both abiotic stress (drought, heat, salt, alkaline and high calcium concentration) and ABA. The transgenic *Arabidopsis* overexpressing *BhDnaJ* confer improved tolerance to drought and drought-heat stresses. The fluorescence parameters compared to the wild type (WT) indicates less photodamage in PSII while maintain higher PSII activity and electron transport rate. No significant difference in the photoprotection parameters between *Arabidopsis* overexpressing *BhDnaJ* and WT was found. By yeast two-hybrid system, three proteins interacted with BhDanJ were screened for association with electron transport and photosynthetic phosphorylation. The results showed that BhDnaJ might interact with the chloroplast proteins directly to protect the structure and quantity, thereby participating in the protection of chloroplasts under stress.

CmCADs and three lignin biosynthesis related enzymes play diverse roles in response to abiotic stresses in oriental melon seedlings

Wei Liu, ***Hongyan Qi***

Shenyang Agricultural University

Cinnamyl alcohol dehydrogenase (CAD) is a key enzyme in lignin monomer synthesis pathway, which is responsible for the conversion of cinnamyl aldehydes to cinnamyl alcohols. In some species, CAD could not only take part in plant development through lignin construction but also play a role in resisting biotic and/or abiotic stresses mainly by activated the lignin synthesis pathway. Our previous research identified five *CAD* genes in the melon genome and named *CmCAD1* to *CmCAD5*, respectively. Three abiotic stresses were set as drought (8% and 15% PEG6000), salt (50 mM and 100 mM NaCl) and wound (leaf and stem wound) according to *CmCADs* promoter analysis that revealed motifs involved in stress response and signal molecule regulation. The results indicated that lignin contents accumulated significantly higher in stems and roots than the control. Lignin staining with phloroglucinol-HCl of stem sections obtained consistent results with lignin analysis. Phenylalanine ammonia-lyase (PAL) and peroxidase (POD) were generally induced to significant levels except for PAL activity in roots under drought stress. CAD activity also increased greatly under the abiotic stresses. *CmCAD1* and *CmCAD2* were generally up-regulated by drought and wound stresses in different organs. But under 100 mM NaCl treatment of salt stress, the expression of *CmCAD1* and *CmCAD2* were sharply elevated only in roots and stems, respectively. *CmCAD3*, *CmCAD4* and *CmCAD5* presented differential expression patterns in different organs under the three abiotic stress conditions. Collectively, under the three abiotic stresses, the accumulation of lignin, induction of lignin synthesis related enzymes (PAL, POD and CAD) and differential responses of *CmCADs* in oriental melon seedlings revealed that *CmCADs* might play diverse roles in resisting abiotic stresses through activating the lignin biosynthesis pathway.

AHP2, *AHP3*, and *AHP5* act downstream of *CKI1* in *Arabidopsis* female gametophyte development

Zhenning Liu[1,2,3], *Li Yuan*[1], *Xiaoya Song*[1], *Xiaolin Yu*[2], *Venkatesan Sundaresan*[1]

1. Department of Plant Biology, University of California

2. Institute of Vegetable sciences, Zhejiang University

3. College of Agriculture and Forestry science, Linyi University

Histidine phosphotransfer proteins (HPs) are key elements of the two-component signaling system, which act as a shuttle to transfer phosphorylation signals from His kinases (HKs) to response regulators (RRs). *CYTOKININ INDEPENDENT 1* (*CKI1*) is a master regulator of *Arabidopsis* female gametophytic central cell specification in a linear pathway with the *Arabidopsis* His phosphotransfer proteins (AHPs). There are five *HP* genes in *Arabidopsis*, *AHP1-AHP5*, but it remains unknown which *AHPs* act downstream of *CKI1* in *Arabidopsis* female gametophyte development. Promoter activity analysis of *AHP1–AHP5* in embryo sacs revealed *AHP1*, *AHP2*, *AHP3*, and *AHP5* expression in the central cell. Various combinations of *ahp* mutants were further constructed, seeds development in siliques were checked, cleared ovules were observed and results showed that mutations in *AHP2*, *AHP3* and *AHP5* caused seed abortion phenotype due to the unfused polar nuclei and degenerated embryo sacs. Besides, female gametophyte cell-specific single and double markers were introduced into the *ahp2-2 ahp3 ahp5-2/+* triple mutant and their expression patterns were observed, and results showed that the central cell and antipodal cell fates were lost and transformed into the egg cell or synergid cell fates in *ahp2-2 ahp3 ahp5-2/+* embryo sacs, which resembled the *cki1-9/+* phenotypes. These data indicate that *AHP2*, *AHP3* and *AHP5* act downstream of *CKI1* in *Arabidopsis* female gametophyte development, which could contribute to clarify the two-component system signaling network.

Study on biomass-based maize leaf morphological structure model

Xianju Lu, *Xinyu Guo, Qi Wu, Zetao Yu*

Beijing Research Center for Information Technology in Agriculture/National Engineering Research Center for Information Technology in Agriculture/Beijing Key Lab of Digital Plant

Maize plant morphology directly influences its eco-physiological function and the aboveground morphogenesis is an important basis of plant morphological construction and visualization. It will be benificial to plant type designing and cultivation management. Leaf is an important aboveground organ, its morphology determines maize photosynthetic area and influences photosynthetic production. For quantitatively analyzing the relationship between the leaf architectural parameters and biomass, field experiments with different varieties (Xianyu 335, Jingke 968 and Zhengdan 958) were carried out in 2015 and 2016 seasons. Leaf morphology parameters such as leaf length, maximum width, leaf sheath length were measured in different growth stages. After the morphology parameters measurement, each leaf's fresh weight and dry weight were measured respectively. Simulation models for leaf architectural of maize were built with the 2016 season dataset of leaf architectural parameters and leaf biomass and validated by the 2015 season dataset. The results showed that the models exhibited satisfactory predictions for leaf blade length, maximum width. The model's coefficient of determination were 0.9023 and 0.9827 for leaf blade length and maximum width respectively. Therefore, the models built in this study are suitable to simulate leaf architecture of mazie and they can be used in maize functional-structural model study.

A putative *miR172*-targeted *PhAPETALA2*-like gene is involved in regulating chasmogamous and cleistogamous floral patterning of *Pseudostellaria heterophylla* (*Caryophyllaceae*)

***Yan Luo**, Peng-Fei Wang, Yong-Mei Xia*
Xishuangbanna tropical Botanical Garden, Chinese Academy of Sciences

Individuals of cleistogamous species can produce both open chasmogamous flowers (CH) that are available for outcrossing and closed cleistogamous flowers (CL) that obligately self-fertilize. There are structural differences and functional differences exit in two floral forms. The genetic basis of production of two floral forms is poorly known. The interaction between microRNA *miR172* and its *APETALA2* (*AP2*) target gene is deeply conserved and has an ancient role in flower developmental regulation in angiosperms. *AP2* is a floral organ identity gene, and negatively regulated by *miR172*. Recent studies in *Arabidopsis*, rice and other flowering plants have shown that *miR172* and its *AP2* target play important roles in the determination of floral organ identity. *Pseudostellaria heterophylla* belongs to *Caryophyllaceae*, which produces both chasmogamous and cleistogamous flowers on the same plant. To further understand flowering and flower organs formation in *P. heterophylla*, we cloned an *APETALA2* cDNA sequence of the AP2/ERF transcription factor family designated *PhAP2*. The length of *PhAP2* is 2,294 bp and encoding 593 amino acids. Bioinformatics analysis with putative orthologous sequences from various plant species suggested that *PhAP2* cDNA sequences encode for AP2-like proteins with the AP2 characteristic motifs and amino acids. Phylogenetically, the isolated sequences were closest to the *APETALA2* gene from *Beta vulgaris* and *Spinacia oleracea* which belong to the Order Caryophyllales. Splice variants were identified, including a variant that potentially produces a shorter transcript without the miRNA172 targeting site. Expression of *PhAP2* was compared in floral organs and developmental stages in and CH flowers and CL flowers. The expression pattern in various developmental stages and reproductive organs was interrogated by RT-PCR. In CH flowers, *PhAP2* was ubiquitously expressed, with highest levels of expression detected in the earlier developmental stages; in mature flowers, highest *AP2* transcript accumulation was detected in petal tissue. The accumulation of *AP2* transcript during flower differentiation from the visible floral bud showed minor variation in CL flower. In situ hybridization demonstrated *PhAP2* accumulation in central floral meristems, sepal primordia both in CH and CL flowers. *PhAP2* accumulation was detected in the stamen primordia in CH flowers but not in CL flowers. A stem-loop RT-PCR was performed to detect relative levels of miRNA in various developmental stages and floral organs of CH flowers and CL flowers. In CH flowers, *miR172* was higher expression in later developmental stages and in stamens and pistils. In contrast, *miR172* was only detected in the later developmental stage. In situ hybridization demonstrated *miR172* was mostly absent from all the developing floral organs. High expression in CH flowers and CL flowers, particularly petal tissue and increased accumulation in the earlier flower developmental stages, implied that PhAP2 might have a role in the control of perianth identity in *P. heterophylla*. *MiR172* was detected in the later flower developmental stages of CH and CL flower.The increase in AP2 transcript accumulation was probably the result of decreased negative regulation exterted by *miR172*, resulting from decreased accumulation of *miR172* itself, consistent with the role of *miR172* in flower development in Arabdopsis. This study provides a new insight into the genetic basis of production of dimorphic flower in cleistogamous species and has great significance for flower morphological evolution in flowering plants.

Ultrastructure, antioxidant enzymes, and photosynthetic performance of a rice leaf photo-oxidation mutant *812hs*

*Jing Ma[1], Guoxiang Chen[1], Zhiping Gao[1], **Chuangen Lv**[2]*
1. Nanjing Normal University
2. Jiangsu Academy of Agricultural Sciences

To explore the physiological mechanism of a rice leaf photo-oxidation mutant *812hs*, effects of high light intensity on morphological traits, photosynthetic performance, protein and activities of antioxidative enzymes of 812HS were investigated using its wild type 812S as control in field growth conditions. The chloroplast ultrastructure was observed as well. Results showed that (1) Morphological traits, chlorophyll content, chloroplast ultrastructure, photophosphorylation, ATP levels, activities of Ca^{2+}-ATPase, Mg^{2+}-ATPase, proteins, reactive oxygen species (ROS) and antioxidant enzymes activities in 812HS were similar to those in its wild type before exposure to a period of high light intensity. (2) After a period of high light intensity, all the above indices of 812HS were affected and shown significant difference in its wild type with the loss of green. Transmission electron microscopy showed that photo-oxidation resulted in significant chloroplast damage. These results were confirmed by inhibited photophosphorylation, reduced ATP content and its coupling factor Ca^{2+}-ATPase, and Mg^{2+}-ATPase activities. Further, overtly increased activities of antioxidative enzymes were observed under photo-oxidation. Malondialdehyde, hydrogen peroxide and superoxide generation rates also increased. The findings indicate that excessive energy triggers the production of toxic ROS and promotes lipid peroxidation in rice plant, causing severe damage to cell membranes, degradation of photosynthetic pigments, and inhibition of photosynthesis.

A324

Shading fruit with opaque paper bag affecting the expression of peach (*Prunus persica L. Batsch*) allergen-encoding genes

***Yingtao Ma**, Jianming Han, Xuejiao Zhao*
Luoyang Normal University

Freshly consumed peach can cause allergic reactions in the worldwide population because of the presence of four classes of allergens (Pru p 1, Pru p 2, Pru p 3, and Pru p 4), and their cross-reactivity with sensitizing allergens in other species. Fruit bagging has been developed into a common field practice in peach cultivation, which not only protects fruit against damage from pests, birds, diseases, and mechanical scratches, but also reduces pesticide residues. Knowledge of influence of fruit bagging on expression of peach (*Prunus persica L. Batsch*) allergen-encoding genes would provide important information to peach growers and consumers for the adoption of agronomic practices to decrease the allergenic potential, and for the consumption of fruits with reduced levels of allergens. In the present research, the expression profiles of some selected genes encoding peach allergen isoforms, including Pru p 1.01, Pru p 1.06B, Pru p 2.01B, Pru p 2.02, Pru p 3.01, Pru p 4.01 and Pru p 4.02 were studied by means of real-time PCR. Peach samples were collected from fruits which were shaded with opaque paper bag, set up to assess the effect of shadowing on the expression of allergen genes. The results indicate that shading significantly affected the transcription of allergen-encoding genes. For Pru p 1 family members were concerned, a decreasing trend in the transcript accumulation was observed in epicarp of bagged fruit, whereas the opposite effect was observed in the mesocarp. As far as Pru p 2.01B expression was concerned, fruit bagging was shown to significantly decrease the transcriptional rate in epicarp, a slightly increasing trend was observed in the mesocarp. With regard to Pru p 2.02, the expression level were both down regulated in the epicarp and mesocarp .In the case of Pru p 3.01 gene, a strong down-regulation were observed both in the mesocarp and the epicarp. As far as the two profilin-encoding genes are concerned, the same trend were found. Fruit bagging was shown to significantly affect Pru p 4.01 and Pru p 4.02 transcription, reversing its expression pattern in the mesocarp. According to these data, new growing practices could be set up to obtain hypoallergenic peach fruits and eventually combined with the cultivation of hypoallergenic genotypes to obtain a significant reduction of the allergenic potential.

A325

Preparation and identification of monoclonal antibody against Pru p 3.01 and development of a double monoclonal antibody-based sandwich ELISA

***Yingtao Ma**[1], Zhongshan Gao[2], Hongxia Wu[3], Pengcheng Fu[1], Yanwei Cheng[1], Ling Zheng[1], Xiaojun Zhou[1]*
1. Life Science College, Luoyang Normal University, Luoyang
2. College of Agriculture and Biotechnology, Zhejiang University, Hangzhou
3. South Subtropical Crops Research Institute, Chinese Academy of Tropical Agricultural Sciences, Zhanjiang

Peach lipid transfer protein (LTP1), Pru p 3.01, is a major allergen causing severe systemic reactions in peach allergic patients in Mediterranean countries and China. In this study, recombinant Pru p 3 was used to immunize Bal b/c mice (experimental animal use permission, SCXK (HU)2012-002, China) and five hybrid cell lines 4#, A7, 6#, 11# and B10 excreting monoclonal antibody against Pru p 3 were obtained by fusing mouse SP2/O myeloma cells with the spleen cells from the immunized mouses. Antibody-producing hybridoma cells were screened by ELISA and Western blotted with rPru p 3 and peach peel extract. Hybridoma cells were then injected into the abdomen of Bal b/c mice, and the anti-Pru p 3.01 mcAbs were harvested from ascites and purified on HiTrap Protein A. Seven monoclonal antibodies (4-1, 4-6, A7-1, A7-2, 6-F7, 11-B and B10-5) were produced from the immunization, the titer of which were 1:20000, 1:10000, 1:60000, 1:20000, 1:20000, 1:2000 and 1:20000, respectively. And the isotype of 4-1 and 4-6 are IgG2a (κ chain) and the rest five is IgG1 (κ chain). The western blotting analysis showed all of these antibodies were highly specific to Pru p 3.01. A monoclonal antibodies-based sandwich ELISA was established with mcAb B10-5 as capture mcAb (bound to the solid phase) and biotinylated mcAb 4-1 as the detector, which shows high accuracy, resolution, reproducity and stability. The specificity of this measurement was confirmed using peach and other fruit nsLTPs. Therefore, these obtained anti-Pru p 3.01 can be used to detect Pru p 3.01 in peach fruit and related samples.

The effect of nano potassium chelate and nitrogen biological fertilizers on qualitative performance of sesame seeds (*Sesamum indicum* L.) in irrigation regimes

***Akram Mahdavi**, Jafar Sinaki, Amini Dehaghy Majid*
Azad university, Damghan branch

Nanofertilizer achieved delivery of nutrients to the plant roots through improving the efficiency of fertilizers dramatic gains such as increased crop yields, lower production costs, and environmental protection. The effect of drought last season is disturbance of balance nutrition in the plant. With the completion of the consumption nutrients, can be plant growth and finally improve product quality in terms of stress. Sesame (*Sesamum indicum* L.) is one of the oldest oil plants of tropical and subtropical region and seeds due to the quantity and quality of protein and oil have high nutritional value. Therefore, the experiment was conducted split plot factorial experiment in which different irrigation regimes (full irrigation, irrigation up to 50% flowering, irrigation up to 50% seed ripening) in the main plots and various combinations of nitrogen (Nitrogen, 100% urea based on soil testing, integrated of 50% urea based on soil testing and nitrogen) and various combinations of potassium (no fertilizer, foliar application of nano potassium chelate, foliar application of potassium dioxide and soil application of nano-chelate potassium) were the subplots. This study was conducted with three replications in Agricultural Research Station, Shahed University of Iran in 2016 on the Darab1 genotype of sesame in which were measured grain yield, percentage and yield of protein content and percentage and yield of oil. The results showed that the effect of different combinations of nitrogen fertilizers, the interaction of different irrigation regimes and nitrogen compounds and triple interaction (nitrogen compounds in potassium compounds in different irrigation regimes) were significant on grain yield. Among the different combinations of nitrogen was achieved the highest yield in the use of urea fertilizer based on soil test (100%), and integrated systems had yield higher than in comparison with biological fertilizer of nitrogen. Effects of different combinations of nitrogen and potassium were significant on protein content and interaction of nitrogen in potassium compound in different irrigation regimes was significant on protein yield. Protein and oil content had the highest mean in the integrated of nitrogen fertilizer. Among the combination of potassium fertilizers, the use of nano-chelated potassium for foliar and foliar application potassium dioxide compared with the other treatments increased the mean grain yield, protein and oil yield. Generally, used foliar application of potassium fertilizer and nitrogen fertilizer integrated system (according to the environmental impact caused by the indiscriminate use of industrial inputs such as chemical fertilizers) in full irrigation system and providing 100% require plant based on soil test from urea in terms of irrigation up to 50% seed ripening increased the quality and quantity of Sesame seed (in terms of protein and oil).

Root and shot allometric relation of seven forage crops under abiotic stresses

Amrakh Mamedov[1], *Khatira Gasimova*[1], *Emin Husiyev*[1], *Vahid Farzaliyev*[2], *Kristina Toderich*[3], *Valida Ali-Zada*[1]
1. Institute of Botany, ANAS
2. Central Botanical Garden, ANAS
3. International Center for Biosaline Agriculture (ICBA)

Knowledge of root and shoot biomass dynamics is vital to improving our understanding of the contribution of abiotic stress on plant growth and yield, transportation of photosynthate, and nutrient cycling, carbon distribution and land development. Allometric relationships between plant organs allows to link plant structural development and primary physiological processes, and hence established relationship in ontogeny can be used as components of crop models, and to estimate plant parameters that are difficult to measure. The objective of the study was (i) to investigate morphological, physiological, and biomolecular mechanisms of the forage crops salinity tolerance, (ii) using allometric relationships to estimate crop performance and variability under current and future climates, and hence (iii) to identify prime adaptation strategies to reduce susceptibility of agro-ecosystems to climate change. During three year we have studied a change of allometry between root and shoot of seven forage crops (Alfalfa, Amaranthus, Maize, Pearl Millet, Quinoa, Rapeseeds, Sorghum) affected by a salt and drought stress in the typical agricultural fields of Central Azerbaijan, characterized by clay soil texture, and different soil salinity level (EC = 4-12 dS/m) and shortage of water resources. During vegetation growth measurements at various phenological stages of crops were conducted, root, shoot and soil samples were taken for appropriate chemical and biochemical analysis. Allometric relationships between height and stem mass or stem diameter, developmental rates of different organs, and between growth rate and cell biomass was established. Results showed that (i) plants growth performance depend on the integrated functioning of both roots and aboveground leaves, and their structure and function are interrelated affecting transportation of macro- and microelements in the soil-root-plant system; (ii) root: shout ratio of the forage crops increased with decrease in root weight of the plants; quinoa and sorghum had one of lowest root: shout ratio, while having highest root weight, showing their better adaptability to combined abiotic stresses, than other crops; (iii) allometry can be used to study the ability of plants to adapt to the environment and abiotic stress condition, and assist to evaluate the contribution of crop varieties and management; (iv) allometric relationship between stem diameter and plant parameters (e.g. root and shoot weight) was established; the power or exponential function described well such relationship and may allow understanding contribution of growth period or crop root, shoot or leaf performance; allometric differences was found (exponent or coefficient of equations) between the crops or cultivars of the same crops and or between control and fertilizer treatments; (v) using easily measurable plant parameters can provide data required to estimate C accumulation rates and water and nutrient requirements for salt tolerant forage crops. The improved knowledge of the mechanisms of resistance of the crops to adverse abiotic factors will help selecting and or breeding cultivars adapted to the most diverse abiotic stresses, and develop techniques for overcoming the constraints imposed by severe environments existing in the region, and promoting an improvement in agricultural sustainability.

Differential expression of wound-induced genes mediating suberization in postharvest tomato fruit

Linchun Mao*,* *Xueyuan Han*, *Wenjing Lu*
Zhejiang University

Fruit wounding occurred at harvest, handling and transportation requires rapid suberization as a major part of the healing process to prevent infection and desiccation. The induction and expression of responding genes are essential for wound-induced suberization. The objective of this research was to determine expression profiles of specific genes involved in wound suberization in tomato fruit. The results showed that obvious suberization process with the accumulation of suberin polyphenolics (SPP) and suberin polyaliphatics (SPA) was observed through confocal autofluorescence microscopy and Sudan IV staining. Certain genes that were specifically involved in the process did not remain uniformly up or down-regulated. Expressions of *SlPAL* encoding phenylalnine ammonialyase and *Sl4CL* encoding 4-coumarate ligase in synthesis of SPP reached the highest at 4 d and 8 d after wounding, respectively. The genes regulating SPA synthesis pathway showed different variation patterns. The expression of *SlLACS1* encoding long chain acyl-CoA synthetases was induced to up-regulation, especially at 8 d after wounding in abscisic acid (ABA) treated group. Instead, *SlLACS2* showed the most enhanced expression at 6 d. Gene expressions including *SlKCS6* and *SlKCS19* encoding β-ketoacyl-CoA synthase*,* *SlCYP86B1* encoding fatty acyl ω-hydroxylase*,* *SlFAR3* encoding fatty acyl-CoA reductases*,* *SlGPAT4* and *SlGPAT6* encoding glycerol-3-phosphate acyltransferase were dramatically up-regulated at 2 d after wounding in ABA treated group, but then slightly declined near completion of the healing at 6–8 d. This differential in the expression profile may be the demonstration of measurable changes in the biological flux of wound-induced synthesis of SPP and SPA. In addition, both polyphenol oxidase (PPO) and lipoxygenase (LOX) activities and gene expressions increased rapidly upon wounding, and then decreased simultaneously with suberization process. The temporary oxidation upon wounding may be important for the initiation of wound suberization.

T4

Two novel MADS-box transcription factor, *FaMADS1a* and *FaMADS2a*, act as negative regulators in the ripening of strawberry fruit

Linchun Mao, *Wenjing Lu, Jingxin Chen*
Zhejiang University

MADS-box genes encode highly conserved gene family of transcriptional factors that regulate abundant developmental processes in plants. In this study, two octaploid strawberry (*Fragaria* × *ananassa*) MADS-box genes, *FaMADS1a* and *FaMADS2a*, were cloned and their tissue-specific expression profiles were analyzed. *FaMADS1a* and *FaMADS2a* were expressed in petal and fruit, and their expression levels decreased significantly in accordance with fruit ripening. Multiple sequence alignments suggested that FaMADS1a protein exhibited conserved MADS_MEF2_like motif, K-box region, MADS domain, SRF-TF motif and ARG80 domain. FaMADS2a protein possesses conserved K-box region. Phylogenetic analysis revealed that FaMADS1a and FaMADS2a belonged to the SEP1/2 and SEP3 clade, respectively. Phytohormone abscisic acid (ABA) suppressed the expressions of *FaMADS1a* and *FaMADS2a* and accelerated the ripening process, while indole-3-acetic acid (IAA) induced their expressions with delayed ripening phenotype. The depression of *FaMADS1a* and *FaMADS2a* might be the essential prerequisite for the expression of *FaDFR* and *FaANS*. *FaMADS1a* and *FaMADS2a* might play a negative role in fruit ripening via the downstream of phytohormone signal transduction pathway connected to related metabolic process.

L-DOPA triggers the early response of *Arabidopsis thaliana* to iron deficiency

Xiangxiang Meng, *Ping Lan**
State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences

L-DOPA (L-3,4-dihydroxyphenylalanine), an uncoded amino acid in some mammals and plants, plays important roles in the maintenance of internal environment of lots of living organisms. It has received increasing attention as one of allelochemicals in plants owing to its potential function to be a bioherbicide without pollution, and besides, as a medicine to alleviate the Parkinson's disease and dopamine-responsive dystonia in hominine. In the current work, the effects of L-DOPA on the responses of plants to iron deficiency were investigated by treating the two-week-old Arabidopsis seedlings with or without 100 mg/L L-DOPA . Time course studies showed that the ferric reductase activity (FCR) was gradually increased along with the processing time, i.e. by 1.5 times ($P < 0.05$), 2 times ($P < 0.01$), 4 times ($P < 0.01$) and 6 times ($P < 0.01$) for 6 hours, 9 hours, 12 hours and 24 hours respectively. Perls staining showed that the Fe^{3+} was immobilized in the whole lateral roots and vascular after 24 hours. In addition, the expression of iron acquisition-related genes, including *FIT, FRO2* and *IRT1*, and genes involved in iron homeostasis, such as *FRD3*, *NAS4* and *IRT3*, was significantly up-regulated by L-DOPA treatment. Melanin was largely concentrated in the roots after treatment for 12 hours. These results suggest that L-DOPA might disturb the iron homeostasis by depositing iron in apoplast through the increase of melanin concentrations.

Molecular and biochemical analysis of chalcone synthase from *Freesia hybrid* in flavonoid biosynthetic pathway

*Xiangyu Meng, Ling Li, Tongtong Zhou, Wei Sun, Yueqing Li, Li Wang**, ***Xiang Gao****
Key Laboratory of Molecular Epigenetics of MOE and Institute of Genetics & Cytology, Northeast Normal University, Changchun

Flavonoids are the most abundant and widely distributed pigments in the plant kingdom, and have a wide variety of biological functions, including protection of cells against UV radiation, resistances against phytopathogens and herbivores, signal molecules in plants and microbes interaction, *etc*. Chalcone synthase (CHS) catalyzes the first committed step in the flavonoid biosynthetic pathway, with the condensation of one molecule of p-coumaroyl-CoA with three molecules of malonyl-CoA, to yeild naringenin chalcone. Presently, a whelming proportion of *CHS* gene family have been well elucidated in core eudicot plants, whereas they were studied randomly in monocot plants, which are of crucial importance to decipher their duplication and functional divergences in monocot plants during evolution. *Freesia hybrida*, a monocotyledonous ornamental species, widely distributes in the world and is becoming increasingly popular as a cut flower. The range of flower colours available in this species includes red, pink, yellow, white, blue, lavender, purple and bicolors. Specialized metabolites analysis showed that five kinds of anthocyanin aglycons, i. e. delphinidin, petunidin, malvinidin, peonidin, and cyanidin, as well as flavonols and PAs were detected in the *Freesia* flowers. In this study, a strategy combining transcriptomic data, expression profiles, enzyme assays and ectopic expression was undertaken to investigate the functional divergences of chalcone synthase family. In total, seven candidate genes (*FhCHS1~7*) were isolated from *F. hybrida* and then analyzed. Multiple sequence alignments showed that both the conserved CHS active site residues and CHS signature sequences were found in the deduced amino acid sequence of FhCHSs. Meanwhile, crystallographic analysis revealed that protein structure of FhCHS1 is highly similar to that of alfalfa CHS2. However, the *in vitro* biochemical analysis indicated that only FhCHS1 and FhCHS6 have the capacity to catalyze the formation of naringenin chalcone. Quantitative Real-time PCR was performed to detect the transcript levels of *FhCHSs* in flowers, different tissues, and flowers exposed under UV-B irradiation, and the results demonstrated that the expression patterns of *FhCHS1* showed significant correlation to the accumulation patterns of anthocyanin during flower development, whereas *FhCHS6* was obviously responded to UV-B treatment. This phenomenon illustrated the fact that *FhCHS1* is the key enzyme involved in the anthocyanin biosynthetic pathway and the up-regulation of *FhCHS6* could be one of the strategies to enhance tolerance against UV-B stress in *F. hybrida*. To further characterize the functionality of *FhCHSs*, their ectopic expression in *Arabidopsis thaliana tt4* mutants and *Petunia hybrida* was performed. The results showed that the over-expression of *FhCHS1* and *FhCHS6* could fully restore the pigmentation phenotype of the mutant plants. In addition, transgenic petunia plants expressing *FhCHS1* also showed flower color alteration from white to pink. In summary, these results suggested that *FhCHS1* and *FhCHS6* might play differential roles in the biosynthesis of flavonoid in *F. hybrida*, and the finds will probably contribute to the investigation of the origination and evolution of CHS gene family in angiosperm.

Gibberellin inhibits floral initiation in the biofuel plant *Jatropha curcas*

Jialong Li, Bz Pan, Longjian Niu, ***Zengfu Xu***
Xishuangbanna Tropical Botanical Garden, Chinese Academy of Science

Jatropha curcas L. has great potential as renewable energy plant due to the high oil content in the seed. However, poor yield is an obstacle for the industrialization of this plant. *J. curcas* has vigorous vegetative growth but relatively poor reproductive growth. A feasible way to improve the seed yield is to inhibit the vegetative growth and increase the reproductive growth. Gibberellin (GA) is an important phytohormone and has been reported to control the transition from vegetative growth to reproductive growth. This study was undertaken to determine the effects of GA on the floral transition in *J. curcas*. The exogenous application of gibberellic acid 3 (GA_3) inhibited flowering, while GA biosynthesis inhibitors promoted flowering. The promotive effect of the GA biosynthesis inhibitor paclobutrazol (PAC) on floral initiation could be diminished by GA_3 treatment. The expression levels of GA biosynthesis genes *Jatropha GA 3-oxidase 3* (*JcGA3ox3*) and the GA receptor genes, *Jatropha GA-INSENSITIVE DWARF1A* (*JcGID1C*) were decreased, while a GA turnover gene, *Jatropha GA 2-oxidase 8* (*JcGA2ox8*), was elevated during floral transition. These results indicated that GA inhibits floral initiation in *J. curcas,* and the transition from the vegetative to the reproductive phase may be related to a change in the GA content of the shoot apex.

Modulating role for ROS in re-establishing desiccation tolerance in germinating seeds of *Caragana korshinskii* Kom

Long Peng
National Engineering Laboratory for Tree Breeding, College of Biological Sciences and Biotechnology, Beijing Forestry University

In close coincidence with visible germination, orthodox seeds lose desiccation tolerance (DT). This trait can be regained under osmotic stress, but the mechanisms are poorly understood. In this study, germinating seeds of *Caragana korshinskii* Kom was investigated focusing on the potential modulating roles of reactive oxygen species (ROS) in DT re-establishment. Seeds with emerged radicles measuring 2 mm long can be rendered tolerant to desiccation by incubation in a polyethylene glycol (PEG) solution (-1.7 MPa). Upon PEG incubation, ROS accumulation was detected in the tip of radicles by nitroblue tetrazolium chloride (NBT) staining and further confirmed by confocal microscopy. The PEG-induced re-establishment of DT was repressed when ROS scavenger was added to the PEG solution. Moreover, ROS act downstream of ABA to modulate PEG-mediated DT re-establishment, and serve as a new inducer to re-establish DT independently. Transcriptomic analysis revealed that DT re-establishment by ROS involved the up-regulation of key genes in phenylpropanoid-flavonoid pathway, and total flavonoids content and key enzyme activity increased after ROS treatment. Furthermore, DT was repressed by phenylalanine ammonia lyase (PAL) inhibitor. Our data suggest ROS play a key role in DT re-establishment by regulating stress-related genes and phenylpropanoid-flavonoid pathway.

The TRAF-family proteins TRAF1a and TRAF1b regulate autophagy dynamics by modulating ATG6 stability in *Arabidopsis*

Hua Qi
Sun Yat-Sen University

Eukaryotic cells use autophagy to recycle cellular components. In autophagy, autophagosomes deliver cytoplasmic contents to the vacuole or lysosome for breakdown. Mammalian cells could regulate the dynamics of autophagy by ubiquitin-mediated proteolysis of autophagy proteins. Here, we show that the Arabidopsis Tumor necrosis factor Receptor-Associated Factor (TRAF)-family proteins, TRAF1a and TRAF1b (previously named MUSE14 and MUSE13, respectively), help regulate autophagy via ubiquitination. Upon starvation, cytoplasmic TRAF1a and TRAF1b translocated to the autophagosomes. Knockout *traf1a/b* lines showed reduced tolerance to nutrient deficiency, increased salicylic acid and reactive oxygen species levels, and constitutive cell death in rosettes, resembling the phenotypes of autophagy-defective mutants. Starvation-activated autophagosome accumulation decreased in *traf1a/b* root cells, indicating that TRAF1a and TRAF1b function redundantly in regulating autophagosome formation. TRAF1a and TRAF1b interacted *in planta* with ATG6, the ring finger E3 ligases SINAT1 and SINAT2, and the RING-finger-truncated SINAT6. SINAT1 and SINAT2 require the presence of TRAF1a and TRAF1b to ubiquitinate and destabilize ATG6 *in vivo*. Conversely, starvation-induced SINAT6 reduced SINAT1- and SINAT2-mediated ubiquitination and degradation of ATG6. Consistent with this, *SINAT1*/*SINAT2* and *SINAT6* knockout mutants exhibited increased tolerance and sensitivity, respectively, to nutrient starvation. These findings demonstrate that TRAF1a and TRAF1b function as molecular adaptors that help regulate autophagy by modulating ATG6 stability in *Arabidopsis*.

A new method for fast extraction and determination of chlorophylls in natural water

Nianwei Qiu
Qufu Normal University

Spectrophotometry is the most classical and common method for determination of chlorophylls in natural water. Although this method had been improved several times in recent years, many problems still remain, such as a long collection time for the algae sample preparation, high cost in filters, low chlorophyll extraction rate from algae, and tedious operation steps. To solve the above problems, a new method for fast extraction was proposed in this study. First, the high-speed refrigerated centrifugation method (HSRC) was used for algae collection from water samples instead of filtration. Second, chlorophyll was extracted with dimethyl sulfoxide (DMSO) at a high temperature to accelerate the extraction rate. Third, the chlorophyll extract was diluted with 90% acetone for accurate determination of chlorophyll concentration. The optimum centrifugation condition for collecting algae was determined as: 5,000 g for 15 min at 4°C and the optimal dilution ratio of DMSO: 90% acetone (v/v) was determined as 1:4. This new method saved the cost of filter, simplified the extraction process, improved the algae acquisition efficiency and increased the chlorophyll extraction rate, thereby improving the experimental efficiency. The specific steps were as follows: The algae in water samples was collected by centrifugation at 5000 g at 4°C for 15 min. The precipitated algae was suspended with 2 ml DMSO. Then the sample was transferred to a 15 mL screw-cap glass centrifuge tube, and the tube was incubated at 65°C for 1-2 h in the dark until the sample turned white. After cooling, the chlorophyll extract was added with 8 mL 90% acetone and well mixed, before centrifugation at 5,000 g for 5 min. The absorbance of the supernatants at 750 nm, 664 nm, 647 nm and 630 nm were used for the calculation of chlorophyll concentrations by the trichromatic equations.

Cytology observation of anther development of the male sterile plant in *Psophocarpus teragonolobus*

Miaohua Quan
College of Biological and Food Engineering, Huaihua University

The anther development process of the male sterile and normal plant in *Psophocarpus teragonolobus* were studied in this paper. The results showed that the microspore abortion of the male sterile plants first took place at microsporocyte stage. Mainly, because its tapetum cells became vacuolated ahead of schedule during the micospore development, which made the tapetum cells couldn't provide enough nutrient for the micorspore development. Following, the tapetum cells were highly vacuolated and expanded in radialdirection at the tetrad and the pollen formation stage, microsporocytes were squeezed, which made grow abnormally and resulted in the abortion finally. In this paper, compared with the fertile pollen development, the abortion process and characteristics of the male sterile anthers in *Psophocarpus teragonolobus* were disclosed, providing a foundation for the greater insight into the abortion mechanism of male sterile plant.

Response of *Stevia rebaudiana Bertoni* to foliar application with yeast or seaweed extracts on growth, anatomical and chemical structure

***Azza Salama**, *Ahmed Attia, Mohamed Negm*
Cairo University

The current study was carried out during the two successive seasons of 2013-2014 and 2014-2015 at Giza Agricultural Research Station, Agricultural Research Center, Giza, Egypt, to investigate the effect of foliar spray with yeast or seaweed extracts and their interaction on some morphological, anatomical as well as chemical characters of stevia (cv. China-1). Yeast extract was sprayed at concentrations of 2 and 4 g/L whereas; seaweed extract at 0.5 and 1.0 ml/L and their interaction, whereas control plants were sprayed with tap water. The results showed a significant increase in plant height, stem diameter, number of branches/plant, fresh and dry weight of leaves/plant when plants spraying with different concentration of yeast or seaweed extract as compared with the untreated plants. The maximum significant increase was recorded when plant sprayed with a mixture of 2 g yeast extract/L and 1.0 ml seaweed extract/L. Also, it was clear from the anatomical characters of stem and leaves that, such treatment increased stem diameter due to the increase in the thickness of cortex, phloem tissue, xylem tissue and parenchymatous area of the pith more than those of the control. As well as, the thickness of midvein, lamina and the dimension of the main midvein bundle increase. The foliar application with mixture of 2 g yeast extract/L+1.0 ml seaweed extract/L resulted in the highest rebaudioside-A and stevioside percentage being, 7.0 and 3.94%, respectively.

Population densities and functional diversity of Rhizobacteria found in root biofilms of agriculture crops in saline soils

Meenu Saraf
Gujarat University

The rhizobacteria play an intrinsic role in enhancing the plant growth by an array of activities leading to biofertilization and biocontrol. In any rhizosphere, the metabolic versatility of a bacterial population is based on its genetic variability and its putative interactive ability with other rhizosphere population of other kind including inter and intra species population with functional diversity. Evaluating the relative strengths of bacterial species richness and estimation on diversity found in rhizosphere of chick pea is of vital importance to the understanding the different function carried out by bacteria which could be specifically suited for saline agriculture. The success of microbes is attributed to effective colonization of plant roots and subsequent growth to form biofilms . To achieve this objective a study was designed targeting the rhizosphere of cicer arietinum, which were planted in various soil conditions on five distinctive sites of Gujarat state (India). These sites were constantly monitored and studied for the species richness and evenness ("heterogeneity") The isolates were checked for their Plant Growth Promoting potentials like Phosphate solubilisation, Siderophore production, Indole acetic acid production, ACC deaminase production, HCN production, EPS production and Ammonia production .The data obtained were used to calculate richness, evenness and diversity indices. The combinatorial estimates provide the information on their distribution and roles in the habitat. The rhizobacteria in their biofilms mode perform well in inhibiting competing organisms, nutrient uptake, quick responses, and adaptation to environmental conditions and communicate to each other via quorum sensing, disease reduction by PGPR also occurs by production of antimicrobial substances and indirectly through induction of systemic resistance. The present study demonstrated the ability of native strains of saline areas to tolerate salinity and show plant growth promoting potential. From total of 176 bacterial isolates, 62 isolates have potential to tolerate salinity up to 1 M NaCl concentration. The five bacterial isolates were screened out that not only can tolerate the high salinity but play an essential role in helping plants to establish and grow in salinity conditions. Isolates were identified by 16sRNA as belonging to *Pseudomonas stutzeri* and *P.mosselii*. Isolate MSC1 increase the root length by 71% and shoot length by 34% compared to untreated plants. MSC4 was another effective growth promoter which increases the root length by 76%. Isolates MSC4 and MSC1 also shows maximum increase in number of flowers by 63% and 54% respectively. Plants inoculated with MSC4 and MSC1 showed increase in number of fruits by 112% and 105% in comparison with uninoculated control. The sequences obtained in this study were deposited in the NCBI GenBank nucleotide sequence database under the accession numbers KC669688 (*Pseudomonas stutzeri*- MBCU1) and KC669689 (*Pseudomons mosselii* – MBCU3). However, this has to be tested with many other crops to confirm the ability of this PGPR to confer salt tolerance under field conditions. Therefore, it is plausible to mention that PGPR are an effective approach for improving the growth of salt-sensitive plants and this strategy could be applied for sustainable agriculture.

Comparison of the light response models of photosynthesis in leaves of *Magnolia sinostellata* under different light intensities and moisture conditions

Qin Yu
Zhejiang A&F University

Our objectives were to find the optimal models for the light response of photosynthesis in leaves of *Magnolia sinostellata* seedlings by comparing the light response curves under different intensities of light and moisture conditions and define the adaptability of *Magnolia sinostellata* to low light. We measured light response of photosynthesis in leaves of *Magnolia sinostellata* under different intensities of light and moisture conditions using Li-6400 portable photosynthesis system, and fitted and analyzed the light response curves by five models: exponential, rectangular hyperbolic, non-rectangular hyperbolic, quadratic function, and modified rectangular hyperbola. (1) Within the set up illumination range, *Magnolia sinostellata* never show obvious the phenomenon of photo-inhibition, the net photosynthetic rate (Pn) is lower than CK under situation W_1, compared to situation W_2: when Photosynthetically Active Radiation (PAR) < 800 $\mu mol \cdot m^{-2} \cdot s^{-1}$, Pn is the biggest under situation $L_{3,}$ and when PAR >800 $\mu mol \cdot m^{-2} \cdot s^{-1}$, Pn will be the biggest under situation L_2. (2) The sequence of fitting effect of the five light response models was in descending order: exponential model > modified rectangular hyperbola model > rectangular hyperbola model > non-rectangular hyperbola model > quadratic function model. (3) the light response parameters in fitting effect indicates: exponential model can figure out more accurate maximum net photosynthetic rate (Pnmax) and light saturation point (LSP), the rectangular hyperbolic model is the best at figuring out light compensation point (LCP), and it is the most reasonable to figure out dark respiration rate (R_d) by non-rectangular hyperbolic model. Among them, *Magnolia sinostellata* seedlings have the characteristics of heliophilic plant and can adapt to the certain environment of low light.

The effect of light quality on sex determination in gametophytes of the fern *Drynaria roosii*

Meiyu Sun[1], *Jingyi Li*[1,2], *Di Wang*[1], *Dong Li*[1], *Hui Li*[1], *Quan Xing*[1], ***Lei Shi***[1]
1. Key Laboratory of Plant Resources and Beijing Botanical Garden, Institute of Botany, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Sex determination of fern gametophytes is influenced by the environmental conditions, especially light. Still, the research about the function of light quality on development of fern sexual organs and sex ratios has been incomplete. *Drynaria roosii* (Nakaike) is homosporous, a source of Traditional Chinese Medicine commonly known as "Gu-Sui-Bu", but the molecular mechanism of gametophytes responding to different light signals in *Drynaria roosii* have remained elusive. Here, we used four different LED-lights (red, blue, green, white; PAR = 30-40 mol m^{-2} s^{-1}) and fluorescent light (control, PAR = 30-40 mol m^{-2} s^{-1}) to treat gametophytes in different developmetal stages (filament stage, prothallial plate stage, cordate prothalli stage, sex differentiation stage) and found that light quality had a significant and reproducible effect on sex determination in *Drynaria roosii* grown in vitro. Our results confirmed the male-promoting effect of red light and female-promoting effect of blue light in *Drynaria roosii*. However, white light and green light had less impact on the sex determination compared with control light. The data also showed that the number of sexual organs (antheridia and archegonia) and sex ratios were induced and altered more dramatically when cordate prothalli stage or sex differentiation stage treated with red or blue light. Furthermore, researches of the gametophyte transcriptome in *Drynaria roosii* have never been reported before. Thus, we applied short-read Next-Generation Sequencing (NGS) to various stages of gametophytes in *Drynaria roosii* treated with different light quality (red, blue, control light) and constructed gene network using Weighted Gene Co-expression Network Analysis (WGCNA) to get further insight into the interactions among related signal pathways during the sex determination. This study provided an initial network-based framework for the function of light qulity on sex determination in gametophytes of the fern *Drynaria roosii*.

Evaluating *SlPIN1* expression distribution in tomato pedicel during abscission using *in situ* hybridization

Zihang Shi, *Tianlai Li*
Shenyang Agricultural University

Auxin transport and distribution is of fundamental importance in organ abscission, much information is still unknown about its function and molecular basis. To address these issues, the temporal and spatial expression of *SlPIN1* -- the auxin efflux carrier -- during tomato (*Solanum lycopersicum*) pedicel abscission were investigated Evaluating *SlPIN1* expression distribution in tomato (*Solanum lycopersicum*) pedicel during abscission by *in situ* hybridization in our research. The expression of *SlPIN1* were down-regulated after flower removal, and differential distribution become apparent among abscission zone (AZ), distal and proximal part of pedicel, indicating different auxin response ability among these tissues. The abscission layer (AL) remained relatively higher expression of *SlPIN1* in early stage, indicating an active auxin flux through AL. Our study revealed a possible role for *SlPIN1* in the regulation of pedicel abscission.

Functional characterization of a *Glycine soja* Ca^{2+}ATPase in salt-alkaline stress responses

Mingzhe Sun[1,2], Bowei Jia[1,2], Junkai Yang[1], Jianwei Li[1], ***Xiaoli Sun***[1]
1. Heilongjiang Bayi Agricultural University
2. Northeast Agricultural University

It is widely accepted that Ca^{2+}ATPase family proteins play important roles in plant environmental stress responses. However, up to now, most researches are limited in the reference plants Arabidopsis and rice. The function of Ca^{2+}ATPases from non-reference plants was rarely reported, especially its regulatory role in carbonate alkaline stress responses. Hence, in this study, we identified the P-type II Ca^{2+}ATPase family genes in soybean genome, determined their chromosomal location and gene architecture, and analyzed their amino acid sequence and evolutionary relationship. Based on above results, we pointed out the existence of gene duplication for soybean Ca^{2+}ATPases. Then, we investigated the expression profiles of the ACA subfamily genes in wild soybean (*Glycine soja*) under carbonate alkaline stress, and functionally characterized one representative gene *GsACA1* by using transgenic alfalfa. Our results suggested that *GsACA1* overexpression in alfalfa obviously increased plant tolerance to both carbonate alkaline and neutral salt stresses, as evidenced by lower levels of membrane permeability and MDA content, and higher levels of SOD activity, proline concentration and chlorophyll content under stress conditions. Taken together, for the first time, we reported a P-type II Ca^{2+}ATPase from wild soybean, *GsACA1*, which could positively regulate plant tolerance to both carbonate alkaline and neutral salt stresses.

Characterization of *TpSnRK 2.2* involved in abiotic stress responses

Chao Wang, *Fan Peng, Yiran Cheng, Songyue Chai, Wendi Shuai, Yonghong Zhou, Yi Wang*
Triticeae Research Institute, Sichuan Agricultural University

To date, more than 50 *SnRK2s* were cloned and characterized in various plants. Increasing studies indicated that SnRK2s play a key role in abiotic stress signaling transduction pathway. In wheat, several SnRK2s were also cloned, but only four SnRK2, TaSnRK2.3,2.4,2.7 and 2.8 were functionally characterized in *Arabidopsis*. In the present study, *TpSnRK2.2*, cloned from dwarfing polish wheat, was characterized in terms of metal transport activity and cellular localization. We found that TpSnRK2.2 was a functional cadmium-efflux transporter in yeast, because it reduced the Cd concentration in yeast. Overexpression of *TpSnRK2.2* in *Arabidopsis thaliana* increased cadmium concentration in root, but there was no difference in shoot when compared with control plants. Subcellular localization using wheat protoplast showed TpSnRK2.2 expressed in the cell membrane, endoplasmic reticulum, and nucleus. Additionally, overexpression of *TpSnRK2.2* also enhanced the tolerance to drought in Arabidopsis. Thus, *TpSnRK2.2* may act as a regulatory factor involved drought stress pathway and heavy metal cadmium transporting.

Holliday junction resolvases mediates DNA repair by homologous recombination in Rice

Chong Wang[1]*, James D Higgins[2], Yi He[1], Pingli Lu[3], Dabing Zhang[1,4], Wanqi Liang[1]*
1. School of Life Sciences and Biotechnology, Shanghai Jiao Tong University, Shanghai 20040, China
2. Department of Genetics, University of Leicester, University Road, Leicester, LE1 7RH, United Kingdom
3. Institute of Plant Biology, School of Life Sciences, Fudan University, Shanghai 200433, China
4. School of Agriculture, Food and Wine, University of Adelaide, Waite Campus, Urrbrae, South Australia 5064, Australia

Yen1/GEN1 are canonical Holliday Junction (HJ) resolvases that belong to the RAD2/XPG family. In eukaryotes, such as budding yeast, mice, worms, and humans, Yen1/GEN1 work together with Mus81-Mms4/MUS81-EME1 and Slx1-Slx4/SLX1-SLX4 in DNA repair by homologous recombination to maintain genome stability. However in plants, the biological function of Yen1/GEN1 remains largely unclear. We characterized the loss of function mutants of *OsGEN1* and *OsSEND1*, a pair of paralogs of Yen1/GEN1 in rice. We first investigated the role of *OsGEN1* during meiosis and found a reduction in chiasma frequency by ~6% in *osgen1* mutants, compared to wild type, suggesting a possible involvement of OsGEN1 in the formation of crossovers. Post-meiosis, OsGEN1 foci were detected in wild-type microspore nuclei, but not in the *Osgen1* mutant concomitant with an increase in double strand breaks. Persistent double strand breaks led to programmed cell death of the male gametes and complete male sterility. In contrast, depletion of *OsSEND1* had no effects on plant development and did not enhance *osgen1* defects. Our results indicate that OsGEN1 is essential for homologous recombinational DNA repair at two stages of microsporogenesis in rice. It was reported that MUS81 is involved in interference-insensitive CO formation. In order to understand OsMUS81 biological function and its relationship with OsGEN1, we used CRISPR to knock out *OsMUS81* in rice cultivar 9522 and got *osmus81* homozygotes. We found seed setting percentage decreased in *osmus81* mutant, which indicated that OsMUS81 also functions in rice reproductive process. *Osmus81 Osgen1* double mutant displayed more severe meiotic defects, suggesting that OsGEN1 and OsMUS81 may be involved in different pathways during meiosis in rice.

Physiological and molecular responses of poplar seedlings to phosphate deficiency

Fei Wang[1,2], *Ping Lan*[2], *Li Wenfeng*[1,2]
1. Collaborative Innovation Center of Sustainable Forestry in Southern China of Jiangsu Province, College of Biology and the Environment, Nanjing Forestry University
2. State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese

Phosphorus is one of the essential nutrients, whose supply is often under the demand for plant development and growth in natural and agricultural ecosystem. While the molecular mechanisms of phosphate (Pi) deficiency responses is well studied in herbaceous plants, limited information has been available on the responses of the woody plants including poplar to Pi deficiency. As an important woody plant, especially on marginal soils, poplar is getting an important model woody plant, with the whole genome sequencing of *Populus* being completed; and with an increasing demand for woody biomass, an extension of poplar plantation is frequently expected. To explore the physiological and molecular responses of poplar upon Pi deficiency, we established a tissue culture system using the poplar cultivar 'soma clone' as the material and the Hoagland solution as the culture media. Based on this system, we found that poplar's growth was severely stunted upon Pi starvation, with the shoot length being reduced to 2/5 of the ones grown under normal conditions; while the primary root length and the excreted purple acid phosphatases activity were increased dramatically. Besides, an obviously early leaf abscission was observed upon Pi deficiency. Transcriptome sequencing is being conducted to further investigate the molecular mechanism of poplar responding to Pi deficiency. This research will greatly facilitate the breeding and cultivation of nutritional-efficient poplars.

Arabidopsis SAURs are critical for differential light regulation of the development of various organs

Ning Sun[1], ***Jiajun Wang***[1], *Zhaoxu Gao*[1], *Jie Dong*[1], *Hang He*[1], *William Terzaghi*[2], *Ning Wei*[3], *Xing Wang Deng*[1], *Haodong Chen*[1]
1. Peking University
2. Wilkes University
3. Yale University

During deetiolation of *Arabidopsis* seedlings, light promotes the expansion of cotyledons but inhibits the elongation of hypocotyls. The mechanism of this differential regulation of cell enlargement is unclear. Our organ-specific transcriptomic analysis identified 32 Small Auxin Up RNA (SAUR) genes whose transcripts were light-induced in cotyledons and/or repressed in hypocotyls. We therefore named these SAURs as lirSAURs. Both overexpression and mutation analyses demonstrated that lirSAURs could promote cotyledon expansion and opening and enhance hypocotyl elongation, possibly by inhibiting phosphatase activity of D-clade type 2C protein phosphatases (PP2CDs). Light reduced auxin levels to down-regulate the expression of lirSAURs in hypocotyls. Further, phytochrome-interacting factors (PIFs) were shown to directly bind the genes encoding these SAURs and differentially regulate their expression in cotyledons and hypocotyls. Together, our study demonstrates that light mediates auxin levels and PIF stability to differentially regulate the expression of lirSAURs in cotyledons and hypocotyls, and these lirSAURs further mediate the differential growth of these two organs.

The photosynthetic response in *Scenedesmus quadricauda* after carbon-ion irradiation

Jie Wang, *Xin Li, Jufang Wang, Wenjian Li, Yan Du, Wei Wei, Dong Lu, Liang Ma*
Gansu Key Laboratory of Microbial Resources and Application, Institute of Modern Physics, Chinese Academy of Sciences

A large proportion of mutants with altered pigment features have been obtained via exposure to heavy-ion beams, a technique that is efficient for trait improvement in the breeding of plants and algae. However, little is known about the changes of the photosynthetic response of microalgae after exposure. In our group, six progenies of *Scenedesmus quadricauda* deficient in chlorophyll a were isolated after carbon-ion exposure that were provided by the heavy ion research facility in Lanzhou (HIRFL), China. Two progenies were picked up because their photosynthetic efficiency and the photoprotection ability were markedly different from the wild type. What is more, the proteomics studies of the two progenies were analyzed. The most differential proteins in the two progenies were from light harvesting complexes. In the other aspect, our group analyzed the chlorophyll fluorescent parameters (Fv/Fm, φPSII, and NPQ), the photoprotective pigment lutein, and the transcriptional expression of Lhcb1 and Lhcb2 in *Scenedesmus quadricauda* after exposure to $^{12}C^{6+}$ ions. Exposure to 20 Gy of carbon ions improved the photosynthetic efficiency of *Scenedesmus quadricauda* more quickly than exposure to 60 or 120 Gy during 48 h of culture after irradiation. The thermal dissipation by *Scenedesmus quadricauda* was initiated more quickly after exposure to 20 Gy than exposure to 60 or, 120 Gy. The transcriptional expression of Lhcb1 and Lhcb2 was up-regulated within 4 h of culture after exposure to 20 Gy of carbon ions. Thus, from the mutant strains we found that light harvesting proteins expressed differently, and the photosynthetic characteristics of the two progenies changed markedly after carbon-ion irradiation. From group mutagenic effects we found that the low dose of carbon ion irradiation caused hormetic effects on the photosynthetic efficiency, thermal dissipation ability and transcriptional regulation of the light harvesting complex II antenna proteins in *Scenedesmus quadricauda*.

RNAi-mediated suppression of hexokinase3 leads to inhibited growth and development, inhanced photosynthesis in *Brassica napus* L.

Xiaomin Wang, *Jingxue Wang*
School of Life Sciences, Shanxi University

Oilseed (*Brassica napus* L.) is an important oil crop, which has great economic development and utilization value. Carbohydrate metabolism plays an important role in plant growth and development. Glucose (Glc) from plant photosynthesis is phosphorylated by hexokinase (HXK) to generate Glc-6-phosphate (Glc-6-P) and enters the glycolysis pathway and converted to pyruvic acid and ATP. HXK is the key and rate-limiting enzyme involved in the glycolysis pathway and plays an important role in plant growth and development. In this study, the plasmid pCaMRNAi containing interferenced *HXK3* gene were introduced into oilseed 7B plants by pollen-mediated method. Using GUS markers, the transgenic plants were identification. Total 97 transgenic plants were identified by PCR amplification. The results of quantitative real-time PCR showed that the expression of *HXK3* gene in transgenic plants was 15.41% ~ 75.43% lower than wild-type plants. Transgenic seedlings grew euphylla later than wild-type plants. During plant growth, the transgenic plants were dwarfer than the wild-type plants, and the leaves of some transgenic plants became much curly. Moreover, the flowering time of transgenic plants was earlier, and some floral organs were abnormal and unable to harvest normal seeds. In addition, the chlorophyll content of the transgenic plants was 10.95% ~ 71.07% higher than that of the wild-type plants, and the photosynthetic rate was also increased. Quantitative real-time PCR showed that the expression of *POA* gene related chlorophyll synthesis in transgenic plants was significantly increased. Further observation, we found that some visible liquid secretion on the leaf surface of transgenic plants, which is proved to be sugar and pests are also more serious. Stained with toluidine blue, the blue color area is larger in wild-type plants than in transgenic plants. Expression of *GPAT*6 gene related fatty acid metabolism in transgenic plants was significantly decreased by quantitative real-time PCR amplified analysis. The function of *HXK3* gene in oilseed was improved by this study.

Identification of cold stress responsive proteins in *Anabasis aphylla* seedlings by iTRAQ proteomics technique

Tingting Wang[1], *Chunxiu Ye*[2], *Ping Jiang*[1], *Guangming Chu*[1], *Mei Wang*[1]
1. Shihezi University
2. Xinjiang Academy of Agricultural and Reclamation Sciences
3. Shihezi University
4. Shihezi University
5. Shihezi University

Cold stress is one of the major environmental factors that affect plant growth, development and geographical distribution. In order to study the protein molecular mechanism of *Anabasis aphylla* seedlings in response to cold stress, we used the iTRAQ technique to identify the differentially protein expression under cold stress. In total, 211 differentially proteins are identified, including 109 up-accumulated proteins and 102 down-accumulated proteins, these cold stress response proteins mainly involved carbohydrate and energy metabolism, protein metabolism and translation, stress response, transcription related, amino acid metabolism, signal transduction and membrane and transport. In our results, glyceraldehyde-3-phosphate dehydrogenase and pyruvate kinase were up-accumulated in differentially proteins expression analysis, that means *A. aphylla* seedling adapted to cold stress throughout changed its energy metabolism pathway. We identified several proteins which involved in protein translation, refolding and degradation in these iTRAQ data, and it suggested that different elongation factors had different functions in response to cold stress. Some ROS scavenging systems enzymes were also identified to be associated with cold stress response such as SOD, POD, MDH and GSH-Px. Protein TOPLESS and mitogen-activated protein kinase homolog NTF6 were found to relate to transcription and signal transduction respectively. 5-methyltetrahydropteroyltriglutamate-homocysteine methyltransferase had an important role in L-methionine biosynthesis. Membrane steroid-binding protein and mitochondrial dicarboxylate transporter which involved in transmembrane transport had been investigated successfully. Such data were discussed in the context of our current understandings of *A. aphylla* seedlings to indicated the molecule mechanisms in the cold response. Meanwhile, the correspondence between mRNA transcript level and proteins abundance were identified by qRT-PCR.

Proteomic characterization of hormone-responsive, differential abundance proteins, which are involved in the regulation of coleoptile growth in maize

Chenhui Xu, *Xiaolin Wu, Wei Wang*
Henan Agricultural University

Coleoptile is a model organ for studying cell elongation since Charles Darwin first described this organ in 1880. The coleoptile is a unique structure in monocot crops, such as maize, wheat and rice. It protects and leads the upward growth of the enclosed primary leaves during seed germination in the soil, which is a key step for the successful seedling establishment. Moreover, the coleoptile contains a small quantity of chloroplasts, which can provide additional nutrients for the seedling through photosynthesis.

In the present study, maize coleoptile was sampled at four growth stages, i.e., initial, slow, rapid, and stable growth stage, based on the growth curve, and used for proteomic, physiological and microscopic studies, so as to identify and characterize differential abundance proteins (DAPs) during coleoptile growth in maize. Total proteins were extracted using phenol extraction and separated using 2-DE. Endogenous hormone change was analyzed by HPLC-MS/MS. Moreover, microsection was made to observe cell morphological change during coleoptile elongation.

As a result, 69 DAPs were identified by MALTI-TOF/TOF analysis. These DAPs are mainly involved in hormone signaling pathway, stress response, heat shock protein, storage protein, carbohydrate metabolism, cell structure, S-adenosylmethionine metabolism, glutathione metabolism and others. Especially, beta-glucosidase involving in cytokinin signaling pathway, proteins involving S-adenosylmethionine metabolism and glutathione metabolism, accumulated in high amount during coleoptile elongation process, implying their importance for coleoptile elongation. Meanwhile, UDP-glucose dehydrogenase, a key enzyme to formation cell wall precursor, alpha-tubulin and beta-tubulin were needed for coleoptile elongation. The cessation of coleoptile growth was found to be associated with the accumulation of abscisic acid (ABA) responsive proteins. Moreover, the expression of the mRNAs of the DAPs, endogenous hormone and cell morphological changes in coleoptiles were also analyzed. This study will be helpful for further understanding of the elongation mechanism of the coleoptile in maize.

KcNHX1 from *Karelinia caspia* confers drought, salt, and heat stress tolerance in *Arabidopsis*

Yanqin Wang
Tarim University

Environmental stresses such as drought, salinity and heat affect plant growth and development. *Karelinia caspia* (*K. caspia*) is a unique perennial herb with remarkable tolerance to environmental stresses because it grows in desert area for long-term. The Na$^+$/H$^+$ antiporter gene was cloned from eremophyte *K. caspia* (*KcNHX1*), to investigate the possible roles of *KcNHX1* in the abiotic stress response of *K. caspia* and the underlying regulatory mechanisms. The overexpression vector was constructed and transformed into *A. thaliana*. The physiological results showed that the overexpression of *KcNHX1* in *A. thaliana* enhanced tolerance not only to drought and salt stress, but also to heat stress in the seedling stage. The overexpression of *KcNHX1* maintained higher seed yield and IAA content in the floral organs under high temperature than wild type plants during florescence. Meanwhile, application of low concentration of IAA led to higher fertility of *KcNHX1* overexpression plants under high temperature. The results indicate that *KcNHX1* might activate the auxin biosynthesis and signal pathway in *A. thaliana* to improve the tolerance to heat. *KcNHX1* from an eremophyte could be applied as a candidate gene for enhancing multiple stress tolerance in other plant species.

Plant physiological and nutritional responses to deficit irrigation

Yaosheng Wang[1], *Weiping Hao*[1], *Changrong Yan*[1], *Yanqing Zhang*[1], *Daozhi Gong*[1], *Fulai Liu*[2]
1. Institute of Environment and Sustainable Development, Chinese Academy of Agricultural Sciences
2. Department of Plant and Environmental Sciences, University of Copenhagen

Increasing shortage of freshwater for agriculture and more frequent and severe drought due to climate change have stimulated research into high efficient strategies to produce more crops per drop water. Deficit irrigation (DI) is a traditionally recommended irrigation strategy intensively studied on a wide range of crops in many regions of the world. In DI the entire root zone is watered with an amount of water less than the potential evapotranspiration during the non-sensitive growth stages and the mild stress has minimal effects on the yield. Therefore, the water use efficiency (WUE) is improved. Partial root-zone drying irrigation (PRI) is a further refinement of DI developed based on the drought-induced root-to-shoot chemical signaling in the drying roots. It causes soil moisture heterogeneity in the two root zones, in which only half part of the root zone is watered in order to keep the leaves hydrated while the other half is allowed to dry to a predetermined level before alternating irrigation between the drying and rewetting zone to sustain the root-to-shoot ABA signaling for controlling stomatal opening. PRI has been demonstrated to remarkably reduce water use, but increase WUE and partitioning of dry mass into fruits or carbon remobilization into grain thereby maintain the yield and increase harvest index. Both PRI and DI can induce the ABA-based root-to-shoot chemical signaling regulating stomatal conductance and leaf expansion growth. Nonetheless, at a similar degree of water saving, PRI can intensify ABA signaling relative to DI, resulting in a better control of plant transpiration causing further improvement of WUE. Moreover, PRI has been shown to improve product quality. Repeated soil drying and rewetting (DRW) cycles occur in rainfed and irrigated agriculture. The intensity and frequency of DRW cycles regulate both microbial physiology and soil physical processes, hereby affecting the mineralization and immobilization of soil nutrients and their bioavailability. PRI induces soil DRW cycles and more soil water dynamics in the root zone, which enhance soil nutrient mineralization process and nutrient substrate availability, thus increase the bioavailability of soil nutrients, resulting in improved nitrogen (N) and phosphorus (P) uptake, in which soil microbes paly an essential role in the mineralization and immobilization turnover process. Practically, PRI can be applied in an easy way that the crops are irrigated every other row in furrow irrigation or by repeatedly using single irrigation pipeline. The application of low-cost drip irrigation pipes together with fertigation can make it promising as a feasible, costless and profitable water- and fertilizer-saving strategy for agricultural production in the regions especially arid regions, where rainfall is scarce. However, there are still some uncertainties regarding effect of drought and deficit irrigation techniques in terms of climate change and intensity and frequency of DRW cycles in the field, which merit further studies.

A355

Transcriptomic and metabolomic studies disclose key metabolism pathways contributing to well-maintained photosynthesis in the drought and the consequent drought-tolerance in rice

Xiaosong Ma, Hui Xia, Haibin Wei, Liang Chen, Hongyan Liu, ***Lijun Luo***
Shanghai Agrobiological Gene Center

In contrast to wild species, drought-tolerance in crops requires a fully functional metabolism during drought (particularly photosynthetic processes) to maintain relatively higher productivity. Photosynthesis is therefore a key metabolic process under drought.

However, the link between drought-tolerance, photosynthetic regulation during drought, and the associated transcript and metabolic foundation, remains largely unknown. We used two rice cultivars with contrasting drought-tolerance (the drought-intolerant cultivar IRAT109 and the drought-tolerant cultivar IAC1246) to explore transcript and metabolic responses to long-term drought. The drought-tolerant cultivar represented higher osmotic adjustment and antioxidant capacity, as well as higher relative photosynthesis rate under a progressive drought stress occurred in a modified field with shallow soil-layers. A total of 4,059 and 2,677 differentially expressed genes (DEGs) were identified in IRAT109 and IAC1246 between the drought and well-watered conditions, respectively. A total of 69 and 47 differential metabolites (DMs) were identified between the two treatments in IRAT109 and IAC1246, respectively. Compared to IRAT109, the DEGs of IAC1246 displayed enhanced regulatory amplitude during drought. We found significant correlations between DEGs and the osmolality and total antioxidant capacity (AOC) of both cultivars. During the early stages of drought, we detected up-regulation of DEGs in IAC1246 related to photosynthesis, in accordance with its higher relative photosynthesis rate. The contents of six differential metabolites were correlated with the osmotic potential and AOC. Moreover, they were differently regulated between the two cultivars. Particularly, great up-regulations of 4-hydroxycinnamic acid and ferulic acid were consistent with the performance of photosynthesis-related DEGs at the early stages of drought in IAC1246. Metabolic pathways of these two differently regulated metabolites were also enriched by DEGs detected in IAC1246. It was therefore 4-hydroxycinnamic and ferulic acid are considered as key metabolites for rice drought-tolerance. They could be applied in rice drought-tolerance improving. In addition, DEGs involved in pathways of these two metabolites were correlated with osmolality and AOC. They are consequently expected to be good candidate genes to improve drought-tolerance. In conclusion, well-maintained photosynthesis under drought should contribute to improved drought-tolerance in rice. Metabolites, such as 4-hydroxycinnamic and ferulic acid, play vital roles in photosynthesis protection under dehydration *via* osmotic adjustments and/or antioxidant mechanisms. A metabolite-based method was thus an effective way to explore drought candidate genes. Metabolic accompanied by transcript responses to drought stress should be further studied to find more useful metabolites, pathways, and genes.

Promoter methylation affects plant regeneration from *in vitro* cultures of *Arabidopsis thaliana*

Fengning Xiang
Shandong University

Methylation within the promoter is a critical regulator of gene expression. A set of plant regeneration related genes showing differential expression between regenerable (RC) and non-regenerable (NRC) *Arabidopsis thaliana* callus were identified by microarray analysis, and of these, 20 were up-regulated in the calli of DNA methyltransferase loss-of-function mutants. The promoters of *FLOWERING WAGENINGEN (FWA)*, *ACETYL-COENZYME A CARBOXYLASE 1 (ACC1)*, *TERMINAL FLOWER 1 (TFL1)*, *MORE AXILLARY BRANCHING (MAX3)* and *At2g05520* were methylated and the genes' expression was down-regulated in one or other of RC and NRC, while the promoter of *At5g55450* was methylated in both RC and NRC, but the gene's expression was only down-regulated in RC. Promoter methylation of *FWA*, *ACC1*, *TFL1* and *MAX3* was associated with histone methylation and deacetylation. The two demethylated mutants *fwa-1* and *fwa-2* were less regenerable than the wild type. The shoot meristem associated *WUSCHEL-RELATED HOMEOBOX* (*WOX*) gene *WOX9* was directly, while *WUSCHEL (WUS)*, *WOX2*, *WOX8* and the auxin efflux protein *PINFORMED1* (*PIN1*) were indirectly repressed. Thus, methylation of the *FWA* promoter appears to be important for the regulation of *FWA* expression and plant regeneration from *in vitro* culture.

Observation on petal epidermis of different color *Phalaenopsis* flowers

Wenfang Xiao[1,2], *Zuo Li*[1,2], *Heming Chen*[1,2], *Fubing Lyu*[1,2]
1. Environmental Horticulture Research Institute of Guangdong Academy of Agricultural Sciences
2. Guangdong Provincial Key Laboratory of Ornamental Plant Germplasm Innovation and Utilization

Phalaenopsis species are popular ornamental plants worldwide because of their long-lived flowers with a wind range of colors and various pigmentation patterns, such as evenly colors, shade, edges, stripes, nets, spots, irregular blotches and combinations of these. Inter-specific and inter-generic hybridization within and between members of the *Orchidaceae* has further widened the range of the patterns. This study designed to explore the relationship between flower color and petal epidermal cells shape in *Phalaenopsis*. Scanning electron microscopy (SEM) was used to explore the petal microstructure differences of *Phalaenopsis*. According to the Royal Horticultural Society Color Chart (RHSCC), flower color of 8 evenly colored flowers was grouped into four classes: white, green-yellow, purple and purple-violet. In addition, transverse section from the middle of the petal of the junction of the ground color and the over color in each spotted flowers were taken using a sharp razor blade, mounted in 0.25% PEG solution which had an osmotic potential close to that of petal cells, and examined using a Zeiss microscope. The two white flowers had papillate epidermal cells; all the other 10 flowers had dome-shaped epidermal cells. In addition, there was a small amount of pores in the petal epidermis of some samples. The upper epidermis cell's shape of the same color from the different varieties of *Phalaenopsis* petals may be different (papillate or dome), but the cell shape in different color regions of the same petal is the same. These finding prove that flower color, no matter ground color or over color, is not the determinant effect of the petal epidermal cell shape in *Phalaenopsis*. The above comparisons study between different color *Phalaenopsis* will provide some reference for the future research about flower color in *Phalaenopsis*.

Ectopic expression of a *SOC1* homolog from *Phyllostachys*

violascens alters flowering time and identity of floral organs in *Arabidopsis thaliana*

Shinan Liu[1,2,3], *Tiantian Qi*[1], *Jingjing Ma*[1], *Tengfei Ma*[1,4], *Luyi Ma*[3], ***Xinchun Lin***[1]
1. Zhejiang Agriculture and Forestry University
2. Guangxi University
3. Beijing Forestry University
4. The Forestry Bureau of Liandu District

As a floral activator, *SUPPRESSOR OF OVEREXPRESSION OF CO1/AGAMOUS-LIKE 20* (*SOC1/AGL20*) gene plays a key role in the flowering pathway of *Arabidopsis*. Bamboo MADS box gene *PvMADS56*, a homolog of *SOC1/AGL20*, was cloned from *Phyllostachys violascens*. Sequence comparison and phylogenetic analysis showed that PvMADS56 was closely related to MADS56-like proteins, which are the members of SOC1-like family. *PvMADS56* was widely expressed in all the tested tissues of flowering and non-flowering bamboo plants, and its function was investigated by ectopic expression in transgenic *Arabidopsis* plants. The results showed that the overexpression promoted flowering in wild-type *Arabidopsis* and complemented the delayed flowering phenotype of *soc1 Arabidopsis*. Meanwhile the transgenic plants displayed abnormal floral organs and leaves, low fertility and dwarfism. Overexpression of *PvMADS56* in the wild-type *Arabidopsis* not only caused early flowering by upregulating *Flowering Locus T* (*FT*) and downregulating *Flowering Locus C* (*FLC*) expression, but also abnormal floral organs by downregulating *APETALA1* (*AP1*), *APETALA3* (*AP3*), *PISTILLATA* (*PI*), and *AGAMOUS* (*AG*). Furthermore, PvMADS56 might be a nuclear protein, and interacted with PvAP1 and PvSEP3 from *Ph. violascens* in the yeast two-hybrid assay. In addition, the activity of *PvMADS56* promoter was enhanced by exogenous abscisic acid (ABA) and methyl jasmonate (MeJA). Taken together, *PvMADS56* may be a multifunctional gene that not only regulates the flowering time but also involves in the identity of floral organs in response to ABA and MeJA.

A359

Callus induction and regeneration via shoot tips of *Dendrocalamus hamiltonii*

Zang Qiaolu, Zhou Ling, Zhuge Fei, Yang Haiyun, Wang Xiaoqin, ***Lin Xinchun***
Zhejiang Agriculture and Forestry University

Bamboos are the members of the grass family, including more than 88 genera and 1,400 species worldwide. Because of rapid growth, high output, highly maintaining soil and water, and other values, they are economically, socially and ecologically important in China. *Dendrocalamus hamiltonii* is one of the three most important bamboo species with sweet shoots in the world and is cultivated for its shoots and timber in Xishuangbanna and Puer, Yunnan province, in China. The inflorescences, embryos and seeds of the bamboos are good resources for explants, but they are difficult to obtain because bamboos rarely blossom and bear fruit. However, shoot tips are available at any time and easy to obtain. By using shoot tips as explants, various media and culture conditions for callus induction and proliferation, shoot differentiation, root induction and plantlet transplantation to develop an efficient and reliable regeneration system with *Dendrocalamus hamiltonii* were tested. Murashige and Skoog (MS) medium supplemented with 3 mg/l 2,4-dichlorophenoxyacetic acid (2,4-D), 1 mg/l benzyladenine (BA), 500 mg/l glutamine (Gln), 500 mg/l proline (Pro), and 500 mg/l casein hydrolysate (CH) yielded the best rates of callus induction and granular-compact callus induction. MS medium supplemented with 1 mg/l BA, 0.3 mg/l kinetin (KT) and 0.3 mg/l naphthaleneacetic acid (NAA) conferred the highest differentiation rate of calli. The maximum rooting rate was obtained in 1/2 MS medium supplemented with 3 mg/l indole-3-butyric acid (IBA), and the roots were long and thick. All hardened plantlets survived after transfer to an equal ratio mixture of peat, vermiculite and perlite. The regeneration system of *D. hamiltonii* developed is efficient and provides a useful tool for genetic transformation in bamboo species.

Photosynthetic characteristics of 12 species epiphytic ferns of polypodiaceae from Ailao Mt. in Yunnan Province

Chengdong Xu[1], *Jianmeng Feng*[2], *Fenliang Kuang*[1]
1. Institute of Bio-resources Research and Utilization in Central Yunnan, Chuxiong Normal University
2. College of Life Science and Agronomy, Dali University

Epiphytic ferns play an important role in construction and maintain of biodiversity in forest ecosystem. To present the adaptability of physiological ecology on epiphytic ferns, the photosynthetic parameter of 12 species epiphytic ferns in Polypodiaceae were measured by LI-6400XT in Ailaoshan National Nature Reserve. Photoresponse curve was fitted by a new model and the interrelation between photosynthetic characteristics and ecological adaptability was analyzed. The result showed that light saturation of the 12 species epiphytic ferns is presented in the lower photo flux density. *Phymatopsis integrifolia* have a mild photoinhibition phenomenon and *Polypodiastrum mengtzeense* have a intense photoinhibition phenomenon, when photo flux density exceed the light saturation point, however, the rest of the epiphytic ferns have a light sleep phenomenon. 12 species of epiphytic ferns are divided into four ecological types which include type of heliophilous and intolerance of shade, type of heliophilous and shade-tolerance, type of shade-requiring and intolerance of shade, and the type of shade-requiring and shade-tolerance, according to light saturation point and light compensation point. There are different characteristics of distribution in the four ecological types.

Rice peroxisome sulfite oxidase 1 is required for chloroplast integrity, photosynthesis, plant development and sulfite response

Dawei Xu[1], *Muhammad Uzair*[1], *Ronghui Pan*[2], *Linda Savage*[2], *Sheng Quan*[1], *Zhu Lu*[1], *Gynheung An*[3], *David Kramer*[2], *Dabing Zhang*[1,4], *Wanqi Liang*[1], *Jianping Hu*[2]
1. Shanghai Jiao Tong University
2. Michigan State University
3. Kyung Hee University

4. University of Adelaide

Sulfur is an essential macronutrient for animals, plants and microorganisms. In plants, sulfite is an intermediate in sulfate assimilation in chloroplasts, and it can also be oxidized into sulfate in the peroxisome by sulfite oxidase (SO). Unlike in animals where SO is mitochondrial, plant SO is exclusively localized to the peroxisome. SO has been shown to play key roles in protecting plants against toxic levels of sulfite in *Arabidopsis*, tomato and poplar plants. However, whether SO is required for plant development under non-stressed conditions was unclear. To determine the role of SO in monocot species such as cereal crops, we characterized rice *Oryza sativa* sulfite oxidase 1 (OsSO1) and its loss-of-function mutant *Osso1*. Here we show that in addition to enhanced susceptibility to Na_2SO_3 treatment and SO_2 fumigation, *Osso1* displays a series of defects under normal growth conditions, including impaired chloroplast structure, loss of chloroplasts, reduced chlorophyll levels and photosynthetic capabilities, and deficiencies in key agronomical traits such as plant height, heading time, and grain weight. Lack of SO leads to accumulation of amino acids and aberrant expression of many genes involved in chloroplast assembly and function, and sulfite metabolism in young leaves. Our study suggests that rice SO not only serves as a "safety valve" for the plant during response to excess sulfite, but also plays a housekeeping role under optimal growth conditions.

Two bHLH transcription factors EAT1 and TDR cooperatively regulate the anther development and pollen wall formation in rice

Jie Xu
School of Life Sciences and Biotechnology, Shanghai Jiao Tong University,

The pollen wall is a specialized extracellular cell wall matrix that protects male gametophytes and plays an essential role in flowering plant reproduction. Elucidation of the regulatory mechanisms underlying pollen wall formation will not only expand our understanding of the functions of transcription factors in anther development, but will also facilitate efforts to manipulate this process for crop improvement. Here, we show that a bHLH transcription factor, ETERNAL TAPETUM1 (EAT1), is crucial for pollen exine morphogenesis. Using evidence generated from various analytical approaches we demonstrate that EAT1 affects pollen wall formation via directly activating 7 lipid metabolism-associated target genes that are putatively involved in pollen wall formation. The role of which were further confirmed by genetic and morphological analyses on one target gene, *OsLTPL64*, in which RNAi knockdown of expression impaired pollen wall architecture. Chromatin Immunoprecipitation (ChIP) - PCR analysis demonstrated that target regulation was determined by the formation of heterodimers with TDR, or homodimer alone, to regulate both overlapping and distinct sets of genes involved in the anther and pollen development. Transient assays in tobacco revealed that EAT1 and TDR can both act directly on two downstream lipid transport related genes, *OsLTPL68/OsC6* and *OsLTPL64*. Taken together, we have shown that EAT1 and TDR function collaboratively as important regulators of rice anther and pollen development, and that EAT1 and TDR have both distinct and shared regulatory pathways responsible for rice male reproductive development.

Identification of chilling-responsive microRNAs and their targets in vegetable soybean (*Glycine max* L.)

Shengchun Xu[1], *Na Liu*[1], *Weihua Mao*[2], *Qizan Hu*[1], *Guofu Wang*[3], *Yaming Gong*[1]
1. Institute of Vegetables, Zhejiang Academy of Agricultural Sciences
2. Center of Analysis and Measurement, Zhejiang University
3. Department of Life Science, Yuanpei College, Shaoxing University

Chilling stress is a major factor limiting the yield and quality of vegetable soybean (*Glycine max* L.) on a global scale. In the present study, systematic identification and functional analysis of miRNAs under chilling stress were carried out to clarify the molecular mechanism of chilling resistance. Two independent small RNA libraries from leaves of soybean were constructed and sequenced with the high-throughput Illumina Solexa system. A total of 434 known miRNAs and 3 novel miRNAs were identified. Thirty-five miRNAs were verified by qRT-PCR analysis. Furthermore, their gene targets were identified via high-throughput degradome sequencing. A total of 898 transcripts were targeted by 54 miRNA families attributed to five categories. More importantly, we identified 51 miRNAs differentially expressed between chilling stress and control conditions. The targets of these miRNAs were enriched in oxidation-reduction, signal transduction, and metabolic process functional categories. Our qRT-PCR analysis confirmed a negative relationship among the miRNAs and their targets under chilling stress. Our work thus provides comprehensive molecular evidence supporting the involvement of miRNAs in chilling-stress responses in vegetable soybean.

Over-expression of *RHR1* enhances root hair elongation under phosphate deficiency in *Arabidopsis*

Caiwen Xue[1,2], *Jiexue Huang*[1,2], *Lan Ping*[1]
1. State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Phosphate (Pi) is a limited crucial macro-nutrient for plants due to its poor mobility in soil. Crops growth and productivity are severely impaired by Pi deficiency. To cope with Pi shortage, plants have evolved various adaptations, including an increase of root hair density and elongation and higher acid phosphatase activity. RHR1 (Root Hair Related 1), a cell-wall associated receptor kinase, has been reported to be a negative modulator of Arabidopsis root hair growth. In this research, we constructed over-expressed transgenic lines of RHR1 driven by CaMV 35S promoter and interrogated its function under Pi starvation conditions. Compared with the wild type plants, the over-expression lines showed significantly longer root hairs and higher acid phosphatase activity under phosphate deficiency condition (0 μM Pi), although they are comparable under Pi replete condition (250 μM Pi). The results indicate that the over expression of RHR1 could improve the adaptations of palnts to Pi deficiency with longer root hairs and higher phosphatase activity, which would contribute to the improvements of crop yields in agricultural system via molecular design.

A365

A phosphate starvation induced gene *AtLIT1* positively regulates iron deficiency response in *Arabidopsis*

Mingke Yan[1,2], *Ping Lan*[1]
1. Institute of Soil Science, Chinese Academy Sciences
2. University of Chinese Academy of Sciences

Phosphorus and iron (Fe) are two essential nutrient elements of both plants and human, and the antagonistic interaction between them has been widely noted in plants. Here we report *Low Iron Tolerant 1* (*AtLIT1*), whose expression is significantly induced by phosphate (Pi) starvation but shows no notable change in phenotype, could markedly alleviate Fe deficiency symptoms in *Arabidopsis thaliana*. Overexpression of *AtLIT1* resulted in approximately two times longer of the primary root compared with the wild type, and increased the overall biomass as well as the proportion of green leaves of plants under Fe deficiency conditions. Real time qPCR analysis showed no significant change for Fe marker genes, such as *IRT1* and *FRO2*, in both Fe deficiency and sufficiency conditions; while, the double mutation of *AtLIT1* and one of its homologous gene resulted in down-regulation of various Fe marker genes. These results suggest that *AtLIT1* is transcriptionally mediated by Pi status, but involves in Fe limitation responses, possibly in a post transcriptional manner, which further expanded the understanding of Pi and Fe interaction and homeostasis in plants.

A366

Genome-wide analysis of PHD-finger protein family in *Glycine max*

Junkai Yang, Jianwei Li, Mingzhe Sun, Bowei Jia, ***Xiaoli Sun***
Heilongjiang Bayi Agricultural University

PHD (Plant homeodomain)-finger proteins are found universally in eukaryotes, and play major roles in regulating transcription and chromatin state. The structure and function of PHD-finger proteins have been well studied in animals. On the contrary, only a few PHD-finger proteins have been characterized to engage in plant growth and development. In this study, we conducted an extensive analysis of soybean PHD family. By using Phytozome and SMART searches, a total of 99 PHD-finger genes (termed as *GmPHD1* to *GmPHD99*) were identified in soybean genome. All these GmPHD proteins contained one or several PHD-finger domains that were comprised of approximately 60 amino acids and a characteristic Cys4-His-Cys3 motif. And further phylogenetic analysis revealed that these *GmPHDs* were clustered into twenty groups (A-T). Members in each group displayed high similarity in terms of intron-exon organization pattern. Among them, 98 genes were unevenly distributed on all 20 chromosomes and contained multiple duplication events. The Ka/Ks ratios analysis suggested that the duplicated genes of the PHD-finger family mainly underwent purifying selection with restrictive functional divergence after the duplication events. Expression profiles analysis indicated that 99 GmPHDs were differentially expressed in various tissues. These results will provide useful information for the further structural and functional studies of PHD-finger genes.

Identification of a novel (-)-5-Epieremophilene synthase from *Salvia miltiorrhiza* via transcriptome mining

Xin Fang[2], *Yue Yang*[1], *Chen-Yi Li*[2], *Xiao-Ya Chen*[1,2], ***Lei Yang***[1]
1. Shanghai Chenshan Plant Science Research Center, Chinese Academy of Sciences, Shanghai Chenshan Botanical Garden
2. Shanghai Institute of Plant Physiology and Ecology, Chinese Academy of Sciences

Terpenes are the largest class of plant metabolites, with diverse functions in plant growth, development, bio-interactions and stress resistance. Aroma is characteristic of *Lamiaceae* family, and the volatiles with biological activities are often the major interests of the resources. Terpenes are often the important constituents of plant essential oils and have a variety of biological functions, among which sesquiterpenes form the largest group and are greatly valuable for their aromatic and pharmaceutical properties. *Salvia miltiorrhiza,* a medicinal plant in the family of *Lamiaceae*, has been used in China for thousands of years to treat coronary heart diseases. Although biosynthesis of tanshinones, a group of diterpenoids in *S. miltiorrhiza*, has been extensively investigated, to date we know little about the formation of monoterpenes and sesquiterpenes in this medicinal plant. Our previous analysis of *S. miltiorrhiza* transcriptome has annotated 24 unigenes as TPSs, most of them have not been functionally characterized. Here, we report the characterization of three sesquiterpene synthases, named SmSTPS1, SmSTPS2 and SmSTPS3, which catalyzed the formation of a new compound, (-)-5-epieremophilene. Additionally, the (-)-5-epieremophilene biosynthesis activity of SmSTPS1 was confirmed by transient expression in *Nicotiana benthamiana.* Despite the similar enzyme activities of SmSTPS1, SmSTPS2 and SmSTPS3, the three (-)-5-epieremophilene synthase genes displayed different spatial expression patterns and responded differently to hormone treatments, implicating their specific roles in plant-environment interactions. Our results provide valuable data to understanding the biosynthesis and composition of terpenes in plant.

Understanding dark metabolism and its regulation to photosynthesis in *Chlamydomonas*

Wenqiang Yang[1], *Tyler Wittkopp*[2], *Matthew Posewitz*[3], *Arthur Grossman*[2]
1. Photosynthesis Research Center, Key Laboratory of Photobiology, Institute of Botany, Chinese Academy of Sciences, Beijing, China
2. Department of Plant Biology, Carnegie Institution for Science, Stanford, CA, USA
3. Department of Chemistry and Geochemistry, Colorado School

of Mines, Golden, CO, USA

Half of entire life of photosynthetic organisms is in the dark, and dark metabolism (heterotrophic and anoxic/hypoxic) is critical and necessary for photosynthetic organisms to recover photosynthesis when receiving light again. Dark metabolism can provide necessary materials and energy, re-oxidize NADH to NAD^+, store metabolites from photosynthesis, keep the correct carbon flux and the normal redox balance. The overall carbon budget of photosynthetic cells requires an understanding of metabolic features that accompany the movement of the cells between light and dark conditions, and specific electron carriers, such as ferredoxins, are tailored for light or dark metabolism. *Chlamydomonas reinhardtii* is a unicellular, soil-dwelling (and aquatic) green alga that has significant metabolic flexibility for balancing redox equivalents and generating ATP when it experiences hypoxic/anoxic conditions. The diversity of pathways available to ferment sugars is often revealed in mutants in which the activities of specific branches of fermentative metabolism have been eliminated; compensatory pathways having little activity in parental strains under standard laboratory fermentative conditions are often activated. The ways in which these pathways are regulated and integrated are little explored. We use Chlamydomonas as model to study dark metabolism, dark anoxic/hypoxic fermentation and photosynthesis as well, which will not only advance our understanding of the dark metabolism and photosynthesis, it should also be able to provide new evidences and insights into genetic improvement of photosynthesis efficiency.

Cardioprotective effect of *Dioscorea* saponins induced by biotransformation via intestinal microflora

Tao Yi, *Hubiao Chen*
School of Chinese Medicine, Hong Kong Baptist University

Dioscorea nipponica Makino (DN), *D. panthaica* Prain et Burkill (DP), and *D. zingiberensis* C. H. Wright (DZ) are three plants with significant medicinal values, which have been successfully developed as effective herbal medicines for treating ischemic heart disease (IHD) in China for decades. In our previous study, we found that the major constitutes of the three herbs are saponins. However, it is still unknown that whether these three herbs act via similar active constituents. As diosgenin has been reported for the protective action in isoprenaline-induced myocardial infarction, we hypothesized that diosgenin is one of the bioactive sapogenin related to the anti-myocardial ischemia (MI) activity of these three herbs. Recently, the effect of intestinal microflora on the drug metabolism has received increasing attention. Anaerobic bacteria presenting in small intestines are quite diverse in species, and different species produce enzymes different in functions; it is these enzymes are also responsible for the drug biotransformation in organism. Incubation of test drugs, particular phytochemicals, with fresh fecal specimen is a common means for investigating this kind of biotransformation. To verify our hypothesis, three total *Dioscorea* saponins were dissolved individually in appropriate amount of DMSO to produce a test solution. A 30 g GAM broth (General anaerobic medium broth) was dissolved in 1000 mL water, filtrated while hot, after treated with anti-bacteria process with high pressure (0.15 MPa) and temperature (121 ℃) for 20 min, cooled to 45 ℃ . The GAM broth solution was then transferred to an anaerobic chamber (37 ℃ , anaerobic condition), and 1 mg vitamin K1 and 6 mg hematin chloride were dissolved in the solution. Then biotransformation vessels (50 mL volume; one vessel per experiment group) were sterilized and filled with 30 mL of GAM broth solution. Vessels were inoculated with 3 mL of fecal suspensions (1:10, w/v) and then 1 mL of each sterile total *Dioscorea* saponins was added. *In vitro* biotransformation was run under anaerobic conditions for a period of 48 h. The the biotransformation mixtures were extracted by 50 mL ethyl acetate for three times. The remaining residues were re-extracted three times with 50 mL water-saturated n-butanol. The combined n-butanol layers were washed with water three times. Then the ethyl acetate and n-butanol layers were mixed homogeneously and concentrated under vacuum, and then diluted to the desired volume with methanol. All the solutions were centrifuged before being injected for LC–Q-TOF/MS analysis. The results demonstrated that diosgenin, as one of the main metabolites, was commonly found in feces from all groups receiving different *Dioscorea* total saponins. The finding of the present study provided a metabolic basis for understanding of the active components and their action modes of *Dioscorea* herbs, and supported their clinical use in IHD management.

This work was supported by the Faculty Research Grant of Hong Kong Baptist University (FRG2/15-16/022) and the Guangdong Natural Science Foundation (2016A030313008).

Cadmium stress inhibits the growth of roots and interferes auxin homeostasis in *Sorghum bicolor* seedlings

Chenliang Yu[1], *Yihua Zhan*[2], *Chenghao Zhang*[1]
1. Zhejiang Academy of Agricultural Sciences
2. Zhejiang University

Phytotoxic effects of cadmium (Cd), a heavy metal pollutant, on plants have been extensively examined. Auxin plays important roles in various aspects of plant growth and development. The relationship between root growth and auxin signaling in Cd-stressed *Sorghum bicolor* was analyzed in our study. Root and shoot length in *S. bicolor* seedlings were significantly reduced after exposure to Cd stress. Inhibition of the root cap growth, lipid peroxidation and cell death by Cd were observed at the root tips. Cd was found to be mainly localized in the meristematic zone using a Cd-specific probe. Cd stress remarkably influenced the cell cycle progression at the root tip by EdU (ethynyl deoxyuridine) assay. IAA content was significantly reduced in the roots of Cd-stressed *S. bicolor*, and this decrease was accompanied by an increase in the activity of IAA oxidase. Auxin transport inhibitors, 1-naphthylphthalamic acid (NPA) and 1-naphthoxyacetic acid (1-NOA), significantly reduced plant tolerance to Cd stress, whereas exogenous supply of 1-naphthaleneacetic acid (NAA) improved Cd tolerance of *S. bicolor* seedlings. Cd stress altered the expression of several putative auxin biosynthetic and metabolic genes as well as auxin transport genes. In addition, NAA interfered with the homeostasis of Cd-induced reactive oxygen species (ROS). These results indicated that Cd stress disturbed the growth of *S. bicolor* seedlings by affecting the homeostasis of auxin and ROS.

A Rice Ca^{2+} binding protein is required for tapetum function and pollen formation

Jing Yu
Shanghai Jiaotong University

In flowering plants, successful male reproduction requires the sophisticated interaction between somatic anther wall layers and reproductive cells. Timely degradation of the innermost tissue of the anther wall layer, the tapetal layer, is critical for pollen development. Ca^{2+} is a well-known stimulus for plant development, but whether it plays a role in affecting male reproduction remains elusive. Here we report a role of Defective in Exine Formation 1 (OsDEX1) in rice (*Oryza sativa*), a Ca^{2+} binding protein, in regulating rice tapetal cell degradation and pollen formation. In *Osdex1* anthers, tapetal cell degeneration is delayed and degradation of the callose wall surrounding the microspores is compromised, leading to aborted pollen formation and complete male sterility. *OsDEX1* is expressed in tapetal cells and microspores during early anther development. Recombinant OsDEX1 is able to bind Ca^{2+} and regulate Ca^{2+} homeostasis *in vitro*, and *osdex1* exhibited disturbed Ca^{2+} homeostasis in tapetal cells. Phylogenetic analysis suggested that OsDEX1 may have a conserved function in binding Ca^{2+} in flowering plants, and genetic complementation of pollen wall defects of an *Arabidopsis (Arabidopsis thaliana) dex1* mutant confirmed its evolutionary conservation in pollen development. A series of Ca^{2+} binding and Ca^{2+}-dependent kinase genes, protease related genes as well as sporopollenin synthesis genes are down regulated in *osdex1* mutant which further suggests the important role of Ca^{2+} on tapetal cell death process and pollen wall formation. Collectively, these findings suggest that OsDEX1 plays a fundamental role in the development of tapetal cells and pollen formation, possibly via modulating the Ca^{2+} homeostasis during pollen development.

Jasmonate regulates plant responses to post-submergence reoxygenation through transcriptional activation of antioxidant synthesis

Libing Yuan, *Yang-Shuo Dai, Li-Juan Xie, Shi Xiao*
State Key Laboratory of Biocontrol, Guangdong Provincial Key Laboratory of Plant Resources, School of Life Sciences, Sun Yat-sen University

Submergence induces hypoxia in plants; exposure to oxygen following submergence, termed reoxygenation, produces a burst of reactive oxygen species. The mechanisms of hypoxia sensing and signaling in plants have been well studied, but how plants respond to reoxygenation remains unclear. Here, we show that reoxygenation in *Arabidopsis thaliana* involves rapid accumulation of jasmonates (JAs) and increased transcript levels of JA biosynthesis genes. Application of exogenous methyl jasmonate improved tolerance to reoxygenation in wild-type *Arabidopsis*; also, mutants deficient in JA biosynthesis and signaling were very sensitive to reoxygenation. Moreover, overexpression of the transcription factor gene *MYC2* enhanced tolerance to post-hypoxic stress and *myc2* knockout mutants showed increased sensitivity to reoxygenation, indicating that MYC2 functions as a key regulator in the JA-mediated reoxygenation response. MYC2 transcriptionally activates members of the *VITAMIN C DEFECTIVE* (*VTC*) and *GLUTATHIONE SYNTHETASE* (*GSH*) gene families, which encode rate-limiting enzymes in the ascorbate and glutathione synthesis pathways. Overexpression of *VTC1* and *GSH1* in the *myc2-2* mutant suppressed the post-hypoxic hypersensitive phenotype. The JA-inducible accumulation of antioxidants may alleviate oxidative damage caused by reoxygenation, improving plant survival after submergence. Taken together, our findings demonstrate that JA signaling interacts with the antioxidant pathway to regulate reoxygenation responses in *Arabidopsis*.

Stage-specific transcriptomic ananlysis of maize germinal cells in developing anther provides insights into mitosis-meiosis transition

Tinglu Yuan, *Weijie Huang, Weihua Tang*
Institute of Plant Physiology & Ecology, SIBS, CAS

In flowering plants, germ lines are induced from somatic meristems within reproductive organs. Within anthers, germinal cell initials first undergo several rounds of mitotic proliferation before synchronously entering meiosis. Current understanding of the transition from mitosis to meiosis is still limited. Using laser microdissection-based expression profiling, we studied the transcriptome dynamics of germinal cells at three sequential stages, i.e. mitotic archesporial cells (AR), enlarging pollen mother cells at the pre-meiosis interphase (ePMC) and pollen mother cells at the early prophase of meiosis (PMC). These cells possess similar transcriptomes that are very different from those of mature pollen, stem pith parenchyma cells andseedlings. Nevertheless, cells undergoing the mitosis-meiosis switch exhibit robust transcriptional changes. The three stages are featured by the expression of genes encoding transcription factor subsets, meiotic chromosome recombination proteins and distinct E3 ubiquitin ligases, respectively. Transcription of genes encoding protein turnover machinery is higher in these three stages of germinal cells than in mature pollen, parenchyma cells and seedlings. Many meiotic genes are transcribed in germinal cells prior to meiosis, and translated in pre-meiosis interphase ePMC. We suggest that the ePMC stage represents a crucial turning point from mitosis to meiosis for developing germinal cells.

Elucidating the role of microRNAs during cotton response to drought and salinity stress

Baohong Zhang[1], *Qinglian Wang*[2], *Fuliang Xie*[1], *Runrun Sun*[2]
1. East Carolina University
2. Henan Institute of Sciences and Technology

Drought and salinity are two major environmental factors adversely affecting plant growth and productivity. However, the regulatory mechanism is unknown. In this study, the potential roles of small regulatory microRNAs (miRNAs) in cotton response to those stresses were investigated. Using next-generation deep sequencing, a total of 337 miRNAs with precursors were identified, comprising 289 known miRNAs and 48 novel miRNAs. Of these miRNAs, 155 miRNAs were expressed differentially. Target prediction, Gene Ontology (GO)-based functional classification, and Kyoto Encyclopedia of Genes and Genomes (KEGG)-based functional enrichment show that these miRNAs might play roles in response to salinity and drought stresses through targeting a series of stress-related genes. Degradome sequencing analysis showed that at least 55 predicted target genes were further validated to be regulated by 60 miRNAs. CitationRank-based literature mining was employed to determinhe the importance of genes related to drought and salinity stress. The *NAC*, *MYB* and *MAPK* families were ranked top under the context of drought and salinity, indicating their important roles for the plant to combat drought and salinity stress. According to target prediction, a series of cotton miRNAs are associated with these top-ranked genes, including *miR164*, *miR172*, *miR396*, *miR1520*, *miR6158*, *ghr-n24*, *ghr-n56*, and *ghr-n59*. Interestingly, 163 cotton miRNAs were also identified to target 210 genes that are important in fibre development. These results will contribute to cotton stress-resistant breeding as well as understanding fibre development.

Identification of two 1-Deoxy-D-xylulose-5-phosphate synthase cDNAs expressed differentially in *Alpinia officinarum*

__Chunrong Zhang__, Xiaomin Tang, Xuanxuan Cheng, Liming Pan, Quan Yang

Guangdong Pharmaceutical University

Alpinia officinarum Hance (Zingiberaceae) is a perennial herbaceous flowering plant native to southeastern Asia. The dried rhizome of *A. officinarum*, named lesser galangal or smaller galangal, is a traditional Ayurvedic, Chinese and Thai medicine with antimicrobial, anti-inflammatory, antioxidant, antiemetic, anti-obesity, antihyperlipidemic, anti-psychiatric, analgesic activities and has been used for relieving stomachache, vomiting, hiccups and diarrhea, treating colds, edema, ascites and cancer, invigorating the circulatory system. With the wide and increasing application, wild resources is on the verge of extinction, and the market products are all cultivated. However, the quality of the cultivated *A. officinarum* varied because of different origins and cultivars. Pathway engineering and molecular breeding are emerging strategies for increasing productivity and quality of medicinal plants. To realize these strategies, numerous key biosynthetic genes for bioactive plant constitutes have been cloned and analyzed. With a pungent, aromatic and ginger-like odor, essential oil makes the characteristic constituent of *A. officinarum*, and has been used for quality evaluation. The main constituents of the *A. officinarum* essential oil are monoterpenes. In plants, monoterpenes are synthesized through the 2-*C*-methyl-D-erythritol 4-phosphate (MEP) pathway in plastids. The 1-deoxy-D-xylulose 5-phosphate synthase (DXS, EC 2.2.1.7) enzyme catalyses the first step of MEP pathway, and has been recognized as a rate limiting enzyme and a regulation point in terpene biosynthasis. Overexpression of plant *DXS* genes can enhance levels of specific isoprenoids in many plants. In our present work, two full-length cDNAs encoding DXS were cloned from the rhizome of *A. officinarum* by homology-based RT-PCR and RACE methods. The new cDNAs were designated as *AoDXS1* and *AoDXS2* with a 2,148 bp and a 2,136 bp open reading frame respectively, encoding polypeptides of 715 and 711 amino acids with calculated molecular mass of 77.23 and 51.48 KDa respectively. Bioinformatic analyses revealed that AoDXS1 and AoDXS2 showed extensive homology with DXSs from other plant species and belonged to class I and class II DXS respectively. The expression of *AoDXS1* and *AoDXS2* was analyzed in rhizomes, roots, stems and leaves of 6-month-old plant by quantitative real-time PCR. Among the detected tissues, *AoDXS1* expressed mostly in stems, while *AoDXS2* expressed mostly in leaves. In all detected tissues, the expression levels of *AoDXS2* were much higher than those of *AoDXS1*. These findings may provide valuable information for future experiments on the molecular mechanisms underlying the isoprenoid biosynthesis via the MEP pathway, and on the pathway engineering and molecular breeding of *A. officinarum*.

Exogenous SA increased the glycolysis in winter wheat (*Triticum aestivum* L.) under low temperature etress

Deyi Meng, Hu Zhao, Bing Wu, Jing Cang, Qinghua Xu, __Da Zhang__

Northeast Agricultural University

Salicylic acid (SA) plays a key role in plant growth, development and the responses of biotic or abiotic stress. As nutrients, osmotic regulation substances and metabolic signals, soluble sugar, can improve plant stress resistance. After exogenous SA treatment winter wheat (*Triticum aestivum* L.), our previous research results showed that: the enzyme activities and gene expression levels of *sucrose synthase* (*TaSuS*), *sucrose phosphate synthase* (*TaSPS*) were increased; the enzyme activities and gene expression levels of *sucrose soluble acid invertase* (*TaSAInv*), *alkaline invertase* (*TaA/N-Inv*) were decreased. For further exploring the effect of exogenous SA on the glycolysis, the strong cold-resistance variety (DN1) and the weak cold-resistance variety (JM22) were selected as experiment materials; That 1 mM SA was sprayed on wheat leaves at trefoil stage was experimental treatment and 5% ethanol was control treatment. Leaves and rhizome were sampled at 5℃ , 0℃ , -10℃ and -25℃ under the condition of natural cooling. We measured the content of fructose and pyruvic acid, and screened the enzyme activities and gene expression levels of *hexokinase* (*TaHxK*), *phosphofructokinase* (*TaPFK*), *pyruvate kinase* (*TaPK*). The results showed, after exogenous SA treatment, the content of fructose and pyruvic acid in leaf and rhizome in DN1 were more definitely increased than in JM22; the enzyme activities and gene expression levels of *HxK* (*TaHxk)*, *PFK* (*TaPFK*) and *PK* (*TaPK*) were up-regulated in DN1. So soluble sugar in glycolysis increased, osmotic adjustment ability enhanced, and then the cold resistance of winter wheat was improved.

The abundance of certain metabolites responds to drought

stress in the highly drought tolerant plant *Caragana korshinskii*

Jiwei Zhang

Key Laboratory of Stress Physiology and Ecology in Cold and Arid Regions, Gansu Province, Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences

Metabolomics offers opportunities for studying the systematic response of an organism to a genetic and/or an environmental change. Here, the metabolic consequences of drought stress were characterized in the highly drought tolerant plant Caragana korshinskii. The time-of-flight mass spectrometry platform employed identified several hundred metabolites in extracts of the leaf, stem, root collar and root of plants which had been either subjected to drought stress or were well-watered. Each of the four organs harbored a number of potential metabolite markers for the drought response. An increased abundance of various small carbohydrates and soluble amino acids in each of the four organs was induced by the stress; these compounds may act as compatible solutes or antioxidants. Across the whole plant there was a fall in the content of several Krebs cycle and glycolysis intermediates, as well as in that of the amino acids glutamic acid and aspartic acid. Pathway analysis suggested that most of the potential metabolite markers were involved in energy metabolism and amino acid metabolism. The implication was that energy metabolism and photosynthesis are compromised during the adaptation of *C. korshinskii* to drought stress. Given the different spectrum of metabolites associated with the drought response in the four organs, it was concluded that each organ employs a distinct strategy to cope with drought stress.

Overexpression of *Actinidia deliciosa pyruvate decarboxylase 2* gene enhances waterlogging and heat stress in transgene *Arabidopsis*

Ji-Yu Zhang[1,2], *Sheng-Nan Huang*[1,2], *Tao Wang*[1,2], *Gang Wang*[1,2], *Zhong-Ren Guo*[1,2]

1. Institute of Botany, Jiangsu Province and Chinese Academy of Sciences

2. Jiangsu Key Laboratory for the Research and Utilization of Plant Resources

Previous report showed that both *PDC* genes were significantly up-regulated in kiwifruit after treatment with waterlogging using Illumina sequencing technology, and kiwifruit *AdPDC1* gene is required during waterlogging but might not be required during other environmental stresses. Here, the function of another PDC gene named *AdPDC2* was analyzed. The expression of *AdPDC2* gene were determined using qRT-PCR, and the results showed that the expression levels of *AdPDC2* in reproductive organs were much higher than those in nutritive organs, waterlogging, NaCl and Heat could induce the expression of *AdPDC2*. Overexpression of kiwifruit *AdPDC2* in transgenic *Arabidopsis* enhanced the resistance to waterlogging and heat stresses at five weeks old seedlings, but could not enhance resistance to NaCl and mannitol stresses at the stage of seed germination and in early seedlings. These results suggested that the kiwifruit *AdPDC2* gene play key role in resistance to waterlogging and heat stresses in kiwifruit.

OsATG8b-mediated autophagy is involved in nitrogen remobilization to seeds in rice

Mingyong Zhang, *Tian Fan*

South China Botanical Garden, Chinese Academy of Sciences

Improving nutrient use efficiency is recognized as an effective measure to reduce excessive input of fertilizers and increase crop yield. Autophagy is an evolutionarily conserved degradation system in eukaryotic cells and plays an important role in N remobilization. Central to autophagy are two conjugation pathways that attach ATG8 to PE and ATG5 to ATG12, which then help with vesicle elongation and enclosure. We identified the rice gene *OsATG8b* and characterized its role in N remobilization by generating transgenic plants with its over-expression and knockdown. Our study showed that *OsATG8b* restored autophagosome formation in yeast *scatg8* mutant and that OsATG8b is localized to autophagosomes in yeast and rice. ^{15}N pulse-chase analysis revealed that *OsATG8b* over-expression transgenic rice plants conferred higher N remobilization efficiency to seeds, while *OsATG8b* knockdown transgenic plants with lower N remobilization efficiency and poorer seed quality. We conclude that *OsATG8b*-mediated autophagy is involved in nitrogen remobilization to seeds in rice. This result may provide strategic guidance for N application in rice molecular breeding and cultivation.

Fine-mapping a key gene controlling rice leaf angle

Qijun Zhang, *Shijian Xia, Yanda Zeng, Chuangen Lu*

Institute of food crops, Jiangsu Province Academy of Agricultural Sciences

Rice (*Oryza Sativa* L.) is a staple food for China, as well as the entire world. Consistently and sustainably high yield is essential for an important guarantee to maintain food security in our nation. And good plant architecture is the key factor of rice high yield. In order to make full use of the light energy and increase the yield, all reported rice ideal plant architectural models are required to leaves drooping and faster growing at seedling stage, while post functional leaves relatively erect and smaller leaf angle. This architecture can help plant improve photosynthetic efficiency, reduce pest damage and increase productivities. So leaf angle is an important factor for rice morphology and largely affects its yield. Therefore, studying and cloning key gene responsible for rice good plant architectural breeding is of great significance. In this study, we used map-based cloning method to fine map a new recessive nuclear candidate gene for a control of leaves drooping at seedling stage, while smaller leaf angle, shorter and more erect leaf blade after 5 leaves and 1 hearts period, larger grain in a mutant generated from Thai aromatic rice “Khao Dawk Mali 105” by radiation mutagenesis. This gene was fine mapped between RM3437 and RM237 on rice chromosome 5, co-segregation with RM18532. Re-sequencing results showed that there was only one candidate gene existed protein sequence difference between wild-type and mutant. The candidate gene encodes a putative E3 ubiquitin ligase predicated by RiceDB, it is similar to the *TUD1* gene, but the mutant phenotype is very different from *tud1*. The results of hormone sensitivity analysis showed that the mutant had a response to Gibberellin, but no response to brassinolide. This study will set up a foundation to clone this mutant gene and use this genetic resource for breeding new rice varieties with ideal plant architecture and high yield.

Involvement of salicylic acid in antioxidative action and proline synthesis in *Brassica napus*

Qian Zhang, *Wei-Feng Xu, Ying-Jiao Zhang*
College of Life Science and Center for Plant Water-use and Nutrition Regulation, Fujian Agriculture and Forestry University

To address the influence of salicylic acid (SA) on antioxidative action and proline synthesis, the content of H_2O_2, proline, the activity of antioxidant enzymes and proline biosynthesis-related genes were analyzed in leaves of *Brassica napus*. The reactive oxygen species H_2O_2 content was considerably accumulated in the plants exposed to SA. Accompany with the increase in H_2O_2, antioxidant enzymes including catalase, ascorbate peroxidase and guaiacol peroxidase were activated, showing a dramatic increase in SA-applied plants. Exogenous SA application highly increased proline in the presence of sulphur (S). Transcript levels of pyrroline-5-carboxylate synthetase 1 (*P5CS1*) and proline dehydrogenase (*PDH*) were up-regulated by SA. The results suggested that SA might enhance oxidative stress resistance by activating proline synthesis and antioxidant enzymes.

Control of seed size by SOD7 and its interacting protein (SIP1) in *Arabidopsis thaliana*

Yueying Zhang[1,2], *Liang Du*[1], *Ran Xu*[1], *Rongfeng Cui*[1], *Yunhai Li*[1]
1. State Key Laboratory of Plant Cell and Chromosome Engineering, Institute of Genetics and Developmental Biology
2. University of Chinese Academy of Sciences

Although the size of seeds is one of the most important agronomic traits in plants, the genetic and molecular mechanisms that set the final size of seeds are largely unknown. We have previously demonstrated that the Ubiquitin receptor DA1 controls seed size through restricting cell proliferation. Through a genetic screening for *da1-1* modifiers, we have identified a suppressor of *da1-1* (*sod7*). *SOD7* encodes a B3 domain transcriptional repressor NGAL2, acts maternally to control seed size by restricting cell proliferation in the integuments of ovules and developing seeds. Overexpression of *SOD7* significantly decreases seed size of wild-type plants, while the simultaneous disruption of *SOD7* and its closest homolog *DPA4*/*NGAL3* increases seed size. Genetic analyses indicate that SOD7 and DPA4 act in a common pathway with the seed size regulator KLU to control seed growth, but do so independently of DA1. SOD7 directly binds to the promoter of *KLU in vitro* and *in vivo* and represses expression of *KLU*. We further identify two SOD7-Interacting Proteins (SIPs), SIP1 and SIP2. Genetic analyses indicate that *SOD7* functions in the same pathway with *SIP1* to control seed and organ size. Therefore, our findings reveal the genetic and molecular mechanisms of SOD7, DPA4, KLU and SIP1 in seed and organ size control, suggesting that these pathways are promising targets for crop yield improvement.

Contribution of the alternative respiratory pathway to PSII photoprotection in C_3 and C_4 plants

Zishan Zhang[1], *Meijun Liu*[2], *Huiyuan Gao*[1]
1. Shandong Agricultural University
2. Xinjiang Agricultural University

The mechanism by which the mitochondrial alternative oxidase (AOX) pathway contributes to photosystem II (PSII) photoprotection is in dispute. It was generally thought that the AOX pathway protects photosystems by dissipating excess reducing equivalents exported from chloroplasts through the malate/oxaloacetate (Mal/OAA) shuttle and thus preventing the over-reduction of chloroplasts. In this study, using the aox1a Arabidopsis mutant and nine other C_3 and C_4 plant species, we revealed an additional action model of the AOX pathway in PSII photoprotection. Although the AOX pathway contributes to PSII photoprotection in C_3 leaves treated with high light, this contribution was observed to disappear when photorespiration was suppressed. Disruption or inhibition of the AOX pathway significantly decreased the photorespiration in C_3 leaves. Moreover, the AOX pathway did not respond to high light and contributed little to PSII photoprotection in C_4 leaves possessing a highly active Mal/OAA shuttle but with little photorespiration. These results demonstrate that the AOX pathway contributes to PSII photoprotection in C_3 plants by maintaining photorespiration to detoxify glycolate and via the indirect export of excess reducing equivalents from chloroplasts by the Mal/OAA shuttle. This new action model explains why the AOX pathway does not contribute to PSII photoprotection in C_4 plants.

Protonema development and gametophyte regeneration of two species of *Bryum* Hedw.

Hong-Zhu Liang[1,2], *Jian-Cheng Zhao*[1], *Lin Li*[1], *Yan-Yan Shang*[1]
1. Hebei Normal University
2. University of Chinese Academy of Sciences

Bryophytes are commonly known as the representative transitional plants from aquatic to terrestrial habitats, which have only simple formation and have not true root and vascular bundle, preferring to aquatic circumstance. Bryophytes, one of the largest groups of the earth plants, contain more than 23,000 species throughout the world. But hitherto, the bryophyte flora is verified continually impoverished throughout the earth. Generally, axenic culturing is regarded as a common propagation phase for the ex situ conservation of bryophytes. Over the recent years, in vitro propagation, one of the typical systems to study morphogenetic models of bryophytes has attracted increasing attention, because of their biological traits and characteristic haploid life style.

In this research, we selected the mature capsules of *Bryum coronatum* and *B. recurvulum* as the research materials, which were collected from the Xiaowutaishan National Nature Reserve of Hebei Province and Fugong County of Yunnan Province, and now they are conserved in the Herbarium of Hebei Normal University (HBNU). After collecting of the materials, firstly they were identified for taxonomic evaluation, then they would be washed and dried by airing, and lastly they would be conserved in the refrigerator by 4°C and -40°C for spores germinating and protonema development purpose. This paper described the protonema development features of *B. coronatum* and *B. recurvulum*, from spore germination to young gametophyte, by solid and liquid cultivating in laboratory. Spores samples for gametophyte cultivation were taken from various mature sporophytes then sterilized in 75% alcohol solution, washed by distilled water, and lastly sown on Knob's medium. Spores were sowed both in the culture dishes (solid medium) and in the conical flasks (liquid medium). Spore germination of *B. coronatum* and *B. recurvulum* are both of the Bryum-type. Spore germination positions of the two species are both locating inside the cell wall. Gametophyte produces both on chloronema and on caulonema, without rhizoids occurring. Hollow cells occurs only on chloronema, where one filiform protonema cracking into two. Gametophytes occurred about 30 days for *B. coronatum* and 40 days for *B. recurvulum* after sowing. The protonemata system occurred on the 16th day after sowing in the liquid culture of *B. coronatum*, the spore germination was 1-2 polar germinating. In comparison with the solid culture, hollow cells and browning cells are more common in the liquid culture. Gametophyte occurred about 80 days after the sowing. In brief, it made it possible to large scale of rapid propagation of bryophyte by the protonema development and gametophyte cultivation research. The taxonomic significances of the protonemata system and gametophyte morphology were discussed in this paper.

Product from programmed cell death involved in rubber granule synthesis in laticiferous canal of *Decaisnea fargesii*

Yafu Zhou[1], *Shaoli Mao*[1], *Xinwei Shi*[1], *Yuchao Wang*[1], *Wenzhe Liu*[2]
1. Institute of Botany of Shaanxi Province
2. Key Laboratory of Resource Biology and Biotechnology in Western China, Ministry of Education, School of Life Science, Northwest University

Controversies have long been dedicated to the manner of rubber granule synthesis. *Decaisnea fargesii* is a latex-producing plant that is characterized by the presence of a special type of secretory structure in the pericarp, the laticiferous canal, which has been confirmed to be a typical programmed cell death process, during which the rubber granules occur and accumulate. In this paper, a combination of light microscopy, scanning electron microscope, transmission electron microscopy and histochemistry are used to detect the relationship between rubber granule synthesis and programmed cell death in laticiferous canal of *Decaisnea fargesii.* During the early developmental stage of the laticiferous canal, little osmiophilic flocculent material or membranous mass structures have been detected in the secretory cells, which expand by combining with the free material from cytoplasm. In the degeneration stage (especially in sunken stage and expanding stage), the precursors of rubber granules are characterized by the osmiophilic flocculent material or membranous mass structures which are close to degenerated plastids, mitochondria, or on the end of swelling endoplasmic reticulum. Sequentially degenerated cellular components integrate into the rubber precursors, and the volume of the rubber granules expands in this process. The rubber precursors or rubber granules are also accumulated within the central vacuole by autophagy, and integrate with the vesicular, flocculent and mass structures continually, even the organelle enveloped by the rubber granule was also observed, finally shapely mature rubber granules form. It could be concluded that synthesis of the rubber precursor or rubber granule in laticiferous canal of *Decaisnea fargesii* is a random event and are not associated with a specific organelle or stage. And components from cellular disintegration are mainly used to synthesize rubber granules during the PCD process, which provides new evidences for rubber granule synthesis in plant.

Unsaturation of very-long-chain ceramides protects plant from hypoxia-induced damages by modulating ethylene signaling in *Arabidopsis*

Lijuan Xie, *Ying Zhou*, *Shi Xiao*
Sun Yat-Sen University

Lipid remodeling is crucial for hypoxic tolerance in animals, whilst little is known about the hypoxia-induced lipid dynamics in plants. Here we performed a mass spectrometry-based analysis to survey the lipid profiles of *Arabidopsis* rosettes under various hypoxic conditions. We observed that hypoxia caused a significant increase in total amounts of phosphatidylserine, phosphatidic acid and oxidized lipids, but a decrease in phosphatidylcholine (PC) and phosphatidylethanolamine (PE). Particularly, significant gains in the polyunsaturated species of PC, PE and phosphatidylinositol, and losses in their saturated and mono-unsaturated species were evident during hypoxia. Moreover, hypoxia led to a remarkable elevation of ceramides and hydroxyceramides. Disruption of ceramide synthases LOH1, LOH2 and LOH3 enhanced plant sensitivity to dark submergence, but displayed more resistance to submergence under light than wild type. Consistently, levels of unsaturated very-long-chain (VLC) ceramide species (22:1,24:1 and 26:1) predominantly declined in the *loh1*, *loh2* and *loh3* mutants under dark submergence. In contrast, significant reduction of VLC ceramides in the *loh1-1 loh3-1* knockdown double mutant and lacking of VLC unsaturated ceramides in the *ads2* mutants impaired plant tolerance to both dark and light submergences. Evidence that C24:1-ceramide interacted with recombinant CTR1 protein and inhibited its kinase activity *in vitro*, enhanced ER-to-nucleus translocation of EIN2-GFP and stabilization of EIN3-GFP *in vivo*, suggests a role of ceramides in modulating CTR1-mediated ethylene signaling. The dark submergence-sensitive phenotypes of *loh* mutants were rescued by a *ctr1-1* mutation. Thus, our findings demonstrate that unsaturation of VLC ceramides is a protective strategy for hypoxic tolerance in *Arabidopsis*.

Genome-wide association study identifies main factors con-

trolling the anthocyanidin accumulation in rice leaves

Jie Zheng*, Zaihui Zhou, Hao Wu, Huabing Zhu, Zijin Weng, Hao Chen*
Huazhong Agricultural University

Genome-wide association study (GWAS) has been widely used to detect associations between genes and crop traits. Anthocyanidin is a natural pigment for protection from damage by biotic and abiotic stresses and for reproduction. The synthesis of anthocyanidin in plants mainly involves 7 to 8 structural genes and several regulatory transcription factors. The anthocyanidin contents in leaves of 49 wild rice species were analyzed using high performance liquid chromatography (HPLC). The result showed that anthocyanidin accumulation was detected more or less in most wild rice species, indicating that the anthocyanidin accumulation is a common phenotype in wild rice. However, purple leaf is a rare phenotype in cultivated rice, demonstrating it is a trait with artificial selection during rice demonstration. The anthocyanidin in leaves of a worldwide germplasm collection consisting of 533 rice landraces were measured by HPLC, and then GWAS was conducted. The result would help illustrate the key factors under artificial selection for non-anthocyanidin phenotype during rice demonstration.

A nucleocytoplasmic trafficking WD40 protein regulates ABA signaling through affecting ABI5 stability

Guobin Jiang, Wang Wan, Xuezhong Xu, ***Guohui Zhu***
College of Life Sciences, South China Agricultural University

Nucleocytoplasmic trafficking of proteins is being recognized as an important step in plant signaling pathways, including responses to hormone, abiotic and biotic stresses and environmental changes. Here, we report a nucleocytoplasmic trafficking WD40 protein directly interacts with ABI5 and affects ABI5 stability, and therefore regulating ABA signaling. Quantitative RT-PCR analysis and GUS staining analysis showed that WD40 protein was ubiquitously expressed, with relative higher expressions in the seedlings and inflorescence of mature plants. Expression level of *WD40* was continuously decreased during seed germination and seedling development, and its transcripts were induced upon exposure to exogenous ABA. Compared with Col-0, *wd40* mutant seemed less sensitive to ABA treatment during seed germination and seedling development. Moreover, WD40 affects ABA-induced stomatal closing and thus positively regulates drought stress tolerance. We also determined the expressions of several typical ABA responsive genes in the Col-0 and wd40 mutant. Expression levels of *ABI3, ABI5, EM1* and *EM6* were less increased in the wd40 mutant compared with Col-0 in response to 0.5μM ABA. Similarity, expressions of *RD29A, RD29B* and *ABI5* were less up-regulated in the wd40 seedlings when treated by 50μM ABA, these results indicated WD40 protein positively regulates ABA signaling. Subcellular localization analysis showed that WD40 protein is a nucleocytoplasmic localized protein. Yeast two-hybrid, BiFC and Co-IP analyses showed that WD40 directly interacts with XPO1A, an importin β-like nuclear transport receptor. WD40 protein was obviously accumulated in nucleus in tobacco cells after leptomycine B (LMB) treatment, suggesting WD40 protein directly interacts with and nuclear exported by XPO1A. Since WD40 is a nucleocytoplasmic localization protein and is involved in ABA response, we have interests to know if the nucleocytoplasmic participation of WD40 is affected by ABA. GFP signals were significantly enhanced in the nucleus of WD40-GFP transgenic plant cells in response to ABA treatment. Western blot analysis confirmed that ABA treatment increased GFP abundance in the nucleus. These date suggested that ABA regulates the nucleocytoplasmic participation of WD40. Interestingly, environmental stresses, i.e. salt and osmotic stress, also enhanced GFP intensities in the nucleus, implying the nuclear retention of WD40 may be a universal mechanism for plants response to environmental stress. Yeast two-hybrid analysis showed that WD40 directly interacts with ABI5, an important transcript factor positively regulating ABA signaling. Western blot showed that *wd40* mutants had less ABI5 protein in response to ABA compared with Col-0 seeds. Moreover, ABI5 proteins were degraded much faster in *wd40* than in Col-0 after removal of ABA treatment. These data indicated WD40 directly interacts with ABI5 and affects ABI5 stability, and therefore regulating ABA signaling.

SCF^{COI1}-mediated jasmonate signaling represses COP1 for inhibiting skotomorphogenesis in *Arabidopsis*

Ziqiang Zhu
Nanjing Normal University

A germinating seedling undergoes skotomorphogenesis to emerge from soil by reaching for light. During this phase, the cotyledons are closed and the hypocotyl elongates. Upon exposure to light, the seedling rapidly switches to photomorphogenesis by opening its cotyledons and suppressing hypocotyl elongation. The RING type E3 ubiquitin ligase CONSTITUTIVE PHOTOMORPHOGENIC 1 (COP1) is critical for maintaining skotomorphogenesis. Here we show that jasmonate (JA) suppresses skotomorphogenesis (JSS) through the SCF^{COI1}-mediated JA signaling. Arabidopsis seedlings treated with JA phenocopy *cop1* mutants in the dark. Then we check the stabilities of several COP1-targetted transcription factors, including HY5 and PAR1/PAR2, and find that JA stabilizes them in a COP1-dependent manner. Seedlings impaired in the expression of *HY5* or overexpression of *PAR1*/*PAR2* are hyposensitive or hypersensitive to JA respectively, which suggests that these transcription factors contribute to JSS. We further demonstrate that JA suppresses COP1 activity probably through at least two distinct mechanisms: decreasing COP1 protein accumulation in the nucleus and reducing the physical interaction between COP1 and its activator, SUPPRESSOR OF PHYTOCHROME A 1 (SPA1). Our work reveals that a defense hormone triggers the switch from skotomorphogenesis to photomorphogenesis through the tandem actions of two evolutionally unrelated E3 ubiquitin ligases (SCF^{COI1} and COP1).

The distribution of characteristic events of programmed cell death (PCD) and its main regulators during the petal senescence of *Gardenia jasminoides*

Jingjing Zou[1]*, Xuan Cai*[2]*, Xiangling Zeng*[1]*, Hongguo Chen*[1]*, Caiyun*

Wang[2]
1. School of Nuclear Technology and Chemistry & Biology, Hubei University of Science and Technology, Xianning, China
2. Key Laboratory of Horticultural Plant Biology, Ministry of Education, Huazhong Agricultural University, Wuhan, Hubei province, China

Programmed cell death (PCD) is a genetically controlled program involving an ordered set of events, which provides a model system to predict exactly when and how the flowers will senesce. In the present study, six developmental stages (stage 1-6) of *G. jasminoides* var radicans were selected to discuss the spatial distribution of PCD across the petal development and senescence. The results show that the DNA degradation, reactive oxygen species (ROS) generation and lipid peroxidation all started late at the veraison stage. However, the rapid increase of ethylene production, decrease of adenosine triphosphate (ATP) levels and the content of soluble sugar were found to occurred since the flower opening, which implied an early regulatory role of ethylene and source of energy during the petal senescence.of *G. jasminoides* var radicans. Thus, cut flowers of *G. jasminoides* var radicans were treated with ethephon, silver thiosulphate (STS) and sugar to further investigate the role of ethylene and energy loss in flower senescence. The results showed that the vase life of cut flowers was significantly prolonged 28.8 h and 16.8 h by 0.2 mM STS and 1% sugar treatments respectively, but reduced 28.8 h and 14.4 h by 50 mg L^{-1} ethephon and 5% sugar treatments, compared to distilled water. Furthermore, the endogenous ethylene production was increased by ethephon and 5% sugar treatments but reduced by STS and 1% sugar treatments throughout vase life. It is concluded that *G. jasminoides* is an ethylene sensitive flower and the petal senescence is regulated by the endogenous ethylene production. Both ethylene and sugar are important regulators during the petal senescence of cut *Gardenia* flowers, and sugar play the regulatory role by increasing the endogenous ethylene production. This work would offer new theoretical basis for postponing the senescence of woody flowers, and provide the academic and practical basis for selecting the long-blooming resources of *Gardenia* flowers.

Effect of light and temperature on the characteristic color compounds and aroma compounds in *Osmanthus fragrans*

Jingjing Zou[1], *Xuan Cai*[2], *Xiangling Zeng*[1], *Hongguo Chen*[1], *Caiyun Wang*[2]
1. School of Nuclear Technology and Chemistry and Biology, Hubei University of Science and Technology, Xianning, China
2. Key Laboratory of Horticultural Plant Biology of Ministry of Education, College of Horticulture and Forestry Sciences, Huazhong Agricultural University, Wuhan, China

Sweet osmanthus (*Osmanthus fragrans*), belonging to the family Oleacea, is an important ornamental and economical woody plant that has been commercially cultivated in China for over 2,500 years. As one of the top ten traditional flowers in China, it is not only widely applied as avenue tree and shade tree in landscape, but also a famous aromatic plant to produce commercial ingrediants for tea, food, spice, wine and soft beverages industries. Flower opening of *O. fragrans* after flower bud differentiation is usually conducted by a period of cold accumulated temperature in. During the flower opening, environment factors, such as the temperature and light conditions, that have great fluctuations will significantly affect flower scent and flower color. However, how and which of color and aroma compounds have been changed was not clear. In our previous study, the characteristic color and aroma compounds, which have contributed most effectively to the flower aroma and flower color have been identified by GC-MS and HPLC-MS during the flower opening. In the present study, changes of these characteristic flower color and aroma compounds treated in different light and temperature were further analyzed, using *O. fragrans* ‘Houban Yingui’ as the plant material. The results showed that, under light treatment, the quercetin-O-glycoside content was higher than in dark treatment and the content of naringenin-O-glycoside was lower, resulting in paler color in light and deeper color in dark. Under dark treatment, linalool and its oxides and trans-β-ocimene contents were decreased; cis-β-ocimene and neo-allo-ocimene were not dectected. Under the low temperature treatment, the contents of quercetin-O-glycoside and naringenin-O-glycoside were higher than in high temperature treatment, resulting in brighter color in low temperature and paler color in high temperature. High temperature accelerated the senescence of corolla lobes, and promoted the release of cis-3-hexenyl butanoate and hexyl butanoate. Low temperature increased the contents of trans-β-ionone, α-ionone and many monoterpenes and their oxides.

Comparative analysis of miRNAs and their targets during blueberry fruit maturation using small RNA and degradome sequencing

Yanming Hou, Xin Xie, Lulu Zhai, Xuyan Li, ***Shaomin Bian***
College of Plant Science, Jilin University

MicroRNAs (miRNAs) are a class of endogenous, non-coding, small RNAs, which regulate gene expression mainly via cleavage-induced degradation of mRNAs in plants. Increasing evidences indicate that miRNAs play vital roles in the regulation of fruit development and ripening. Blueberry is an important small berry fruit crop with economical and nutritional value. However, it is totally unknown about the miRNAs and their targets involved in blueberry fruit development and maturation. In this study, using high-throughput sequencing of small RNAs and degradome fragments, 84 known miRNAs belonging to 28 families and 16 novel miRNAs were identified in white fruit (WF) and blue fruit (BF) libraries, which represent fruit ripening onset and in-progress, respectively. Among them, 41 miRNAs were shown to be differentially expressed during fruit maturation; and 16 miRNAs representing 16 families were further chosen to validate the sRNA sequencing data by stem-loop qRT-PCR. Meanwhile, 178 targets were identified for 41 known and 7 novel miRNAs in WF and BF libraries, and targets of miR160 were validated using RLM-RACE approach. Moreover, the expression patterns of 6 miRNAs and their targets were examined during fruit development and ripening. Finally, integrative analysis of miRNAs and their targets revealed a complex miRNA-mediated regulation network involving a wide variety of biological processes such as auxin signal pathway and hormonal crosstalk, cell enlargement, and fruit coloration during blueberry fruit ripening. The findings will greatly facilitate future investigation of the mechanisms that regulate blueberry fruit development and ripening.

Genome-wide analysis of *DUF221* gene family in *Glycine soja*

Jianwei Li, *Junkai Yang, Bowei Jia, Mingzhe Sun, Xiaoli Sun*
Heilongjiang Bayi Agricultural University

DUF221 belongs to the transmembrane calcium-permeable cation channel proteins. It plays vital roles in hyperosmotic stress responses. However, up to now, little studies were reported about the *DUF221* gene family, especially in legume crops. Hence, we used bioinformatic method to screen *DUF221* family genes in soybean genome, and identified a total of 21 *GmDUF221* genes. Chromosomal location and synteny analysis revealed that 21 *GmDUF221s* located on 15 chromosomes, and possessed 8 gene duplication events. Analysis of the Ka (non-synonymous substitution rate)/Ks (synonymous substitution rate) ratios suggested that the duplication of soybean *DUF221*genes mainly underwent purifying selection. We further constructed a phylogenetic tree, and found that they were clustered into four subfamilies (I-IV), and members within each subfamily displayed similar intron-exon organization pattern. Furthermore, we also suggested that soybean DUF221 family protein sequences were highly conserved, including three conserved functional domains (Late exocytosis, Cytosolic domain of 10TM putative phosphate transporter and Calcium-dependent channel), 25 conserved motifs and at least 6 transmenbrane domains. Expression patterns analysis indicated that soybean *DUF221* family genes were differentially expressed in various tissues. Among them, *GmDUF221j-2* was highly expressed in flower, leaf and root. These results could provide new valuable information and will facilitate further research.

2. College of Life Sciences, Ningxia University, Yinchuan 750021, P. R. China
3. Fujian Academy of Forestry, Fuzhou 350012, P .R. China
4. College of Forestry, Fujian Agriculture and Forestry University, Fuzhou 350002, P. R. China
5. Department of Biology, The University of Iowa, 210 Biology Building, Iowa City, Iowa 52242, United States of America

The woody mangrove *Kandelia candel* experiences daily flooding cycles in its natural habitat. To explore molecular mechanisms for physiological adaptation to flooding, the role of protein phosphorylation that may play in *K. candel*'s flooding response was investigated by a large-scale quantitative phosphoproteomic analysis using isobaric tag for relative and absolute quantitatiion (iTRAQ). A total of 2,141 unique phosphopeptides and 2,603 non-redundant phosphorylation sites were identified from 1,516 phosphoproteins in *K. candel* leaves. In addition to known phosphorylation motifs, three new motifs [GSP], [GxxSP], and [RSxS] were discovered. Ninety-six differentially expressed phosphoproteins including those involved in pyruvate metabolism and energy production altered their phosphorylation levels in response to flooding. The physiological parameters relevant to flooding response including photosynthesis, pyruvate metabolism, and ROS production were investigated and all found to be robust under flooding conditions. The consistent results between the physiological analysis and the phosphoproteomics reinforce each other to demonstrate that the physiology of *K. candel* is adapted to flooding and that protein phosphorylation plays a role in this adaptation.

A putative MYB-like transcription factor involved in secondary cell wall formation in *Arabidopsis*

Chunming Wang, *Meihui Yu, Junxian He*
School of Life Sciences and State Key Laboratory of Agribiotechnology, The Chinese University of Hong Kong

Secondary cell walls (SCWs) are important for plants to support their growth and adapt to changing environments. SCWs are composed mainly of three biopolymers, namely lignin, cellulose and hemicellulose. Studies have suggested that the biosynthesis of these biopolymers is regulated by a complex transcriptional network. However, the details of this transcriptional network have not been fully uncovered. From an activation tagging based genetic mutant screen in *Arabidopsis*, we identified a new mutant, *rif1* (*Respressor of Interfascicular Fibers 1*), which has severe defects in secondary wall formation in stems, making the plant cannot stand erectly. Microscopy study indicated that the SCW deposition in interfascicular fibers of *rif1* is completely missing, and SCW components assay showed that the levels of the three biopolymers are all significantly decreased in the *rif1* mutant. *RIF1* encodes a MYB like transcription factor in *Arabidopsis* which has not been characterized before. RIF1 is localized in nucleus and has putative transcriptional regulatory activity. From a protoplast transcription transient assay, we demonstrate that RIF1 acts as a transcriptional repressor and negatively regulate several important SCW biosynthesis genes. Our results suggest that RIF1 may define a novel negative transcription regulator in SCW formation in plants. This work was supported by the GRF grants (14121915 and 14148916) and the AoE grants (AoE/M-05/12, AoE/M-403/16) from the Research Grant Council of Hong Kong, the Shenzhen Science & Technology Research & Development Funding - Peacock Scheme, and the Direct Grants from The Chinese University of Hong Kong.

Drought stress release increased growth rate but did not affect levels of storage carbohydrates in scots pine trees

Leonie Schönbeck, *Arthur Gessler, Andreas Rigling, Marcus Schaub, Mai-He Li*
Swiss Federal Institute for Forest, Snow and Landscape Research

(WSL)

For trees, energy storage in the form of non-structural carbohydrates (NSCs) plays an important role for survival and growth, especially during stress events such as drought. It is hypothesized, that tree individuals that experience long-term drought stress use up larger amounts of NSCs than trees that do not experience drought. Consequently, such drought-induced depletion might lead to a decrease in tree vigor and carbon starvation, a mechanism that is subject of intensive debates in recent literature. Hence, if carbon starvation is occurring during drought, drought stress release should again increase NSC concentrations. A long-term (13 years) irrigation experiment is being conducted in the Pfyn forest, the largest *Pinus sylvestris* dominated forest in Switzerland, located in the dry inner-Alpine Swiss Rhone valley (average precipitation ~600 mm/year, with frequent dry spells). Water addition (~600 mm/year) is executed every year during the growing season between April and October. Tree height, stem diameter and crown transparency are being measured since 2003. In February, July and October 2015, roots, stem sapwood and needles were harvested from 30 irrigated and 30 control trees and 5 different crown transparency classes. Shoot length, needle morphology, soluble sugars, starch concentrations, needle $\delta^{13}C$ and $\delta^{15}N$ were measured. Shoot and stem growth were higher in irrigated trees than in control trees. Growth decreased with increasing crown transparency in both treatments. Only in July, needle starch levels were higher in irrigated trees than in control trees but there was no treatment effect for wood and root starch concentrations. Tissue starch and sugar levels were negatively correlated with crown transparency, particularly in the roots (p<0.001), independent of the treatment. Needle $\delta^{13}C$ values were higher in the control trees than in the irrigated trees, where needle $\delta^{13}C$ values were positively correlated with increasing transparency (p<0.01). Annual shoot growth was positively correlated with starch levels in the roots. The results show that 13 years of irrigation did lead to increased growth but not to increased NSC levels hence not confirming our initial hypothesis. $\delta^{13}C$ levels indicate that control trees experienced more drought stress than irrigated trees. However, we found irrigated trees from high crown transparency classes with similar $\delta^{13}C$ levels as for non-irrigated control trees. The release of drought stress has benefited the initially vital trees, whereas the initially inferior trees still show signs of drought stress. The results point to a 'winner takes it all principle', where differences between individuals increase when environment conditions improve. This caused the irrigation treatment not being effective in generally releasing drought stress and NSC depletion in all trees. As increasing crown transparency over both treatments is correlated with decreasing growth and decreasing NSC levels, there are still indications that reduced NSC is related to reduced tree vigor under drought.

A journey of evolution: Phytohormones responses in wound-induced regeneration of land plants

Regina Yeo

National Institute of Education

The evolutionary transition of plants from the aquatic environment to the terrestrial environment is one of the major events in the history of life. On land, plants are highly vulnerable to attack and wounding by herbivores. Thankfully, plants have remarkable regenerative abilities due to their high degrees of developmental plasticity. As such, plants have long exploited the mechanism of regeneration as a response to injuries via regenerating wounded tissues or lost structures. The replacement of a wounded or lost structure in plants can occur via the development of an intermediate mass of specialised tissue, called callus. Phytohormones are known to play vital roles in modulating plant regeneration where optimal plant fitness relies on the regulation of these phytohormones that link damage-associated signals to appropriate changes in growth and development for regeneration to ensue. Although extensive studies have been carried out on the relations of phytohormones to plant development and growth, the evolutionary origin of phytohormone signalling in plant regeneration remains elusive. Furthermore, it is important to note that there are marked differences in basal plants and the higher plants with regards to their initiation, processes and capabilities of regeneration. Through evolution, plants have evolved sophisticated and highly regulated regeneration systems to defend against attackers or sustained injuries. Here, we investigate selected phytohormone signalling pathways to determine their engagement across the plant lineages, from the evolutionary lower to higher plants, in the process of wound-induced regeneration.

Enhancement of *Vicia faba* drought tolerance by gamma irradiation

Mona G. Dawood[1]*, H. Kamel* [2]*, Magdi T. Abdelhamid* [1]

1. National Research Centre, Cairo, Egypt

2. Nuclear Resrarch Center, Cairo, Egypt

For ameliorating the negative effects of moderate and severe drought stress on faba bean plants, two pot experiments were conducted to examine the effect of different doses of gamma radiation (10,25 and 50 Gy). Data revealed that 10 and 25 Gy enhanced germination percentage, fresh and dry weight of seedling, meanwhile 50 Gy showed inhibition effects. Drought decreased plant height, branches number/plant, leaflet length, specific leaf area (SLA), leaf weight ratio (LWR), net assimilation rate (NAR) and relative growth rate (RGR) accompanied by significant increases in soluble protein, phenolic content, proline and free amino acid in dry faba bean leaves. In well watered plants, 10 and 25 Gy caused marked increases in plant height, leaflet lengths, SLA, NAR and RGR relative to control, meanwhile, 50 Gy showed opposite trend. In drought stressed plants, 10 and 25 Gy caused gradual increases in plant height, whereas, 50 Gy decreased plant height relative to corresponding control. Otherwise, leaflet lengths of plants undergo medium or severe drought showed variable responses under the effect of different doses of gamma radiation. Plants undergo severe drought showed that all doses of gamma radiation increased SLA and LWR and decreased NAR and RGR. All doses of gamma radiation caused significant increases in phenolic content, proline and free amino acids, accompanied by significant decreases in soluble protein percentage in drought stressed plants. It could be concluded that 25 Gy was the optimum dose in ameliorating harmful effects of drought stress on faba bean plants.

Two SUMO proteases SUMO PROTEASE RELATED TO FERTILITY 1 and -2 are required for fertility in *Arabidopsis*

Yong-Fu Fu

Institute of Crop Sciences, Chinese Academy of Agricultural Sciences

In *planta*, SUMO is proved to be implicated in extensive cellular processes, including flowering-time control and responses to biotic and abiotic stresses. Here, we report that two proteases, SUMO PROTEASE RELATED TO FERTILITY (SPF) 1 and 2, regulate the fertility in *Arabidopsis thaliana*. The *spf1* single mutant exhibits abnormalities in flower structure and embryos, while the *spf2* single mutant exhibits largely wild type. However, *spf2* enhances the phenotype of the *spf1* mutant, so that the *spf1 spf2* double mutant exhibits severe abnormalities in micro- and mega-gametophytes and embryos, suggesting the two genes function redundantly. *SPF1* and *SPF2* genes are expressed highly in reproductive tissues, and impairment of them results in misexpression of generative- and embryo-specific genes. The SPF1 and SPF2 proteins display *in vitro* the activity of a SUMO-processing protease, while SPF1 displays desumoylating activity *in vivo* on its potential substrate EDA9 (EMBRYO SAC DEVELOPMENT ARREST9). The SUMO-conjugates accumulate at higher levels in the inflorescences, but not in seedlings, in the *spf1 spf2* double mutant than in the wild type. SPF1 and SPF2 also display their own specificity on substrates and interacting proteins. Our results indicate that SPF1 and SPF2 are two SUMO proteases contributed to fertility in *Arabidopsis*.

Diversity and seasonality of arbuscular mycorrhizal Fungi of *Artemisia halodendron* community in Horqin sandy land

Tebuqin Borjigin[1,2]*,* ***Yuying Bao***[1]

1. Inner monglia university

2. Inner mongolia medical university

Artemisia halodendron is an important plant in Horqin sandy land and plays an important role in the stability and development of local plant communities. But its dominance shows a declining trend in the succession process of shifting sandy land to the fixed sandy land. In the 6-9 months of 2006, in the Naiman dune belongs to Horqin sandy land, we studied the shifting sandy land, semi fixed sandy land and fixed sandy land, and collect the rhizosphere soil samples of *Artemisia halodendron* in 0-5 cm, 5-15 cm, 15-30 cm layers, and study the mycorrhizal infection rate and AM fungi diversity. The results showed that the roots of *Artemisia halodendron* were I- type (Intermediate type), the highest colonization rate and the maximum spore density appeared in the 0-5 cm soil layer, and decreased with soil depth. We identified 5 fungal genera and 21 species of AM fungi in the rhizosphere of *Artemisia halodendron*, of which 12 species belonged to Glomus, 3 species belonged to Diverspora, 3 species belonged to Gigaspora, 2 species belonged to Acaulospora, 1 species belonged to Entrophospora. There were 11 kinds of species appeared in all kinds of sandy land, they were *Acaulospora rehmii, Acau. scrobiculata, Diversispora etunicatum, Dive. spurcum, Glomus claroideum, G. constrictum, G. microaggregatum, G. tortuosum, Scutellospora calospora, Scut. pellucida, Scut. persica. Entrospora infrequens,* and *Glomus intraradices* only appeared in fixed sandy land, *Glomus fasciculatum and G. luteum* only appeared in the semi fixed sandy land, *Glomus deserticola, G. geosporum, G. hyderabadensis, G. manihotis* and *G. mosseae* don't appear in shifting sandy land. The dominant genera were the *Gigaspora*. From the sandy land type, AM fungi species were 11 in shifting sandy land, 19 in semi fixed sandy land, 19 in fixed sandy land. For one month the AM fungi species number were, fixed sandy land>semi fixed sand> shifting sandy land. It implied a close relationship between plant degeneration and AM fungal community changes. With the fixed degree of sandy land the AM fungal communities increased, and reduced the dominance of *Artemisia halodendron* population. The results provide a basis for studying the relationship between plant community and ecological distribution of AM fungi.

Metabolomic analysis of alfalfa (*Medicago sativa* L.) root with symbiotic rhizobia under alkali stress

Hua Cai, *Tingting Song, Huihui Xu, Liu Jiang*

Northeast Agricultural University

With respect to salinity stress, alkaline salt causes more severe damage to plants than neutral salt, due to the additional effect of pH stress. However, the mechanism by which plants respond to alkali stress is not fully understood. Here, we studied the effects of root nodule symbiosis on alkali stress in alfalfa using comparative metabolomics. *Rhizobium*-nodulized (RI group) and non-nodulized (NI group) alfalfa were treated with 200 mmol/L $NaHCO_3$ and root samples were subjected to malondialdehydyde (MDA), proline, glutathione (GSH), superoxide dismutase (SOD), and peroxidase (POD) content analysis, as well as metabolite profiling with gas chromatography combined with time-of-flight mass spectrometry (GC/TOF-MS). Phenotypically, the RI alfalfa exhibited a greater resistance to alkali stress than NI plants. Physiological analysis and metabolic profiling revealed that RI plants accumulated more antioxidants (SOD, POD, GSH), osmolytes (sugar, glycols, proline), organic acids (succinic acid, fumaric acid, and alpha-ketoglutaric acid), and metabolites that are involved in nitrogen fixation. Our pairwise metabolomics comparisons revealed that RI alfalfa exhibited a distinct metabolic profile in conferring alkali resistance relative to NI alfalfa. Our study provides new information about the relationship between non-nodulized, rhizobium-nodulized alfalfa and alkali resistance, giving valuable insight into the mechanisms mediating alkali resistance in legume crops.

Molecular regulation mechanism of cold resistance response of MiR398 interacts with cold-resistant lncRNA in winter wheat

Jing Cang, *Qiuwei Lu*

Northeast Agricultural University

Dongnongdongmai 1 (dn 1) was the first freezing-tolerant (resistant to low temperature of -30 ℃) winter wheat that can live through the winter in extreme frigid region in Heilongjiang Province. miRNAs targets was regulated by miRNA, then initiated the cold resistant response. lncRNA (long noncoding RNA) competitivly binded miRNA and coregulated the expression level of miRNA targets. Our previous study indicated that during the natural cooling process the expression of miR398 and its target gene CSD in winter wheat was significantly different.The expression level of miRNA was also affected by the expression level of some noncoding RNA, such as lncRNA. So the cold resistance of winter wheat was affected, but the mechanism was not cleared. dn1 was used as materials, the rhizomes were sampled under natural cooling condition in fields. Using high throughput sequencing, molecular biology and bioinformatics technology combined with cell biology and physiological and biochemical analysis method, MiR398 and the interaction of lncRNA in the cold function, expression regulation model were studied, the members of ceRNA (lncRNA-miRNA-target mRNA) were determined and their function was identified.It is revealed that the complex biological regulation network between miR398 and lncRNA and target mRNA provides a new idea for the study of regulating mechanism of winter wheat miRNA, At the same time, miRNA-lncRNA can affect the morphological characteristics and growth and development of plants, and can also provide theoretical guidance for the cultivation of crops.

Genetic and pathogenic diversity of *Ralstonia solanacearum* causing potato brown rot in China

Li Wang, Bingsen Wang, Guozhen Zhao, Xingkui Cai, ***Huilan Chen***
Key Laboratory of Potato Biology and Biotechnology, Ministry of Agriculture /College of Horticulture and Forestry Sciences, Huazhong Agricultural University

Causing potato brown rot, *Ralstonia solanacearum* (*R. solanacearum*) strains are reported as one of the most destructive bacteria to potato (*Solanum tuberosum* L.) in China. In this study, 113 strains were isolated from potato, collected in the four major agroecological zones in China. The study showed that 102 strains belonged to the phylotype IIB sequevar 1 (race 3 biovar 2). The 11 remaining strains belonged to the phylotype I, sequevar 13,17 18,16 or 14 M, a new sequevar closely related to sequevar 14. Thirty-four strains were further characterized according to their virulence at low temperature on three wild potato species. IIB-1 strains all belonged to high and moderate virulence, while others belonged to the low virulence group, which had limited pathogenicity.

Functional characterization of the *Ginkgo biloba GbDXR* gene promoter in transgenic tobacco

Hua Cheng[1,2]*, Jun Xiang*[1,2]*, Honghui Yuan*[1,2]
1. College of Life Sciences, Huanggang Normal University
2. Economic Forest Germplasm Improvement and Comprehensive Utilization of Resources of Hubei Key Laboratories

1-Deoxy-D-xylulose 5-phosphate reductoisomerase (DXR) is one of the key enzyme that catalyze the first critical step of the MEP pathway for terpene trilactones biosynthesis. By using genomic walking method, a 3111 bp 5′ flanking region (promoter sequence) of the *GbDXR* gene was obtained. The *GbDXR* gene promoter (named *GbDXRP*) was analyzed in the plant cis-acting regulatory element databases and various of cis-elements were found in the sequence. Except the large number of basal TATA box and CAAT box, *GbDXRP* include a lot of specific elements that can response to light regulated, plant hormones and most adversity stress. To study the function of *GbDXRP*, the fusion vectors PCAMBIA1304+ (DXRP1~P5) and PCAMBIA1304-*35SP* (negative control) were constructed and infiltrated into tobacco epidermal cells by LBA4404. According to the epifluorescence results, all the five promoter fragments (DXRP1~P5) could promote the expression of green fluorescent proteins (GFP) in where? Deletion analysis of the *GbDXRP* in transgenic tobacco indicated that the promoter have an efficient promote function, even the promoter fragment is less than 1000 bp. The significant positive relationship between the *GbDXR* gene expression level and the content of terpene trilactones under Uv-B, Drought and Ethylene treatments just reflect the regulatory function involved in *GbDXRP* expression and lactone terpene accumulation in *G. biloba.*

Proteomic profiling of the interactions of Cd/Zn in the roots of dwarf polish wheat (*Ttiticum polonicum* L.)

Yiran Cheng[1]*, Xiaolu Wang*[1]*, Chao Wang*[1]*, Rujiao Wang*[1]*, Fan Peng*[1]*, Xue Xiao*[1]*, Jian Zeng*[2]*, Xing Fan*[1]*, Houyang Kang*[1]*, Lina Sha*[1]*, Haiqin Zhang*[1]*, Yi Wang*[1]
1. Triticeae Research Institute, Sichuan Agricultural University
2. College of Resources, Sichuan Agricultural University

Cd and Zn have been shown to interact antagonistically or synergistically in various plants. In the present study of dwarf polish wheat (DPW)roots, Cd uptake was inhibited by Zn, and Zn uptake was inhibited by Cd, suggesting that Cd and Zn interact antagonistically in this plant. A study of proteomic changes showed that Cd, Zn, and Cd+Zn stresses altered the expression of 206,303, and 190 proteins respectively. Among these, 53 proteins were altered significantly in response to all these stresses (Cd, Zn, and Cd+Zn), whereas 58,131, and 47 proteins were altered in response to individual stresses (Cd, Zn, and Cd+Zn, respectively). Sixty-one differentially expressed proteins (DEPs) were induced in response to both Cd and Zn stresses; 33 proteins were induced in response to both Cd and Cd+Zn stresses; and 57 proteins were induced in response to both Zn and Cd+Zn stresses. These results indicate that Cd and Zn induce differential molecular responses, which result in differing interactions of Cd/Zn. A number of proteins that mainly participate in oxidation-reduction and GSH, SAM, and sucrose metabolisms were induced in response to Cd stress, but not Cd+Zn stress. This result indicates that these proteins participate in Zn inhibition of Cd uptake and ultimately cause Zn detoxification of Cd. Meanwhile, a number of proteins that mainly participate in sucrose and organic acid metabolisms and oxidation-reduction were induced in response to Zn stress but not Cd+Zn stress. This result indicates that these proteins participate in Cd inhibition of Zn uptake and ultimately cause the Cd detoxification of Zn.

Other proteins induced in response to Cd, Zn, or Cd+Zn stress, participate in ribosome biogenesis, DNA metabolism, and protein folding/modification and may also participate in the differential defense mechanisms.

Whole genome re-sequencing of a dwarf mutant induced by carbon ion beam irradiation in *Arabidopsis thaliana*

***Yan Du**, Libin Zhou, Lixia Yu, Shanwei Luo, Tao Cui*
Institute of Modern Physics, Chinese Academy of Sciences

In the post genomics era, mutants play an important role for gene function exploring. Therefore, acquiring various variants and studying on them are useful for understanding the mechanism of plant development and molecular design for plant breeding. In recent decades, due to its unique advantages in Physics and Biology, heavy ion beams, with high mutation rate and wide mutation spectrum, have been widely used in plant breeding as a novel and efficient physical mutagen. In present work, an *Arabidopsis thaliana* variant numbered #541 displaying dwarfism phenotype was induced by carbon ion beams accelerated by the Heavy Ion Research Facility in Lanzhou (HIRFL). In fact, dwarf is one of essential agronomic features and the important research field in life science as well as the research focus in plant breeding. The height of #541 adult plants was only 20.73% that of the wild type plants, however there was no difference in the final number of siliques in single plant between #541 and WT, even though the length of the penultimate and antepenult silique of #541 was shorter than that of WT. As the ever-increasing release of whole genome of various plant species, a direct and effective way to identify the mutations that underlying variation phenotypes of interest is the whole genome re-sequencing. To mine the genes that are responsible for the mutant phenotypes quickly, young leaves of Lab-WT and #541 M3 lines were collected for DNA extraction. And then the genomic re-sequencing was performed by IIIumina HiSeq TM 2500 system. The variations shared by WT and #541 were filtered in order to detect the real mutations that induced by irradiation. Based on the above filter criteria, finally there were 22 SNP (Single Nucleotide Polymorphism), 4 small InDel (insertion-deletion) were detected out through bioinformatics analysis. Among them there were 6 mutations happened in the exon (1 was synonymous, 2 were missense, 1 was nonsense, 2 were frame shift), 19 located in the upstream or downstream regions, while 1 in untranslated regions. The mutations which occurred in intron or up and down stream regions had less probability to change the gene function or expression level, therefore, only the sites whose effects resulted in non-synonymous and frame-shift mutation were considered to be the candidate mutations which related to #541 phenotypes. Thus AT1G49210.1, AT3G15410.1, AT1G64900.1, AT1G62800.2 were screened out according to the SnpEff annotation. Gene Ontology (GO) indicated that the above candidate genes involved in zinc ion binding, leucine-rich repeat (LRR) family protein, cytochrome P450 (CYP89A2), and aspartate aminotransferase, respectively. According to the algorithms of VarScan, AT1G49210.1 was a homozygous mutation, while others were heterozygous. Considering that the dwarfism phenotype of #541 exhibit stable inheritance, since AT1G49210.1 was the most possible candidate gene that might be responsible for the dwarfism of #541.

The complete chloroplast genome of *Primulina* and two novel strategies for development of high polymorphic loci for population genetic and phylogenetic studies

*Chao Feng[1], Meizhen Xu[1,2], Chen Feng[1,2], **Ming Kang**[1]*
1. Key Laboratory of Plant Resources Conservation and Sustainable Utilization
2. University of Chinese Academy of Sciences

Chloroplast genomes can provide important information for phylogenetic and population genetic studies. Recent advances in next-generation sequencing (NGS) techniques greatly facilitate the sequencing whole chloroplast genomes for multiple individuals. In this study, three complete *Primulina* chloroplast genomes were assembled from genome survey data, and then two novel strategies were developed to yield highly polymorphic markers. The first protocol was to develop lineage-specific highly variable marker from the true high variation regions (Con_Seas) across the whole cp genomes, instead of traditional noncoding regions. The experimental evaluation results based on a set of *Primulina* species showed that the newly developed markers are more variable than traditional ones. While the second method, which were developed to assemble fragments (poTs) and sub-super-marker (Cp-Contigs) through our SACRing pipeline, fundamentally altered the strategies of phylogenomic and population genetic studies based on cp markers, from traditional Sanger sequencing to RAD-Seq. This method was firstly proposed here, and successfully applied in population genetic studies from three natural populations of *Primulina*. We believe that these two novel strategies may provide a reference to similar research in other non-model species, and the newly developed high polymorphic loci in this study would promote the phylogenetic and population genetic studies in *Primulina* and other genera of the family Gesneriaceae.

Populations of *Arabidopsis thaliana* from Tibet, a unique ecotype at high elevation

*Tianshu Sun, Yihao Shi, Chenqi Zhu, Xuefei Wang, **Hongya Gu***
State Key Laboratory for Protein and Plant Gene Research, School of Life Sciences, Peking University

Arabidopsis thaliana is found in different geographic regions with different climatic conditions. Six populations were collected from Tibet, the upper reaches of the Yangtze River, China. They are found in habitats at 3,800-4400 meters above sea level, and they formed a monophyletic clade based on chloroplast DNA. These populations have distinct morphological and physiological characters such as very short, sometimes multi-branched, low germination rate, very sensitive to freezing temperature, and *etc.* The low tolerance to freezing temperature is partially due to the malfunctioning of a group of C-repeat binding factor (*CBF*) genes which have been found playing an important role in responding to low temperature in plants. The expression level of *CBF1~3* is lower in all 6 populations than that of Col ecotype at 4°C, and a loss-of-function mutation was found in *CBF2* and/or *CBF3* of these populations. An RNA-seq analysis was performed on the plants treated at 4°C for 3 h and 12h. It was found that at 3 h, the 6 populations shared 98 exclusive up-regulated genes which were mainly involved in responses to various phytohormones such as ABA, auxin, and JA, and to cold and salt stress; while Col had 198 exclusive up-regulated genes involving in regulation of gene expression, protein autophosphorylation, ethylene signaling pathway, and systemic acquired resistance. At 12 h, the 6 populations had a totally different set of up-regulated genes from Col. We will discuss about the adaptation significance of these variations, together with the genetic and molecular characterizations of some other interesting traits in this unique ecotype from Tibet.

Functional analysis of *Rphq4*, a locus for quantitative resistance to leaf rust (*Puccinia hordei*) in barley

*Yajun Wang, Hongjiang Han, **Xiaoquan Qi***
Institute of Botany, Chinese Academy of Sciences

Barley is encountered with numerous diseases such as leaf rust, powdery mildew, sheath blight. The leaf rust resistance controlled by quantitative trait loci (QTLs) has been characterized by the combined components, such as longer latent period, fewer and smaller uredia, lower spore production and slower disease progress, and is usually considered to be more durable and broad-spectrum. *Rphq4*, an adult plant resistant QTL, was mapped on the short arm of 5H chromosome in barley. Map-based cloning showed that two genes are underline *Rphq4* locus. Virus induced gene silencing (VIGS) indicated that both *Rphq4-G1* and *Rphq4-G2* were required in resistance to *Puccinia hordei*. The full-length candidate genes driven by ubiquitin promoter have been cloned into a binary vector to transform into susceptible lines, Golden Promise. The T1 transformed plants have been obtained and will be used for functional validation of *Rphq4-G1* and *Rphq4-G2*.

Arabidopsis glutamate:glyoxylate aminotransferase 1 (Ler) mutants generated by CRISPR/Cas9 and their characteristics

*Yaping Liang, Xiuying Zeng, Xinxiang Peng, **Xuewen Hou***
South-China Agricultural University

Genome editing technology provides an easy tool to edit genomes of plant, animal and microorganism. CRISPR/Cas9 is the most successful and broadly applied genome editing technology nowadays. In this paper, CRISPR/Cas9 was used to edit photorespiration key enzyme gene *GGAT1* (*GLUTAMATE:GLYOXYLATE AMINOTRANSFERASE 1*) of *Arabidopsis* (Ler). Two *GGAT1* target sgRNAs were constructed into pYLCRISPR/Cas9-DN, and flowering *Arabidopsis* (Ler) plants were transformed through *Agrobacterium tumafacien*-mediated floral dip method. Eleven chimeric and two heterozygous *GGAT1* edited T1 lines of target 1 were screened out from positive transgenic lines, respectively. A TCC-deletion and T-deletion homozygous T2 lines were generated from above 13 T1 lines. The edited mutation sites were stable through generations no matter the T-DNA was existed or not; the genetic separation of mutation sites obeyed the Mendel single gene separation rule; no mutations were detected at the possible off-target site; the two independent *ggat1* mutants had similar photorespiration phenotypes and down-regulated GGAT enzyme activity. All these results indicated that genetically stable *ggat1* (Ler) mutants were generated by CRISPR/Cas9 genome editing technology, and these mutants will promote the dissection of how *AtGGAT1* is regulated.

Development and characterization of 18 polymorphic SSR markers for *Barthea barthei* (Melastomataceae)

Guilian Huang
Sun Yat-sen University

Premise of the study: To examine genetic diversity and population differentiation, SSR markers were developed and characterized in *Barthea barthei*, an evergreen shrub with the southern mainland China-Taiwan disjunct distribution.
Methods and Results: We used Illumina HiSeq to develop a genomic library for SSR identification. 18 SSR loci were polymorphic in 60 individuals from three populations of *B. barthei*. The number of alleles per SSR locus ranged from two to nine at the species level and at the population level, the observed heterozygosity and expected heterozygosity per locus varied from 0 to 0.850 and from 0 to 0.809, respectively. Higher genetic differentiation between the two populations of *B. barthei* var. *barthei* (Fst = 0.474) was observed, relative to that between the two varieties (Fst = 0.387 and 0.418, respectively).
Conclusions: These polymorphic genomic SSR markers may be useful for understanding phytogeographic history of *B. barthei*. Lower genetic differentiation between the two varieties than the populations suggests that the taxonomic treatment may not hold.

The effect of $12C^{6+}$ heavy ion irradiation on proliferation, differentiation and mutation of rhizomes of *Cymbidium* 'JunHao'

Jenny Lee
South China Agriculture University

The objective of this study is to breed the new variety of *Cymbidium* interspecific hybrids that has beautiful flower color, dark leaf color, variegation leaf and easy flowering instead of grey orange flower color, late florescence not within Chinese New Year, light leaf color and no variegation leaf. Investigations were carried out on mutagenic effects of different does of 0,30,50,70,90,120 Gy of $12C^{6+}$ heavy ion radiation on proliferation, differentiation and mutation of rhizomes of *Cymbidium* 'JunHao' and preliminary selection of variants form by observing the phenotypic variation. Heavy ion irradiation played the role of inhibition in proliferation and differentiation of rhizomes, the higher the irradiation was, the stronger the inhibition effect was. Proliferation and differentiation of rhizomes irradiated with 50 Gy heavy ion came to be normal in SC_1 generation, while 70 Gy did in SC_2, and differentiation recovered in SC_3 generation. 50 Gy radiation had an obvious positive effect on differentiation of posterity rhizomes of *Cymbidium* 'JunHao'. 50 Gy was the most appropriate irradiation does. The phenotypic variation rates of plants regenerated from rhizomes irradiated by 50,70 and 90 Gy were 67.35%, 68.97% and 100.00%. Regenerated plants were found mutant in sturdy or weak, erect, dark or light, more leaves, wide leaves, variegation, deformity and so on. The above genetic stability needs to be confirmed further.

Characterization of a PVY isolate — PVY-CJ breaking down the resistance of *va* genotype tobacco in China

Ruo Li[1], *Xiuqing Wan*[1], *Xia Liu*[2], *Chan Qiao*[1], *Zunqiang Li*[1], *Xiao Cui*[1,3], *Yuehan Zhu*[1,3], *Zhaokui Guo*[1]

1. Tobacco Science Research Institute of Heilongjiang Province, China Tobacco Corporation

2. School of Basic Medical Sciences, Mudanjiang Medical University

3. School of Life Science and Technology, Mudanjiang Normal University

Potato virus Y (PVY) which is able to infect many Solanacae crops including potato, pepper, tomato, tobacco is a plant virus with very important economical and agronomical impacts on agricultural production. PVY is also one of the main diseases of tobacco production and causes huge economic loss globally every year. Cultivated tobacco plants infected by PVY showed dwarf, vein and stem necrosis, leaf mottling symptoms resulting in dramatic reduce of the yield and quality of tobacco leaves. PVY is the type member of *Potyviruses* genus. The virus has a single-stranded positive-sense RNA genome of about 10 kb in length. A recessive resistant gene *va* had been introduced into cultivated tobacco since a X-ray treated tobacco variety Virgin A Mutant (VAM) was released in 1958 (Koelle *et al.,*). Since then *va* had been deployed in PVY resistant breeding for many years. The selection pressure of *va* on PVY inevitably led to the emergence of mutated PVY population which could overcome the resistance of *va* and this breaking down of *va* resistance has been reported in *va* genotype tobacco growing field globally according to a field survey of Cooperation Centre for Scientific Research Relative to Tobacco (CORESTA) on a worldwide basis (Verrier *et al.,*). Here we report a PVY isolate collected in China which breaks down the resistance of *va* genotype tobacco for the first time. The PVY isolate we named as PVY-CJ was collected from a VAM tobacco plant on a tobacco growing field in Ning An of Hei Longjiang Province of China in 2016. The infected tobacco plant showed typical vein necrosis, leaf mottling symptoms caused by PVY. Using multiplex PCR assay, PVY-CJ was characterized as PVY^{NTN} strain (Ali *et al.,*). The whole genome of PVY-CJ was then obtained by using RT-PCR method (Zhang *et al.,*). Sequence analysis showed that PVY-CJ had a 9,614 nt ORF encoding a polyprotein of 3,061 amino acid residues. The full-length genome sequence of PVY-CJ was subjected to phylogenetic analysis against 60 full-length PVY sequences deposited to the GenBank (Hu *et al.,*). Result showed that PVY-CJ clustered with PVY^{NTN} strains. How PVY-CJ breaks down the resistance of *va*? We then did some primary analysis on the genome sequence of PVY-CJ. Some previous investigations indicated that the Virus Genome-linked Protein (VPg) was responsible for the *va* adaption of PVY to resistant tobacco cultivars (Masuta *et al.,*), while virulence gain in PVY occurred rapidly and preferentially by substitution at position AA105 in the VPg (Janzac *et al.,*). The amino acid sequence of VPg of PVY-CJ was aligned with several other PVY^{NTN} strains. The sequence alignment result showed that there was a substitution of lysine (K) to glutamic acid (E) at position AA105 of VPg of PVY-CJ compared with those of other PVY^{NTN} strains. This result is in accordance with previous investigations. More work may be needed to confirm the role of this single amino acid substitution on the resistance breaking down of PVY-CY on *va* genotype tobacco.

Rice gene co-expression network during anther development

Hong Lin[1,2], *Jing Yu*[1], *Simon Pearce*[3], *Zoe Wilson*[2], *Dabing Zhang*[1]

1. School of Life Sciences and Biotechnology, Shanghai Jiao Tong University

2. Division of Plant & Crop Sciences, School of Biosciences, University of Nottingham

3. Faculty of Biology, University of Manchester

In plants, anther and pollen development includes many important biological events. Complex regulatory relationships occur between genes during this process. Better understanding of the relationships between gene interactions and biological events will help crop breeding and increase yields. In rice, many genes have been confirmed as being responsible for anther development in different stages. However, large numbers of genes in the regulatory network remain unknown. Gene co-expression has been revealed as a good way to characterize global gene interactions because genes in the same pathway or with similar functions usually show very similar expression patterns over different biological processes and experimental conditions. In this work, a rice gene co-expression network during anther development named RiceAntherNet is presented. It was generated from 57 Affymetrix Rice Genome Arrays that specifically focus on anther tissue during whole anther development processes in wild-type rice samples. A website is provided to present expression profile in rice anthers during different stages for users' reference. Microarray datasets of 9 male sterile mutants, including *msp1, ostdl1a, gamyb-2, tip2, udt1-1, tdr, eat1, ptc1* and *mads3-4* mutants were used to focus on example clusters related to anther development. 3 clades with distinguish expression patterns were further constructed to highlights genes associated with particular biological process. Especially for clade1, all 7 reported genes in it have been confirmed to participate in pollen wall formation in rice, furthermore, 16 orthologs in Arabidopsis have been reported as key genes during pollen development in Arabidopsis, which suggest that the rest unknown genes may be involved in the same developmental process. The RiceAntherNet provide a useful library for novel gene identification during anther and pollen development in rice.

Identification of miRNAs involved in light-induced anthocyanin biosynthesis in bagging-treated red Chinese sand pear, 'Mantianhong'

Hainan Liu, *Jun Wu*, Yangfan Zhu, Gaifang Yao, Meiling Ming, Yaojun Chang*
Nanjing Agricultural University

Bagged fruits of red Chinese sand pear cultivar ‘Mantianhong (*Pyrus pyrifolia* Nakai cv. Mantianhong)’ have been found to turn red after debagging during ripening stage. miRNAs play very important roles in many developmental processes, such as flower bud formation, flowering, leaf, root and other morphological formation, fruit ripening, and developmental phase transition (juvenile-adult-reproductive transition), as well as stress, hormonal responses and disease resistance in plants. We investigated the roles of miRNAs in response to debagging to explore whether miRNAs paticipate in this phenomenon of ‘Mantianhong’. Six small RNA libraries and seven transcriptome libraries were primarily constructed from peels of ‘Mantianhong’ pears subjected to bagging followed by sunlight re-exposure treatments (0 h, 4,8 and 10 day) (debagging group) in ripening stage, and taking peels without bagging removal (bagging group) as control. A total of 279 known miRNAs belonging to 40 miRNA families and 416 novel miRNAs were identified via high-throughput sequencing, and 50,452,493 clean reads at average were generated by Illumina sequencing of debagging and control groups after removing low-quality sequences. Some miRNAs and their corresponding target genes were found to be differentially expressed compared debagging group with control, which indicated that miRNAs affected anthocyanin accumulation through their targets in pear. To further explore the effect of debagging on miRNAs regulating the expression of anthocyanin related genes, the expression of four differentially expressed miRNAs and their target genes, which expressed differentially in transcriptome libraries, were identified by qRT-PCR, miRNA-mediated mRNA cleavage sites of two target genes were detected by 5’ RLM-RACE (RNA Ligase Mediated Rapid Amplification of cDNA Ends). Results showed that miRNAs play different roles in the whole stage of anthocyanin accumulation. Additional analysis of gene ontology for the differentially expressed miRNAs after debagging treatments and their predicted target genes showed that they were involved in light response and play important roles in light-induced anthocyanins biosynthesis in red-skinned Chinese sand pear.

Cloning and characterization of a novel dehydrin gene, sidhn, from *Saussurea involucrata* Kar. et Kir. that enhances cold and drought tolerance in transgenic tobacco

Hongling Liu
College of life science, Shihezi University

Saussurea involucrata Kar. et Kir. is a hardy, dicotyledonous plant capable of tolerating severe abiotic stress conditions. In a previous study, we created a cDNA library to determine what factors are associated with the cold acclimation response of S. involucrata. A full-length cDNA of a dehydrin-like gene (SiDHN) was obtained by RT-PCR. The SiDHN gene was characterized in this study. The full-length SiDHN cDNA consisted of 703 bp containing an open reading frame of 333 bp and specified a protein of 111 amino acids. An alignment of the deduced amino acid sequence showed that SiDHN shared 36% identity with Helianthus annuus Agrobacterium tumefaciens was used to transform pBIN438-SiDHN constructs into tobacco. The germination rates of the transgenic plants were measured as well as their resistance to freezing and drought stress. The transgenic plants showed greater resistance to freezing and drought stress than the wild-type. This study demonstrates that SiDHN confers cold tolerance and drought resistance. We suggest that SiDHN has potential to be used to genetically improve the resistance of plants to abiotic stress.

De novo sequencing and characterization of juvenile sporophyte transcriptome of a fern, *Dicranopteris dichotoma*

Liting Liu, *Quanquan Jia*
Jiangxi Academy of Forestry

The sporophyte transcriptome of *Dicranopteris dichotoma* was sequenced by Illumina MiSeq 250 to provide molecular information of its growth, development, metabolism, and the micro evolutionary mechanism. The functional annotations, metabolic pathways and microsatellite analysis of some Unigenes were conducted using bioinformatics methods. A total of 18 463 296 reads containing 4. 62 Gbp of sequence information were generated. A total of 63 169 unigenes were formed by initial sequence splicing, with an average read length of 863 bp and N50 value of 1 587 bp. 26 826 unigenes were annotated using BLASTX searches against the Nr, Nt and SwissProt databases. The unigenes of the transcriptome of *D. dichotoma* were roughly divided into cellular components, molecule function and biological processes categories of 47 branches by gene ontology, of which related with cellular process cell, binding, metabolism processes and catalytic activities. Further annotated based on COG category, Unigenes could be grouped into 26 functional categories. KEGG pathway analysis showed that Unigenes could be divided into 276 classes based on their metabolic function. Meanwhile, 13 286 SSRs (simple sequence repeats) were mined with repeat motif of 2 to 6 bp by MISA. The trinucleotide repeats were most dominant, accounting for a total of 40. 41%. AG/CT (14. 45%) and AAG/CTT (12. 39%) were the most common repeat motifs. Polymorphic SSR markers were developed from repeat motifs, which could be used for genotyping of different individuals of *D. dichotoma*. A higher quality of transcriptome database was obtained in this study, which could reveal the general characteristics of gene expression in the process of growth and development, and lay the foundation for further gene function mining and the large-scale development of molecular markers of *D. dichotoma*. In this study, 23 Unigene sequences which closely related to heavy metal-binding proteins were obtained, furthermore, their functional predictions showed that they were mainly composed of copper, zinc and cadmium. The results proved that *D. dichotoma* has a strong ability to absorb heavy metals at the molecular level. It is great value in the restoration of heavy metal pollution wastelands.

Transcriptome-wide identification and expression analyses of *MATE* genes in response to aluminum toxicity in *Medicago sativa* L.

Xueyang Min, *Zhengshe Zhang, Xingyi Wei, Yanrong Wang, Wenxian Liu*
The State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University, Lanzhou, 730020, P.R. China.

Crop yields are significantly reduced by aluminum toxicity on acidic soils. The Multidrug and toxic compound extrusion (MATE) transporters contribute to multidrug resistance by extruding a wide variety of drugs across cell membranes, including aluminum translocation. Alfalfa (*Medicago sativa* L.) is the most extensively cultivated forage legume, yet most alfalfa cultivars are not aluminum tolerant, and the analysis of MATE family has not been reported in this species. In this study, a total of 88 *MsMATE* genes were identified at the whole transcriptome level. The predicted protein products ranged from 106 to 595 amino acids, with molecular weights from 13.22 to 65.29 kDa. The number of transmembrane helices of these proteins ranged from 0 to 12, and their predicted isoelectric point varied from 4.76 to 9.79. In addition, the subcellular location of these proteins are mainly in the plasma membrane. Phylogenetic analysis of *MsMATE* could classify them into four subfamilies comprising ten smaller subgroups, with diverse potential functions such as aluminum detoxification/iron translocation, flavonoids accumulation, disease resistance and response to abiotic stresses. Ten MsMATE transporters could be clustered together with the previously reported aluminum detoxification and iron translocation related MATE proteins, suggesting their similar potential functions in alfalfa. We further explored the expression pattern of all putative *MsMATE* genes in different tissues by using RNA-Seq data and qRT-PCR method. The most of MsMATE transcripts were found to be expressed in various tissues and showed differentially expression patterns, suggesting that they might be involved in regulating growth and development in alfalfa. Considering the limited functional understanding of MATE transcripts in this important forage legume, our findings will be valuable for the functional investigation and application of this gene family in alfalfa and other related legume species.

Characterization of the fatty acid desaturase genes in *Medicago truncatula*: Structure, phylogeny, and expression patterns

Zhengshe Zhang, *Xueyang Min, Xingyi Wei, Yanrong Wang, Wenxian Liu*
The State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou University, Lanzhou, 730020, P.R. China.

Fatty acid desaturases (FADs) introduce double bonds into the hydrocarbon chains of fatty acids to produce unsaturated fatty acids, and play critical roles in plant development and acclimation to environmental stresses. However, no reports about characterization of the *FAD* genes have been reported in the model dicotyledonous grass species *Medicago truncatula.* In the present study, 20 full-length *FAD* genes in *M. truncatula* were identified in a genome-wide level, including ten *MtFAB2* genes, three *MtFAD2* genes, one *MtFAD5* gene, and two genes each for *MtFAD3*, *MtFAD6*, *MtFAD7*. These *MtFAD* genes were distributed on seven chromosomes except the chromosome 8. Based on a phylogenetic analysis, the *M. truncatula* FAD proteins were clustered into six subfamilies with their counterparts from other plants, and the gene structures and protein sequences were considerably conserved in each subfamily. For the extron-intron gene structures, all the *MtFAD3* and *MtFAD7* clusters (encoding the ω-3 *FADs*) have the same structure, while for the genes encoding the ω-6 *FADs* (*MtFAD2.1*, *MtFAD2.2*, *MtFAD2.3*, *MtFAD6.1* and *MtFAD6.2*) were quite different. Ten MtFAB2 proteins shared conserved structural with the known plant soluble FAD proteins. The other MtFADs belonged to the membrane-bound FADs and contained three highly conserved histidine boxes. Additionally, the putative endoplasmic reticulum retention signal was found at the C-termini of the MtFAD2 and one MtFAD3 proteins, while the N-termini of MtFAD5, MtFAD6, MtFAD7 and two MtFAB2 contained a predicted chloroplast signal peptide, which was consistent with their associated metabolic pathways. Furthermore, the gene expression analysis showed that *MtFAD2.2*, *MtFAD2.3*, *MtFAB2.9*, *MtFAB2.10* and *MtFAD3.1* were universally expressed in all tested tissues, whereas the other *MtFAD* genes were preferentially expressed in the seeds. This study would provide an important foundation for future cloning and functional studies of *FAD* genes in *M. truncatula* and other related legume species.

Genetic diversity and population structure of flower lotus (*Nelumbo Adans.*) cultivars assessed by SSR markers

Xiaojing Liu, ***Fengfeng Du****, Yajun Chang, Naiwei Li, Dongrui Yao*
Institute of botany, Jiangsu province and Chinese academy of sciences

Lotus (*Nelumbo* Adans.) is an important aquatic crops in Asia, Oceania and North America. Flower lotus is widely used in aquatic gardens for its high ornamental value. To determine its genetic diversity and population structure, 36 flower lotus accessions were genotyped with 17 pair SSR primers. A total of 76 alleles were generated and 87.5% were polymorphic. The polymorphism information content (PIC) value ranged from 0.20 to 0.81. Analysis of unweighted pair-group method with arithmetic mean (UPGMA) clustering and principal coordinate analysis (PCoA) distinctly grouped flower lotus accessions from Chinese lotus, American lotus and Sino-American hybrids into different clusters. However, the hybrids dispersed among clusters. Population structure analysis further confirmed the clustering of lotus accessions, and it also indicated that there were several subgroups within Chinese lotus population. The genetic diversity and population structure of flower lotus accessions herein are beneficial for germplasm utilization and genetic improvements of flower lotus in the future.

Genome-wide identification and expression analysis of the MATH-domain proteins in rice (*Oryza sativa*)

Lujun Yu*, Chen Qinfang, Xiao Shi*
State Key Laboratory of Biocontrol, Guangdong Key Laboratory of Plant Resources, Collaborative Innovation Center of Genetics and Development, School of Life Sciences, Sun Yat-sen University

The MATH (meprin and TRAF homology) domain contained a conserved 180 amino acids region and played functions in the protein and protein interaction. *In silico* investigation revealed 81 MATH domain proteins in the full complement of sequenced rice genome. MATH domain genes were categorized into diverse classes according to the phylogenetic analysis and domain organizations, indicating their relation among the various subfamilies. Chromosomal localization and duplication analysis indicated their unevenly distribution on 11 chromosomes without in chromosome 9, with 57 genes being present on rice tandemly duplicated chromosome regions. The rice MATH detailed expression analysis revealed that 29 *OsMATH* genes were differentially expressed during panicle development, with 35 *OsMATH* during seed development, and 43 *OsMATH* genes were differentially expressed under salinity, drought, or cold abiotic stresses. These data provide the valuable information for the further functional genomics study of rice MATH domain-containing genes.

Comparative transcriptomics study reveals two distinct phases of C_4 evolution

Ming-Ju Lyu

Partner Institute of Computational Biology, Shanghai Institutes for Biological Sciences, CAS

C_4 photosynthesis is a remarkable complex trait, not only because species using this biochemistry have higher light, nitrogen and water use efficiencies than their C_3 ancestors, but also because the trait has emerged independently in more than 60 evolutionary lineages. Determining the evolutionary trajectory of C_4 photosynthesis from the ancestral C_3 pathway would elucidate the basic principles of complex trait evolution and help guide engineering of C_3 crops for higher yields. Here, we use the genus *Flaveria*, an evolutionarily significant group that contains C_3, C_3-C_4 intermediate, C_4-like and C_4 species, to systematically characterize transcript abundance and predicted protein sequence changes at different stages of C_4 evolution. This study revealed the following: a) gene transcript abundance, protein amino acid sequence and leaf anatomy changed in a coordinated manner during C_4 evolution; b) formation of a C_4 cycle and augmentation of C_4 photosynthesis represent two distinct phases of C_4 evolution, where cyclic electron transport (CET) plays two distinct roles; c) novel links to metabolic or regulatory processes in addition to CET for C_4 evolution were present, including starch metabolism, protein degradation, cellulose metabolism, and amino acid transport; moreover potential functional sites in the proteins associated with these processes were identified. Overall, this study demonstrates the power of using a comparative transcriptomics approach to gain insight into the evolutionary history of a complex trait.

Multi-scale modelling scheme of maize venation networks

Liming Ma

National Engineering Research Center for Information Technology in Agriculture (NERCITA)

Leaf venation networks is built from lignified xylem and phloem tissue and serves multiple functions, including transport of water and sugars, mechanical support, and herbivory resistance . Because of this diversity in function, these networks are of interest to a wide range of fields, including plant physiology, systematics, and physics. However, the study of these networks is limited by slow and destructive imaging methods. Here, we use micro-CT and confocal microscope which are rapid, of high resolution, and nondestructive to build a three dimensional model of maize venation networks. We acquired serials of cross-sectional images using micro-CT, which included vein features in a wide section of maize leaf. Both major and minor veins could be consistently visualized with the use of iodine contrast agent. Internal feature of the vein was obtained by confocal microscope. After fluorescent dyeing, we acquired microscopic characteristics of xylem and phloem tissue through Z-Stack scanning method. Dataset from micro-CT and confocal microscope were combined to build maize venation model. The generated models are easy to compute the structural and topological properties of leaf veins and their components (the number of connected components, adjacency relationship, volume *etc.*). What is more, they can be used, for example, to simulate the water transports in leaf veins and investigate hydraulic resistance.

Effect of aspergillus niger and trichoderma viride on the increase in plant biomass of *Casuarina equsetifolia*

Shalini Tiwari, *Arun Arya*

Maharaja Sayajirao University of Baroda

Casuarina is a tree crop that provides fuel wood, land reclamation, dune stabilization, shelter belts and pulp production. Roots of this plant are associated with a number of microbes in rhizospheric zone. They have the basic physiology for survival in diverse situation, and they often serve to colonize the plant which grow in poor soils. Many species of *Casuarina* grow on soil with low fertility, some thriving on light soil, others on heavy soil, *C. equsetifolia* thrives in dunes or near the seaside. The outstanding ability of various *Casuarinas* to grow vigorously on poor soils is due partly to their unusual symbiosis with an actinomycetes *Frankia*, that enables them to use nitrogen directly from the atmosphere. *Frankia* which plays a key role on the growth of *Casuarina*, there are other bioinoculants present around the root, which are very important and beneficial for the plant. Mycorrhizal fungi may enter the root and facilitate the uptake of minerals, notably phosphorus and some trace elements. Furthermore, a range of unidentified microorganism interact with the plant to produce dense mats of “Proteoid roots”. The role of various fungi and phosphate solubilizing fungi on the growth of the plants was done in various ways like root shoot ratio, fresh and dry weight, photosynthetic capacity, nutrient utilization and seedling quality. *Frankia* nodules were also collected and observed from these treated plants. Seedlings of *C.equsetifolia* were grown in the botanical garden of MS University of Baroda, Vadodara. These were inoculated with fungi like *A. Niger and T.viride,* either individually or in combinations. Growth was recorded at different time intervals. Inoculation of bioinoculats affected seedling growth, improved seedling quality and nutrient uptake. Nodules were also collected after harvesting and different characteristic were recorded. Nodules recorded from *A.niger* were more in number and bigger in size than *T.viride*. *A.niger* and *T.viride* showed the better growth as compared to other fungi.

Three-dimensional reconstruction and anatomical trait analysis of maize root

Xiaodi Pan[1,2], *Ying Zhang*[1,2], *Meng Shao*[1,2], *Liming Ma*[1,2], *Jinglu Wang*[1,2], *Jianjun Du*[1,2], *Xinyu Guo*[1,2]
1. Beijing Key Lab for Digital Plant
2. National Engineering Research Center for Information Technology in Agriculture

Roots play an essential role in the acquisition of water and nutrients from soils, and are an important component in plant stress tolerance and adaptation. Root anatomical traits have significant effects on root functions, such as acquisition of resources from the soil, water transport within the plant, and metabolic cost of soil exploration. However, two-dimentional microscopic images are often used to acquire useful information on anatomical features, which are not capable of displaying the spatial organization of microstructures and their interactions. In recent years, X-ray computed tomography (CT) provides an attractive alternative for imaging and analysis on the internal anatomy of plant tissues, which is a non-destructive and non-invasive 3-D imaging technique that enable plant tissues to be studied in their natural state. This technique has been widely applied to 3-D imaging of plant leaves, stem vasculature, and crop seeds. However, there have been few reports about its application on root anatomy. In this work, we plan to establish a rapid and non-destructive method for 3-D reconstruction of maize root depending on X-ray micro-CT and develop a 3-D image analysis software for micro-CT data, which is available for high-throughput 3-D information extraction and analysis of root anatomical traits. The above all is in favor of the further understanding of root 3-D anatomy and modelling of hydromechanics.

Genome-wide identification, phylogenetic analysis of the *UXS* gene family in cotton

Yuxin Pan
North China Univrsity of Science and Technology

UDP-Xylose Synthase (UXS) is an enzyme in plants and participate in cell wall noncellulose. Phylogenetic analysis suggested that *UXS* genes could be divided into four subgroups and members within the same subgroup shared similar exon-intron structures and subcellular location. Notably, gene colinearity information indicates 50% cases of aberrant tree topology of gene subgroups, and helps obtain corrected phylogeny, *UXS* genes were subjected to significant positive selection on key evolutionary nodes.

TpNRAMP3 and *5* from dwarf polish wheat (*Triticum polonicum* L.) transport Cd and Co

Fan Peng, *Chao Wang, Yiran Cheng, Songyue Chai, Wendi Shuai, Yonghong Zhou, Yi Wang*
Triticeae Research Institute, Sichuan Agricultural University

Many heavy metal transporter families, such as P_{1B}-ATPase-HMA (P<sub>1B-ATPase-Heavy metal associated proteins), YSL (Yellow-stripe 1-like proteins), ZIP (Zinc-regulated transporters-like proteins) and NRMAP (Natural resistance-associated macrophage proteins), were identified in plant. In rice and Arabidopsis, seven and six NRAMPs were cloned, respectively. Most of them were functionally identified. However, no information of this family was reported in wheat. In the present study, two *NRAMPs*, *TpNRAMP3* and *TpNRAMP5*, were cloned from dwarf polish wheat. Their lengths of open reading frame were 1647 bp and 1623 bp, individually encoded 548 and 540 amino acids. They were mapped on 7BL and 4AS, respectively. *TpNRAMP3* contains 13 exons and 12 introns; *TpNRAMP5* contains 12 exons and 11 introns. At the seeding stage, *TpNRAMP3* was mainly expressed in the leaves; it was markedly up-regulated in the roots by Cd and Fe. Conversely, *TpNRAMP5* was mainly expressed in the roots; its expression in the leaves was slightly up-regulated by Cd and Zn, but was not by Pb, Fe or Cu. Expression of these two genes in yeast indicated that TpNRAMP3 and TpNRAMP5 transported Cd and Co, but did not transport Zn, Fe or Al. Meanwhile, TpNRAMP3 expressed in cell membrane and endoplasmic reticulum using wheat protoplast. These findings suggested that these two genes play an important role in the translocation of Cd and Co in dwarf polish wheat.

Non-destructive and fast visualization and quantification of maize kernel 3D structure using X-ray micro-computed tomography in standardized laboratory

Meng Shao, *Xinyu Guo*
Beijing Key Lab of Digital Plant, Beijing Research Center for Information Technology in Agriculture, Beijing Academy of Agriculture and Forestry Sciences

Observing the internal structure of plant organs or tissues is one of an important content of plant developmental biology and plant functional genetics. However, traditional optical microscopic observation methods have some disadvantages such as sample preparation process is time consuming, destructive, and constrained to two dimensions or limited in optical depth. X-ray micro-CT which is a non-destructive imaging technology don't need sample preparation process and can obtain non-destructive three-dimensional image of plant organs. Exploring the application of this technology in 3D anatomy of maize seeds, is seeking to establish an accurate and fast method for identifying plant phenotypic traits and studying the influence on morphological structure by environmental or genetic factors. Using X-ray micro-CT scan and take 3D reconstruction of maize seeds which are Nongda 178 harvested from drought treatment environment. Graphic image analysis software (Simpleware) was used to realize image segmentation process of 3D anatomy of maize seeds. The 3D images of maize seeds were obtained by X-ray micro-CT. Different structures such as pericarp, embryo, endosperm and cavity on different sections were observed by doing different levels virtual slices on 3D images of maize seeds. Among these structures, the cavity structure can reflect the endosperm enrichment degree of maize plants which were affected by environmental factors such as drought in the process of growth and development. Segmentation of the different structures of maize seeds were obtained by using "floodfill", "region grow", "dilate" and "erode" and the morphometric parameters were acquired by using Simpleware software. This article is the first time to perform the global anatomical 3D segmentation of the compartments of maize seed. It demonstrate the X-ray micro-CT can overcome the traditional optical sectioning complicated sample preparation process and adapt to operate in standardized laboratory to obtain three dimensional structure internal plant tissues. Meanwhile, we achieved the image segmentation of different structures of maize on the three dimensional, and calculate morphological parameters of these different compartments.

Comparative molecular cytogenetic analysis of five wild *Vigna* species (Fabaceae)

Chaowen She[1,2,3], *Ying Mao*[1,2,3]

1. Key Laboratory of Research and Utilisation of Ethnomedicinal Plant Resources of Hunan Province, Huaihua University

2. Key Laboratory of Xiangxi Medicinal Plant and Ethnobotany of Hunan Higher Education, Huaihua University

3. College of Biological and Food Engineering, Huaihua University

The genus *Vigna* Savi (Fabaceae) includes over 100 species distributed throughout the Old and New Worlds. However, chromosome characterization of *Vigna* species has been minimal to date. In this study, the genome organization of five wild *Vigna* species; *V. luteola*, *V. vexillata*, *V. minima*, *V. caracalla* and *V. trilobata,* was determined by sequential combined PI and DAPI (CPD) staining and dual-colour fluorescence *in situ* hybridization (FISH) with 5S and 45S rDNA probes. For phylogenetic analysis, genomic *in situ* hybridization (cGISH) with *Vigna umbellata* genomic DNA probe onto somatic chromosomes was also conducted. Quantitative karyotypes were established using chromosome measurements, fluorochrome bands, and rDNA FISH signals. All species have chromosome number 2n = 2x = 22, and symmetrical karyotypes composed of metacentric and submetacentric chromosomes. CPD staining revealed the 45S rDNA sites in all species, (peri)centromeric GC-rich heterochromatin in *V. luteola*, *V. caracalla* and *V. trilobata*, and proximal AT-rich heterochromatin in *V. caracalla*. rDNA FISH revealed one 45S locus in *V. luteola* and *V. caracalla*, two 45S loci in *V. vexillata* and *V. trilobata*, and five 45S loci in *V. minima*; two 5S loci in *V. caracalla* and one 5S locus in the other four species. cGISH of *V. umbellata* genomic DNA to the chromosomes of all species produced strong or weak signals in all pericentromeric regions of *V. luteola* and *V. trilobata*. The combined data indicated that *V. luteola* and *V. trilobata* are closely related to each other, and relatively distant from the other three species.

GmHMA3, a P1B-ATPase, transports Cd from cell wall to organelles in soybean

Wendi Shuai[1], *Chao Wang*[1], *Yujing Liu*[1], *Yan Huang*[2], *Kangfu Yu*[3], *Yonghong Zhou*[1], *Yi Wang*[1]

1. Triticeae Research Institute, Sichuan Agricultural University

2. College of Life Science, Sichuan Agricultural University

3. Harrow Research and Development Centre, Agriculture and Agri-Food Canada

A single point mutation in GmHMA3 (Glycine Max heavy metal-associated) was tightly associated with the seed Cd concentration. The GmHMA3w (wild type) functions as a Cd/Zn transporter in yeast. Therefore, it was recommended as a target gene responsible for limiting the Cd concentration in soybean seeds. In the present study, knocking down of GmHMA3w using virus-induced gene silencing (VIGS) reduced the Cd concentration in roots and leaves and enhanced the Cd tolerance. Overexpression of GmHMA3w significantly increased the Cd concentration in roots, but significantly reduced Cd concentration in stems, which indicated that GmHMA3w inhibited root-to-shoot Cd translocation. Subcellular localization of GmHMA3w and 3a indicated that GmHMA3w localized at the plasma membrane and the organelles (except of chloroplasts). Therefore, GmHMA3w transported Cd from cell wall to organelles, so that decreasing the Cd tolerance and reducing the biomass production, finally limiting the Cd transport from root to stem and controlling the Cd accumulation in whole plants and tissues. Meanwhile, GmHMA3w did not transport Z, Fe, Co and Pb. Therefore, it is a Cd specific transporter.

In vivo tracking of genetically encoded FRET based isoleucine nanosensors

Shruti Singh

Jamia Hamdard

With the advancement of the technology, microorganisms are metabolically engineered *in vivo* for the production of biological molecules. To investigate the cellular and subcellular levels of metabolites, genetically encoded fluorescent nanosensors are used. The fluorescence resonance energy transfer (FRET) phenomenon is employed to sense the presence of small molecules (substrate, products and cofactor) in *E. coli* and eukaryotic cells. Fluorescent protein attached to an additional protein sequence that makes it sensitive. The isoleucine periplasmic binding protein (LivJ) was sandwiched between the cyan fluorescent proteins (CFP) and yellow fluorescent protein (YFP) for real time monitoring of isoleucine levels, within live cells as it is an essential amino acid that has stimulant activity. These genetically encoded nanosensors provide a new tool for fluxomics or changes in metabolites levels during cell migration. FRET nanosensors are used in bio imaging, labelling, separation, disease diagnosis and analysis of proteins for deep tissue imaging in mammals.

Large-scale analyses of *BES1* gene family reveal the distinct evolutionary patterns between Brassicaceae and Poaceae species

Xiaoming Song
North China University of Science and Technology

The BES1 gene family, an important class of plant-specific transcription factors, play key roles in the BR signaling pathway in plants, regulating various development processes, such as leaf development, stem elongation, pollen tube growth, xylem cell differentiation, senescence, and photomorphogenesis. Until now, there has been no large-scale pan-genomis analysis of *BES1* gene family between Brassicaceae and Poaceae species. Here, we identified 132 *BES1* genes in 19 representative angiosperms, and performed a comprehensive analysis by checking their evolutionary pattern, gene synteny, gene duplication, positive selection, and interaction network. The evolutionary pattern of *BES1* genes was determined through analysis of phylogeny and conserved motif. We detected an additional domain contained M_4 to M_8 in groups F_1 and F_2, which did not exist in all other groups. The WGD/T or segmental duplication contributed the most to expansion of this gene family among all 6 Brassicaceae species, while dispersed duplication contributed the most to expansion in 3 Poaceae species. The percentage of *BES1* genes located in collinear blocks was significant larger than genome-wide level among nearly all examined species, and this percentage in Brassicaceae was higher than Poaceae. There were more positive selection nodes in Brassicaceae than Poaceae species. In conclusion, this study provides useful resources for future studies on the function of *BES1* genes in other related species.

Phylogeography of *Pseudotaxus chienii* (Taxaceae), an old rare species endemic to China

Ning Li[1], *Zhen Wang*[2], *Ting Wang*[3], ***Yingjuan Su***[1]
1. Sun Yat-sen University
2. Nanjing Agricultural University
3. South China Agricultural University

Pseudotaxus chienii is the sole species in monotypic genus *Pseudotaxus* of Taxaceae endemic to China. The species is a dioecious shrub to 4 m tall with distinguished features including white stomatal bands and aril. *P. chienii* is widely but fragmentally distributed in China including montane regions of southern Zhejiang, southwestern Jiangxi, northwestern Hunan, and central Guangxi. The plant grows in warm temperate regions, where is temperate, cool, foggy, and humid with annual precipitation around 1,800-2,000 mm. As an old rare species, *P. chienii* well adapts to cold and arid environment. However, it is unknown how *P. chienii* responded to the Quaternary climatic cycles, and whether phylogeography of the plant conforms to the expansion–contraction (EC) model or exists *in situ* survival. Here, we sequenced three chloroplast DNA (cpDNA) intergenic spacer fragments (*trn*L-*trn*F, *trn*D-*trn*T, and *psb*C-*trn*S) and two nuclear DNA (nDNA) regions (ITS and *NEEDLY3*) in populations of *P. chienii*, respectively, which covered its entire distribution range. We determined 18 chloroplast haplotypes based on the concatenated cpDNA fragments. The haplotype diversity and nucleotide diversity at the species level were 0.751 ± 0.020 and 0.00059 ± 0.00005, respectively. In addition, nine ITS ribotypes and six *NEEDLY3* haplotypes were revealed. Compare to *NEEDLY3* (0.647 ± 0.033), the ITS (0.805 ± 0.014) had a higher level of haplotype diversity, and lower nucleotide diversity (ITS: 0.00471 ± 0.00016; *NEEDLY3*: 0.00593 ± 0.00031). Private haplotypes were identified in several populations of Zhejiang and Guangxi, which possessed high chloroplast and nuclear haplotype diversity and nucleotide diversity. Neutrality tests (Tajima's *D* and Fu's *FS*), the Bayesian skyline plots analyses, and approximate Bayesian computation (ABC) approach consistently showed that no population expansion occurred across the entire geographic distribution. The results of AMOVA indicated that the majority of genetic variation were partitioned among populations. Mantel test revealed that the pattern of isolation by distance existed in cpDNA ($r = 0.440014$; $P = 0.0091$) and *NEEDLY* ($r = 0.639079$; $P = 0.0012$). We identified three groups through the BARRIER analyses, which were further conducted to isolation-with-migration (IM) models analyses with two pairs. The results showed that gene flow in both directions was close to zero for each pairwise comparison. Ecological niche model indicated that no significant range shift for the potential distribution of *P. chienii* during the last glacial maximum (LGM). We speculated that *P. chienii* likely survived *in situ* and existed multiple refugia during the LGM, which was further confirmed by ancestral area reconstructions. This work was supported by the National Natural Science Foundation of China (31570652), and the National Natural Science Foundation of Guangdong Province (2016A030313320).

Preliminary investigation on the genetic variation of *Amentotaxus argotaenia* (Taxaceae) based on gSSR and EST-SSR markers

Xiaoxian Ruan[1], *Qiqi Huang*[1], *Zhen Wang*[2], *Ting Wang*[3], ***Yingjuan Su***[1]
1. Sun Yat-sen University
2. Nanjing Agricultural University
3. South China Agricultural University

Amentotaxus argotaenia (Taxaceae) is a vulnerable species endemic to China. It has a wide distribution range with small isolated populations. The species has well adapted to habitat fragment and ecological heterogeneity across 11 provinces of South and Central China such as Fujian, Guangdong, Guangxi, Guizhou, and Zhejiang. The ISSR fingerprinting has indicated that *A. argotaenia* complex have low genetic diversity. However, the low level of genetic diversity is unable to provide raw material for adaptive evolution. Hence, it is necessary to accurately evaluate genetic variation of *A. argotaenia* using different molecular markers. First, we developed gSSR and EST-SSR through FIASCO method and transcriptome, respectively. Totally, 22 EST-SSRs and 23 gSSRs with polymorphism were isolated. For EST-SSRs, the number of observed alleles and the effective number of alleles were ranged from 3 to 10 and 1.097 to 3.506 per locus, respectively. For gSSRs, the number of observed alleles and the effective number of alleles was 1-13 and 1.00-7.86 per locus, respectively. These markers also successfully cross-amplified in *A. yunnanensis*. Then, we separately evaluated genetic variation of *A. argotaenia* from four natural populations using these developed EST-SSRs and gSSRs. The results showed that *A. argotaenia* possessed mediate genetic variation and high genetic differentiation. However, compared to EST-SSRs, the genetic diversity based gSSRs was higher, whereas genetic differentiation was lower. AMOVA analysis indicated that majority of genetic variation was within populations. The Mantel test based on the two markers solidly showed that *A. argotaenia* lacked pattern of isolation by distance. The STRUCTURE results of EST-SSRs and gSSRs were inconsistent. In addition, no adaptive loci was detected using Bayescan and Dfdist. MAXENT predicted that the future suitable habitat of *A. argotaenia* was decreasing in comparison with the current one. The results will lay a solid foundation for further investigating adaptive evolution and conservation strategies of *A. argotaenia*. This work was supported by the National Natural Science Foundation of China (31570652), and the National Natural Science Foundation of Guangdong Province (2016A030313320).

A comparative study on chloroplast genome between the invasive species *Mikania micrantha* and its indigenous congener *M. cordata* in south China: Structure variation, identification of highly divergent noncoding regions, divergence time estimation, and phylogenetic analysis

__Yingjuan Su__[1], Lu Huang[1], Zhen Wang[2], Ting Wang[3]

1. Sun Yat-sen University
2. Nanjing Agricultural University
3. South China Agricultural University

Mikania micrantha and *M. cordata* are only two species in genus *Mikania* (Asteraceae) in China. They exhibit high similarity in morphology, life history, and growth characteristics. However, their impacts on the environment are totally different. In south China, *M. cordata* is no harmful to native plants or habitats, while *M. micrantha* is a noxious exotic invasive weed. Comparison of differences between invasive species with its indigenous close congener can provide new insights to profoundly comprehend invasive characteristics and mechanisms. Hence, we obtained complete chloroplast genome sequence of *M. cordata* through the Illumina sequencing, and compared it to *M. micrantha* chloroplast genome. The *M. cordata* chloroplast genome was 151,984 bp in length, and possessed typical quadripartite structure. Numbers and distributions of protein coding genes, tRNA genes, and rRNA genes of *M. cordata* were identical to *M. micrantha* chloroplast genome. The main difference of two *Mikania* species laid in genome length and *ndhF.* Fourteen highly divergent regions, 235 SNPs, and 58 InDels between two *Mikania* species were identified. Phylogenetic inferences and age estimations separately demonstrated a sister relationship between *M. micrantha* and *M. cordata* and divergence of early Pleistocene. Twelve cpSSR loci were detected to be polymorphic, and adopted to preliminary survey genetic diversity and adaptation of *M. micrantha* populations. The results will lay a solid foundation to further investigate invasive mechanism of *M. micrantha*. This work was supported by the National Natural Science Foundation of China (31570652), and the National Natural Science Foundation of Guangdong Province (2016A030313320).

A434

The complete chloroplast genome sequence of *Neolepisorus ovatus* (Polypodiaceae), an important medicinal and ornamental fern

Liu Shanshan[1], Zhen Wang[2], Ting Wang[3], __Yingjuan Su__[1]

1. Sun Yat-sen University
2. Nanjing Agricultural University
3. South China Agricultural University

It is the first report on complete plastid genome of *Neolepisorus ovatus*, which is an important medicinal and ornamental fern. The complete chloroplast genome of the fern is 151,936 bp in length with 41.34% GC content. The chloroplast genome exhibits typical quadripartite structure possessing a pair of two inverted repeats (24,609 bp), a small single copy (SSC, 21,601 bp), and a large single copy (LSC, 81,117 bp). The *N. ovatus* genome encodes 132 genes, including 89 protein-coding genes, 35 tRNA genes, and eight rRNA genes. Among of them, 16 genes including six protein-coding genes, six tRNA, and four rRNA genes are duplicated within the IR regions. In total, 15 genes (*rps*16, *atp*F, *rpo*C1, *pet*B, *pet*D, *rpl*2, *ndh*B, *ndh*A, *rpl*16, *trn*G-UUC, *trn*L-UAA, *trn*V-UAC, *trn*A-UGC, *trn*I-GAU, and *trn*T-UGU) contain one intron, whereas three genes (*rps*12, *ycf*3, and *clp*P) occur two introns. The ML phylogenetic analysis based on 18 complete cpDNA from ferns showed that *N. ovatus* is has a close sister relationship with *Cyrtomium devexiscapulae* and *Cyrtomium falcatum*. The complete cpDNA of *Neolepisorus ovatus* genome will be useful for phylogeny and comparative chloroplast genomics of ferns.

Expression regulation of *FATTY ACID ELONGATION1* expression by swapping: sequence variation, epigenetic modification, or spatial-temporal localization?

__Xiaoqin Sun__, Zhao Lei, Jiayu Xue, Yueyu Hang

Institute of Botany, Jiangsu Province and Chinese Academy of Sciences

FAE1 is a key gene in control of erucic acid synthesis in plant seeds. The expression of the *FAE1* genes in *Brassica napu*s and *Capsella rubella*, representives of high and low erucic acid species, was characterized to provide insight into the regulation of very long chain fatty acid (VLCFA) biosynthesis in seeds. Almost none methylation was detected either in *B. oleracea* or *C. rubella*, suggesting that the modification of promoter methylation might not be a predominant mechanism. The swapping constructs were specifically designed so that the contribution of the variations in the coding regions or promoters to the changes in the *FAE1* expression levels could be quantified and compared in parallel. Significant higher fold change in erucic acid content was observed by swapping coding regions than by swapping promoters, indicating that the coding region should be a major determinant of catalytic power of KCS proteins. It was proposed that the common motifs might be essential to the preservation of the basic gene expression patterns such as the seed specific expression; by contrast, the occurrence variation of common *cis*-elements or the presence of species-specific *cis*-elements might be a plausible mechanism for changes of the expression levels in different organisms. Meanwhile, the conflicted observation in previous reports associated with the *FAE1* expression is discussed here, and we suggest that caution should be taken in selecting a plant transformation vector and in the interpretation of the results obtained from vectors carrying the CaMV 35S promoter within their regions.

SSR primers of *M. Truncatula* were tested for their transferability in fababean and genetic and analysis on segregation distortion of molecular markers in f2 population

***Yingying Tian**, Wanwei Hou, Yujiao Liu*

Qinghai University, Xining Qinghai Academy of Agricultural and Forestry Sciences

In this study, 216 SSR primers of *M. Truncatula* were tested for their transferability and polymorphism by PCR amplification with the genomic DNA of four fababean varietys. F_2 materials derived from a cross between Yun122×TF42 were used as mapping population in cotton. The results indicated that the transferability rate of *M. Truncatula* SSR in fababean was 76.39%, and the ratio of polymorphism SSR primers in these crops was 9.4%. Among the 84 polymorphic markers analyzed 19 markers (76%) showed the genetic distortion ($p<0.05$) in the F2 population. Among these segregation distortion SSR markers, 12 SSR marker alleles were distorted to the male parent TF42 (63.2%), 3 SSR markers allels were distorted to the female parent Yun122 (15.8%), and 4 SSR marker alleles were distorted to the heterozygote (21%).

The reproductive pathways of floating *Ulva prolifera* and the response mechanisms to stress

Guangce Wang

Institute of Oceanology, Chinese Academy of Sciences

Macroalgae are the important component of the marine ecosystem, which are important to the offshore environmental protection and ecological balance. *Ulva prolifera* is multicellular types of algae, artificial breeding in the South China Sea area such as Zhejiang province, used as food or feed, *etc*. The green tide has been developed in the Yellow Sea, China since the year 2008, of which free-floating *U. prolifera* is one of the causative species. In the late spring of 2008, without prior warning, the actual coverage area of *U. prolifera* was about 3800 km^2 and the thickness was about 0.5 m in less than two weeks. The influencing area was tens of thousands square kilometers, which directly affected the 2008 Beijing Olympic Games sailing competition in Qingdao. The key research of the project aims to study the photosynthetic carbon fixation in the rapid accumulation and floating state of the thalli and the molecular mechanism of upper floating thalli to stress.

(1) Rapid reproductive means and mechanism of sporogenesis in floating *Ulva prolifera*

In nature environments intact thallus of floating *Ulva prolifera* is easily cut into fragments by seawater flow, gnawing of animal, and ship propeller. Those thallus fragments are an important origin that results in rapid biomass accumulation of *Ulva prolifera*. During fragments excised from intact thallus were cultured in laboratory, the cell in thallus fragments changed greatly. Those cells developed into sporangium after 48 h culture. Subsequently zoospores were released form those sporangia.

The cells in fragments of floating *Ulva prolifera* were vegetative during 0-48 h culture. Meanwhile photochemical quantum yield of PS I Y (I) and effective PS II quantum yield Y (II) were relatively stable and the variation tendencies between them were similar. The formation of sporangia and spore release occurred after 48 h and spore release reached maximum degree at 60 h in culture. At 48 h Y (II) dropped to its lowest level, while Y (I) rose to its highest level. Those changes suggested that linear electron flow (LEF) declined while cyclic electron flow around PS I (CEF) was enhanced markedly at sporulation onset. These results indicated that both CEF enhancement and the oxidation of the plastoquinone pool are essential for sporulation onset. The further research suggested carbon fixation in photosynthesis has a relationship with sporulation. The decline of LEF can decrease inorganic carbon fixation.

(2) The pigment composition of floating *U. prolifera* thalli and the carbon source for photosynthetic carbon fixation process

U. prolifera thalli in free-floating mats could be separated into three groups according to color: light green, intermediate green, and dark green. The effective photosystem II quantum yield (YII) of the light green thalli cells had the highest value. These thalli, which are on the surface of the mats, usually are exposed to the air for long periods of time, during which it is difficult for them to acquire dissolved inorganic carbon from the seawater. In addition, although the thalli in the lower layers of the mat are in contact with seawater, photosynthesis is limited because of limited exposure to sunlight. So, why the growth rate of free-floating *U. prolifera* is extremly high when green tides occur? Our results found that *U. prolifera* thalli can utilize CO_2 in the air directly. CO_2 assimilation was enhanced as CO_2 increased in the air, even when under moderate stress, such as dehydration and salt stress.

(3) The tolerant mechanism of *Ulva prolifera* to desiccation

During green tides, massive mats of the floating *U. prolifera* could be accumulated rapidly and the thickness of the floating mats were closed to 0.5 m. Moreover, the thalli on the surface of the mats usually undergo desiccation stress lasting several hours in the daytime. We found that during desiccation, the PSI-driven cyclic electron flow in *U. prolifera* increased significantly. Although the activity of cyclic electron flow is lower than that of linear electron flow which dominates under optimal conditions, the cyclic electron flow might provide some protection of the photosynthetic apparatus and extra ATP under desiccated conditions. In addition, the activity of PSI was restored faster than that of PSII during re-hydration. Based on these results, we propose that the physiological tolerance and stability of photochemical systems, especially PSI-driven cyclic electron flow, might be one of the most important factors that make *U. prolifera* well suited to withstand repeated cycles of desiccation and re-hydration during daily low and high tides. These results will increase our understanding of the tolerant mechanism of the intertidal macro-algae to desiccation and will lay the foundation for the solution of green tides.

Integrated gene expression analysis of maize (*Zea mays L.*) leaves under biological stress reveals several sensitive loci related to pathological mechanism

Jinglu Wang, *Xinyu Guo*
Beijing Key Lab of Digital Plant, National Engineering Research Center for Information Technology in Agriculture

Large-scale expression profiling has become a favorable method for understanding the molecular mechanism of plant expression, and some progress has been made in botany research. Among these, microarray technology was used as a practical method to analyze the gene dysfunction contributed to maize leaves under different stress, in particular, the abiotic stresses. Recent years, plenty of gene expression profiling studies of the changes of maize leaves under biological stress have been published. But the heterogeneity of each study is apparent because of various chip platforms and data processing procedures. As a consequence, an integrated analysis for the genome-wide expression data sets of maize leaves should be conducted. In order to make the results comparable, the same pre-processing and quality control procedures are necessarily used to analyze each data set separately. Notably, a standard linear mixed-effects model would be used to compute the differentially expressed genes. And pathway enrichment analysis of the DEGs would conducted by DAVID to explore their functions. Through the analysis of the differences in gene expression between healthy leaves and leaves infected by pathogens, we can not only identify some candidate loci, but also can help us understand the phenotypic differences between different maize species.

2. Center for Genomics and Computational Biology, North China University of Science and Technology, Tangshan, Hebei 063000, China

Polyploidy contributes to the divergence and domestication of land plants. However, for the sophisticated complexity of plant genomes due to recursive polyploidizations, often it is much difficult to deconvolute their structures . By performing comparative genomics analysis, we managed to make a hierarchical and event-related alignment of the 8 Poaceae, Pineapple, Cotton, Cacao, and Grape genomes, deconvoluted layers of the aligned genomic regions correspond to ancestral polyploidizations and speciations, and deciphered gene-colinearity-supported paralogs derived from these events. Similarly, we showed multiple cotton genome structures affected by decaploidy in their common ancestors. With these data sets, we explored how polyploidization contributed divergently to copy number variation of gene families. These present efforts laid a solid foundation further genomics exploration in plant research community and beyond.

Subcellular locations of potential cell wall proteins in plants: Predictors, databases and cross-referencing

Qinbin Zhang, *Xiaolin Wu*, ***Wei Wang***
Henan Agricultural University

The cell wall is the most striking feature that distinguishes plant cells from animal cells. It plays an essential role in cell shape, stability and growth as well as protection against environmental stresses. Despite being present in small amounts, cell wall proteins (CWPs) continue to emerge as crucial components of the plant cell wall. In general, the cell wall proteome consists of components such as *sensu stricto* CWPs, apoplast proteins, and extracellular secreted proteins. Compared with proteins in intracellular compartments, the bioinformatic prediction of the subcellular location of possible CWPs is challenging because many aspects of these proteins have not been experimentally characterized. Furthermore, there are no specific, accurate predictors. Currently, there is a need for the bioinformatic analysis of a tremendous number of protein sequences (including possible CWPs) that have been generated from genomic, transcriptomic and proteomic research. By introducing the biological relevance of the cell wall and CWPs, we critically evaluate state-of-the-art predictors for the subcellular location of CWPs based on a large, independent database of Arabidopsis and rice proteins. We also propose promising predictors that are suitable for CWPs. Furthermore, we outline the publicly available databases that can be used for cross-referencing the subcellular location of CWPs. Lastly, we propose a flowchart of subcellular location predictions and a cross-reference of possible CWPs. We also discuss challenges and perspectives in the bioinformatic analysis of CWPs. This work provides practical guidance regarding CWPs for non-specialists in bioinformatics.

Mitochondrial phylogenomics of Nectriaceae (Ascomycota, Fungi)

Xin-Cun Wang, *Zhao-Qing Zeng*, ***Wen-Ying Zhuang***
State Key Laboratory of Mycology, Institute of Microbiology, Chinese Academy of Sciences

Nectriaceae includes a group of fungi with agricultural, industrial and medicinal importance. Phylogeny of the family inferred from multiple nuclear genes have been thoroughly studied, however, phylogenetic inference based on mitochondrial genes is hitherto lacking. In this study, 26 mitochondrial genomes representing 21 genera of the family were determined using the next-generation sequencing technology. The genomes are all circular molecules. The genome size ranges from 27,129 bp to 149,875 bp, and the GC contents are from 25.95% to 32.61%. Gene prediction revealed at least 42 genes encoding 15 conserved proteins, no less than 25 tRNAs, and large and small ribosomal RNAs. All genes are located on the same strand. The number of introns in the protein-coding genes reaches up to 40, while no intron was found in ten mitochondrial genomes. The mitochondrial genome size was correlated with numbers of intron and tRNA, but had no effect on phylogeny of the family. The same gene order of 42 genes was shared by eight species. Genome rearrangements include gene lost, tRNA gene translocation and duplication. GC content and some variations in mitochondrial genome structure carry phylogenetic information. The gene order of 15 protein-coding genes was conserved in Nectriaceae, which were also found in other four families of Hypocreales and the related orders of the class Sordariomycetes. It represents an ancestral state in the class. Mitochondrial phylogeny of Nectriaceae was reconstructed using the concatenated amino acid sequences of the 15 protein-coding genes derived from 42 mitochondrial genomes. The tree topology was very similar to that obtained from the multiple nuclear genes. Potential changes among genera of the family were roughly investigated. Mitochondrial genomes of Nectriaceae will give us a better understanding of phylogeny and evolution of the group and its related fungi.

Ancestral karyotype reconstruction unravels independent genomic repatterning between Triticeae and *Brachypodium*

Zhenyi Wang

North China University of Science and Technology

Based on the theory of our latest research results, we found that *Brachypodium distachyon* was not of enormous relevance for comparative genomics, evolutionary studies of large genomes of the Triticeae, wheat and barley have their unique evolution process, rather than the other researchers concluded that, the common ancestor of *Brachypodium* and the core Pooideae had a genome structure quite similar to that of rice, genome rearrangements between *B. distachyon* and Triticeae are independent of rearrangements between *B. distachyon* and rice, consistent with the phylogeny. The results of our study is different from their researches, the common ancestor of Triticeae and rice had a genome structure quite similar to that of *Brachypodium distachyon*, the genome evolution of Triticeae is distantly related to *Brachypodium distachyon*, while related to rice. Thus rice could serve as an anchor genome to help locate important chromosomal locations in Triticeae crops.

Preliminary functional characterization of a rice mitogen-activated protein kinase (MAPKK-426)

Jian Wei, Jianshuo Zhang, Yalu Guo, Jianan Shi, Shijuan Dou, Liyun Li, Lijuan Liu, ***Guozhen Liu***

College of Life Sciences, Hebei Agricultural University

Rice is one of the most important food crops and also an important model plant in the world. Most of the mitogen-activated protein kinase (MAPKs) in plant is serine/threonine protein kinase, which stimulated by a variety of extracellular stimuli and transmit signals to the nucleus. In this research, a MAPKK was chosen as target (Namely MAPKK-426). Over expression and RNA interference vectors were constructed rice TP309 was transformed by Agrobacterium-Mediated protocol In T0 generation, 20 over expression Lines was obtained, PMI protein detection by western blot analysis verified 17 of them are positive and 3 are negative ones. Fifty-one lines were obtained via two different RNAi constructs and detected by NPT-II antibody. It showed that 22 positive and 29 negative. In T1 generation, genomic DNA were extracted and PCR analysis were carried out. Three homozygous lines and 2 heterozygous lines were identified in 5 over expression lines tested. Ten homozygous lines and 16 heterozygous lines were identified among 26 lines derived from two RNAi constructs. In T2 generation cultivated from positive seeds, 4 homozygous lines and 4 heterozygous lines were identified in 8 over expression lines detected by PCR, 10 homozygous lines and 10 heterozygous lines were identified from RNAi constructs. To monitor the expression of target protein, western blot analysis was carried out by specific antibody, it showed that the expression of target protein were up-regulated in 6 over expression lines, while it down-regulated in 3 homozygous RNAi Lines. It also found that RNAi plants showed dwarf and etiolation compared with the control in tillering stage. Taken together, stable transgenic rice with over or down-regulated MAPKK-426 Lines were identified with phenotypic changes, which will helpful for the functional characterization of the gene.

Genome-wide analysis of DREBs subfamily in foxtail millet

Songchang Shi*, Zhang Ruye, Zhao Zhenting, Yang Lei, Ge Weina*

College of life sciences, North China University of Science and Technology

DREBs (dehydration responsive element binding) are unique transcription factors in plants, and play important roles in drought, cold, salt and other environmental stresses. Bioinformatic analysis of the DREB subfamily was performed at the genome-wide level in foxtail millet (*Setaria italic*). 65 genes encoding DREB were found in the millet genome, which were distributed on 9 chromosomes. According to the sequence characteristics, they were divided into six groups (A1 to A6). Each group has their own characteristic in the gene structure and the composition of protein motifs. Segmental duplication and tandem duplication play important roles for the expansion of the *SiDREB* subfamily. *SiDREB* genes were strongly positive selected during the evolution of millet, and that was also the reason for the rapid evolution of *DREB* genes. These results will lay a foundation for further study on the function of *DREB* genes, and provide some clues for revealing the mechanism of the resistance of millet.

Distinct transcriptome profiles reveal gene expression patterns during fruit development and maturation in five main cultivated species of pear (*Pyrus L.*)

Jun Wu, *Ming-Yue Zhang, Cheng Xue*
Centre of Pear Engineering Technology Research, State Key Laboratory of Crop Genetics and Germplasm Enhancement, Nanjing Agricultural University

The transcriptomes of five pear cultivars, 'Hosui' (*P. pyrifolia*), 'Yali' (*P. bretschneideri*), 'Kuerlexiangli' (*P. sinkiangensis)*, 'Nanguoli' (*P. ussuriensis*), and 'Starkrimson' (*P. communis*) were sequenced at seven key fruit developmental stages, from fruit setting to maturation and fruit senescence after harvesting. In total, 33,136 genes that could be mapped by reads, were analyzed. Most gene expression cluster models showed a steadily decreasing trend. Gene expression patterns had obvious differences according to maturity type, that is, post-ripening cultivars were still vigorous at maturity, and showed a higher proportion of up-regulated genes; non post-ripening cultivars had a gradually decreasing tendency during fruit maturation. Meanwhile, differentially expressed genes related to fruit quality and development, such as stone cells, sugar, acid and hormones, were identified. Co-expression analysis revealed that several ethylene synthesis genes and polyphenoloxidase-related genes interacted with each other directly, and an indirect relationship was reflected between ethylene synthesis genes and ethylene response genes. In addition, the highly diverse SNPs represented the great differences between oriental and occidental pears. Understanding how RNA-seq based gene-expression patterns and differential gene expression contribute to fruit quality allows us to build models for gene-expression for fruit development of *Pyrus* species.

Improving eating and cooking qualities of rice grain by molecular marker-assisted breeding

Mingwei Wu[1,2], *Chunming Liu*[1]
1. Key Laboratory of Plant Molecular Physiology, Institute of Botany, Chinese Academy of Sciences
2. University of Chinese Academy of Sciences

Rice (*Oryza sativa* L.), one of the important cereal crops, is the major stable food for more than 50% population in the world. Increasing rice grain yield is a crucial challenge, and improving its eating and cooking quality (ECQ) is also an important breeding goal. Starch is the major storage material in rice seeds, which comprises two main types of glucan homopolymer: amylose and amylopectin. The eating and cooking qualities of rice grain are closely related to the ratio of amylose to amylopectin and the architectural features of amylopectin. For improving the ECQ of cultivated species in Northeast of China, the apparent amylose content (AAC) and Rapid Visco Analyser (RVA) profile of 130 rice varieties were measured; nine rice varieties showed highly starch quality were used as donor candidates, and hybridized with the cultivated specie Longjing26 in Northeast of China expecting ultimately to obtain the superior rice variety. Meanwhile, we hope to find some quantitative trait loci (QTLs) related to the starch quality by constructing Recombinant Inbred Line (RIL). Now, some AAC related QTLs have been found by mapping the Recombinant Inbred Line of RCC147xLongjing26; next, we hope to use those QTLs to improve ECQ of Longjing26

Batch annotation tool, a novel automatic annotation tool for chloroplast genome

Ping Wu, *Shiliang Zhou*
Institution of Botany, Chinese Academy of Science

Chloroplast genomes is widely used in plant phylogenetic studies, especially for angiosperms due to widespread maternal inheritance. Previously the application of chloroplast genome sequence was limited to several genes or fragments, such as rbcL, matK, trnH-psbA, *etc.* In recent year, the price of high throughput sequencing was dramatically decreased, and the sequencing technique for chloroplast became mature. All of above lead to an explosion for sequencing chloroplast. In spite of this, the lack of automatic and accurate annotation tools slowed the pace of utilizing these data. The annotation of chloroplast still stay on the manual phases that researchers have to waste lots of time on software or website. Moreover, the correction of errors caused by those tools merely depend on their experience, which may bring possible mistakes that was neglected before. Herein, we developed a native software Batch Annotation Tool (BAT) to solve this problem. Based on existing chloroplast genomes in Genbank integrated into BAT, there are two strategies for choice. First, BAT could use high resolution fragments such as ycf1 and trnH-psbA to identify given input sequence to find the most similar reference genome and then generate annotation information according to reference sequence. This method is suitable for numerous similar samples, for example, that chloroplasts from same species but comes from different habitats. Second, BAT splits given sequence into discontinuous parts and search them in the database of BAT by similarity. To reduce errors, BAT repeats this process with different parameters to get multiple possible annotations and keep the most common one. This method could be used to annotate chloroplasts without allied species in database or various chloroplasts comes from distant species at one time. BAT could batch annotate chloroplast genomes quickly, robotically and only require assembled FASTA format sequence of genomes as input. With little manual intervention, accurate annotation file was generated as proper format that is suitable for submitting to Genbank. We hope this tool could reduce the work of data process and accelerate the utilization of chloroplast genome in plant phylogenetics.

Composition and function of the epiphytic microbial community of the red alga *Gracilaria lemaneiformis*

Xinfei Xie
Institute of Hydrobiology, Department of Ecology, Jinan University

The red alga, *Gracilaria lemaneiformis*, is cultivated widely along the coast of China and has proved to be an effective bioremediation in coastal ecosystems. Even though the important role of *G. lemaneiformis* in improving water quality has been acknowledged, little is known about the composition and function of the epiphytic microbial communities living on its surface. In this study, we use 16S rRNA gene amplicon and ITS sequencing, and GeoChip 5.0 to determine the composition, function and variability of the epiphytic community on the surface of *G. lemaneiformis* as well as the free-living microbial community in the surrounding water. Significant divergences in composition and function of the microbial community were observed between epiphytic groups and free-living groups according to a dissimilarity test. Some epiphytic genera, such as *Croceitalea*, *Formosa*, *Granulosicoccus*, *Leucothrix*, *Polaribacter*, *Aureobasidium*, *Penicillium* in high relative abundances specialize in an alga-associated lifestyle with agarolytic or algal polysaccharides degrading potential. Genes associated with adaptation or response to the seaweed surface is overrepresented in the epiphytic community. Most genes mediate attenuation of the biogeochemical cycle, while assimilatory N reduction, sulfide/sulfur oxidation, chlorinated solvents and herbicide related compounds are accelerated in the epiphytic community compared with the free-living community. Our results demonstrated that the special microbial community on the surface of *Gracilaria lemaneiformis* plays an indispensable role in its life cycle. Understanding the composition and function of the epiphytic microbial community of *G. lemaneiformis* helps define the basic nature of the interaction between epiphytic microbes and the host seaweed.

Functional analysis of PmNF-YB transcription factors in *Prunus mume*

Jie Yang[1,2], *Xueli Wan*[1], *Junwei Zhang*[1], *Manzhu Bao*[1]

1. Key Laboratory of Horticultural Plant Biology, Ministry of Education, College of Horticulture and Forestry Sciences, Huazhong Agricultural University

2. School of Nuclear Technology and Chemistry and Biology, Hubei University of Science and Technology

Mei flower (*Prunus mume* Sieb. et. Zucc.) is one of the tradition famous flowers and has very long cultivation history in China. It has high economic value and outstanding ornamental features, such as trees' pose, flower's fragrance and color. In this study, a total of 6 *PmNF-YA*, 13 *PmNF-YB*, and 8 *PmNF-YC* genes in the *Prunus mume* genome were identified and annotated by bioinformatics procedures. Based on Real-time PCR analyses, we investigated the gene expression patterns of all *PmNF-Y* genes in ABA, osmotic, salt, ROS stresses. *PmNF-YA1/2/4/5/6*, *PmNF-YB3/4/8/10/11/13*, and *PmNF-YC1/2/4/5/6/8* were found to be up-regulated expression under ABA and osmotic treatment. The expression levels of *PmNF-YA1/2/3/4/5/6*, *PmNF-YB1/3/8/10/11/13*, and *PmNF-YC1/2/5/6/8* were obviously induced by ROS stress. In addition, only 2 *PmNF-Ys* (*PmNF-YA2* and *PmNF-YB3*) also enhanced expression in salt stress. These findings suggested that *PmNF-Y* genes may be involved in multiple abiotic stresses response. Based on the gene expression patterns analysis of *PmNF-YB* genes under abiotic stresses, three *PmNF-YB* genes (*PmNF-YB3*, *PmNF-YB8* and *PmNF-YB13*), whose expression levels were increased significantly under abiotic stresses, were cloned from *P. mume* 'Xue Mei' and overexpression vectors were constructed. Then these genes were transformed to *Arabidopsis* to investigate their functions in plant stress response. We found that transformed *Arabidopsis* with over-expressing *PmNF-YB3* or *PmNF-YB8* exhibited higher seed germination and faster root elongation under salt and osmotic treatment compared to wild type. So, the result showed that transgenic *Arabidopsis* overexpressing *PmNF-YB3* or *PmNF-YB8* improved tolerance to salt and osmotic, while overexpression of *PmNF-YB8* or *PmNF-YB13* in *Arabidopsis* showed higher survival rate than wild type under drought stress, which hinted that these *PmNF-YB* genes were involved in response to abiotic stresses.

A new origin discovery of hybridization and introgression in *Nicotiana tobaccum*: An universality of the complex process of allotetraploid evolution

Wang Yi[2], *Li Huayang*[1], ***Yang Long***[1]

1. Agricultural Big-Data Research Center, College of Plant Protection, Shandong Agricultural University

2. Beijing Key Laboratory of Grape Science and Enology and Key Laboratory of Plant Resource, Institute of Botany, Chinese Academy of Sciences

Nicotiana tabacum is the most important model plant in the plant science, it plays a vital role in the molecular science and plant protection studies. Previous studies reveal *N. sylvestris* (S genome) is the maternal donor and *N. tomentosiformis* (T genome) is the paternal donor of *N. tabacum*. Although *N. otophora* (O genome) is a sister species to *N. tomentosiformis*, limited evidence suggests that *N. otophora* is an alternative paternal donor, too. In this study, we used 6 draft genomes of the *Nicotiana*, including three wild types (*N. sylvestris, N. tomentosiformis* and *N. otophora*), three cultivation types (*N. tabacum* var. K326, *N. tabacum* var. TN90 and *N. tabacum* var. BX). Using the comparative genomics and bioinformatics methods, all wild types were clipped into 100-mer sequences and mapped to the genome of the cultivation, and then the mapped region were surveyed according to the depth of the mapping result. The results show that the modern cultivation type contains the genetics information of all three wild types, more than 2.15 G bases genome are found high conversed between the wild and modern cultivation types. Among these conserved regions, the distribution frequency is very consistent across each cultivation type. The average frequency of *N. tabacum* is 54.10% from S genome, 40.04% from T genome and 5.86% from O genome. That means that *N. otophora* also is one of the donor of *N.tabacum.* The genome of modern cultivation types are mainly come from the S, T and O genome. It is supposed that there are three steps of the origin of the modern cultivation types. Firstly, the genome of O and T combine into a middle species. Secondly, the middle species hybrid with the genome S. Thirdly, an allotetraploid comes from natural doubling of chromosomes of hybrids. Besides these, there may be some other wild types also take part in the origin of *N.tabacum.* In the comparison and concluding, a new origin model of *N. tabacum* is conjectured as follow: S × {[

(O × T) × T] × T}. This model shows the main hybrid generation process of *N. tabacum*. In this model, S genome (50%) as the maternal donor crosses with the hybrids from O and T genome at the nearest generations. And an interspecific hybrid from T genome (43.75%) backcross three times with O genome (6.25%) is the paternal donor of *N. Tabacum*. This finding provides a valuable evidence for the presumed origin of hybridization and introgression in *N. tabacum*, and also provides an universality of the complex process of allotetraploid evolution.

The recent discovery of PYR/PYL/RCAR-type ABA receptors has been one of most significant advances in plant science. In mammals, endosome sorting acts as an important pathway to down-regulate different types of receptors, but this kind of regulation of hormone signaling is poorly understood in plants. Here, we report that an ubiquitin E2-like protein, VPS23A, also a key component of ESCRT-I, negatively regulates ABA signaling. *VPS23A* has epistatic relation with *PYR/PYL/RCAR* type ABA receptors and deletion of *VPS23A* enhances the activity of key kinase OST1 in ABA signaling pathway under ABA treatment. Moreover, VPS23A interacts with PYR1/PYLs and K63-linked diubiquitin, and PYL4 possesses K63-linked ubiquitinated modification *in vivo*. VPS23A affects the subcellular localization of PYR1 and stability of the PYL4 by *vps23a* mutant analysis. These findings supports that VPS23A affects PYR1/PYL4 via vacuole-mediated degradation besides 26S proteasome system, further strengthen our understanding of both the turnover of ABA receptors and ESCRTs in plant hormone signaling.

A brine shrimp (*Artemia salina* L.) larvae drug toxicity screening model based on microfluidics

Qiyuan Chen, Ying Liu, Yuhuan Wu, ***Zhiming Yu***
College of Life and Environmental Sciences, Hangzhou Normal University

The vast majority of plants can't avoid or evade danger and adversity like animals. They have to tolerate the environmental, biological and other adverse effects in their situation. To cope with harmful and unfavorable conditions, plants have to rely on their own chemical diversity during their metabolic pathways. Our smart and industrious human ancestors have used the plants' secondary metabolites to treat many serious diseases. So far, humans have found a lot of drugs from the plants. For example, Artemisinin, extracted from plant *Artemisia annua* L. (Asteraceae), is one of the most effective malaria treatment today. Terpene lactones, extracted from *Ginkgo biloba*, have been clinically proven and widely used in clinic as inhibitors of platelet activating factor. Plants' secondary metabolites are a treasure house for mankind, but the current research results are only the tip of the iceberg. How to track active ingredients in a simple and effective way is a prerequisite for discovering more valuable compounds from medicinal plants. As a toxicology and pharmacological pre-screening model materials, Brine shrimp (*Artemia salina L.*) lethality assay is low-cost and user friendly. Early use of this model only concerned its IC50 (half maximal inhibitory concentration), so some of the target analytes' potential biological characteristics are not given sufficient attention. For this reason, smarter model should be proposed. Brine shrimp, a genus of aquatic crustaceans, has changed little externally since the Triassic period. While the phototaxis of brine shrimp larvae has been studied and widely identified, there are few published articles using this feature to develop a screening model. We have subtly constructed a new screening model by using brine shrimp larvae's phototaxis feature. To assess the test subjects' pharmacological and toxicological activity precisely as well as scientifically, we have introduced microfluidic technology to our brine shrimp model. The brine shrimp larvae exposed to the testing samples are cultured in darkness. After treatment, a beam of light passes through microfluidic chip which is connected to the culture pond. Due to the desire to the light, the more energetic larvae will swim into the tubular space. The space only allows one larva entering once a time and also has no enough space to make the larvae turn around. According to the swimming distance of a larva, we can get quantitative data about the sample' physiological activity to the brine shrimp larvae. Using this new evaluation system, we can give standards for chemical compounds or crude extracts from medical plants. From these standards, we may understand the potential properties and the possible biological value of the compounds.

The project was supported by NSFC (Grant No. 31200913 and No. 41571049)

CPK11 phosphorylates the transcription factor FD in *Arabidopsis thaliana*

Min Yuan[1,2], *Kyle Bender*[1], *Steve Huber*[1], *Yoshie Hanzawa*[1]
1. University of Illinois at Urbana and Champaign
2. North China University of Science and Technology

Calcium-dependent protein kinases (CPKs), a class of Ser/Thr protein kinases constituting a large multigene family, are known as a sensor of Ca^{2+} flux and play important roles in various physiological processes, including cell growth, development and stress responses in plants. Recently, CPK6 and CPK33 are implicated in the regulation of flowering time control through phosphorylation of a bZIP transcription factor, FD. Here we report characterization of CPK11 in phosphorylation of FD. CPK11 is distantly related to CPK6 and CPK33. *CPK11* gene was cloned into the PET28a expression vector and transformed into *E.coli* strain BL21 to obtain the His_6-CPK11 recombinant protein. The His_6-CPK11 re-

combinant protein was induced by 0.5mmol/L IPTG at room temperature. The Ni-NTA system was used to purify the His_6-CPK11 recombinant protein and the purified protein was specifically detected by anti-His antibody in the western blot assay. Our *in vitro* kinase assays demonstrated that His_6-CPK11 phosphorylated GST-tagged FD protein. Our result provides further evidence to support the role of CPKs in FD phosphorylation in flowering control.

MicroRNA roles in cotton fiber initiation and early development

Baohong Zhang[1], *Qinglian Wang*[2]
1. East Carolina University
2. Henan Institute of Science and Technology

Cotton fiber development is a fundamental biological process; investigating cotton fiber initiation and development provides a unique window into the regulation of cell differentiation, cellulose biosynthesis, and further increasing cotton fiber quality and yield. For several decades, a great deal of research has been aimed at elucidating the underlying molecular pathways. Nevertheless, the mechanisms by which cotton fiber differentiates and develops remains unclear. In our previous studies, we found that microRNAs (miRNAs) are differentially expressed among cotton fiber and other tissues. Comparing the miRNA expression profiles based on deep sequencing technology, we found that both conserved and novel miRNAs have unique pattern in cotton developing ovule. To further test the potential role of miRNAs during cotton fiber development, we selected 58 miRNAs and profiled their expression in fiber with different development stages (from -2 DPA to 20 DPA) in both wild type and fibreless mutants. Using transgenic, RNAi and genome editing technologies show that overexpression and knockout/knockdown of an individual miRNAs affected cotton fiber development and further affect cotton fiber length and quality.

The complete chloroplast genome of dendrobium (Orchidaceae): Phylogenetics and a 'cp-DNA-Barcode'

Zhimin Zhong, ***Guifang Zhang***, *Xiaoping Lai, Xiaoqiao Yan, Yifan Li*
Guangzhou University of Chinese Medicine

DNA barcoding is currently a widely used and promising tool for rapid and accurate identification of plant species. However, because of a much slower mutation rate, a universal barcode in plants has not found yet. *Dendrobium*, one of the largest and most diverse genera of Ochidaceae, is generally under severe threat of extinction mainly due to over-collection and habitat destruction. Methods for accurate classification and identification of *Dendrobium* species are critical in the fields of biological conservation and sustainable utilization of *Denbrobium* as plant resources. Here, the complete chloroplast genome (cp-genome) of 50 samples from 41 *Dendrobium* species was sequenced by using Illumina and PacBio sequencing platform. The sequences were assembled using the Hierarchical Genome Assembly Process 2 (HGAP2) protocol from SMRT Analysis version 2.0 package (18), resulting in the complete circular 152,185 bp cp-genome. The cp-genome of *Dendrobium officinale 'zhong ke* Ⅳ *hao'*was assembled using the SOAPdenovo (v2.04) and Celera Assembler (v8.0) and annotated with Dual Organellar GenoMe Annotator (DOGMA). Genetic distances and neighbor-joining analysis was performed with Mega 6.06. The success rate of PCR amplification and sequencing was 100%. Many single-nucleotide polymorphisms (SNPs) demonstrated a significant divergence between the inter- and intra-specific genetic distance of cp-genomes. Our results showed that the cp-genome could be function as a the 'cp-DNA-barcode' and the traditional Chinese medicine regional marker sequences, which could be used to infer phylogenetic relationships of *Dendrobium* species and to identify the same *Dendrobium* species from different origins. In addition, results of a phylogenetic tree and principal component analysis showed that the cp-genome could be effectively used to classify and identify this family and could provide a reference for study of the molecular systematics of *Dendrobium*. Additionally, these new potential 'cp-DNA-barcodes' would contribute to the phylogenetic analysis of plants more generally.

Preliminary functional characterization of a rice mitogen-activated protein kinase (MAPK-520) in the resistance response mediated by *Xa21*

Jianshuo Zhang, Yalu Guo, Jian Wei, Jinjiao Ma, Jianan Shi, Shijuan Dou, Liyun Li, Lijuan Liu, ***Guozhen Liu***
College of Life Sciences, Hebei Agricultural University

Rice is one of the most important food crops in the world, and it is also an important model organism in plant molecular biology. Bacterial blight is one of the most serious diseases in rice causing dramatic yield losses. *Xa21* is the first cloned resistance genes in rice against *Xanthomonas oryzae* pv.*oryzae* (*Xoo*), which encoding a receptor-like kinase. It is proposed that MAPK cascade play important role in the *Xa21*- mediated signal transduction pathway. Most of the mitogen-activated protein kinase (MAPKs) in plant belongs to serine/threonine protein kinase, which stimulated by a variety of extracellular stimuli and transmit signals to the nucleus. In this research, a MAPK was choosen as target (Namely MAPK-520). Over expression (OX) and RNA interference vectors were constructed, rice TP309 confers *Xa21* gene was transformed by agrobacterium-mediated protocol. In T0 generation, 25 OX lines were obtained, PMI protein detection by western blot analysis verified 18 of them are positive and 7 are negative ones. Thirty-eight lines were obtained via two different RNAi constructs, and detected by NPT- II antibody. It showed that 28 positive and 10 negative. In T1 generation, genomic DNA was extracted and PCR analyses were carried out. Eight positive OX lines and 20 positive RNAi lines were found. In T2 generation, 3 homozygous lines were identified by PCR in OX lines, 9 homozygous lines were identified from RNAi constructs by PCR. To monitor the expression of target protein, western blot analysis was carried out by specific antibody, it showed that the expression of target protein of 3 PCR positive OX lines were up-regulated, while it down-regulated in 6 RNAi lines. Innoculation of *Xoo* at tillering stage revealed alteration of resistance mediated by *Xa21*. Taken together, stable transgenic rice with over or down-regulated MAPK-520 lines were identified, which will be helpful for the functional characterization of the gene in the process of *Xa21*-mediated resistance.

Comparative genomics research of *Amborella* and several flowering plants

Lan Zhang, *Min Yuan*

North China University of Science and Technology

Angiosperm, as the most important plants in the worldwide, has experienced a complicated evolution. In order to illustrate the evolution process of angiosperm, the genomes of *Amborella, Arabidopsis*, rice, grape, peach and cacao were taken as the study objects in this study. The genomes of *Arabidopsis* have went through another two times diplodization event, while the genomes of *Arabidopsis*, grape, peach and cacao have experienced the same eudicot-common triplication. Rice has went through three times diplodization event. *Amborella*, the single living species of the sister lineage to all other extant flowering plants, provides a unique reference of ancestral gene content and genome structure in the most recent common ancestral of all living angiosperms. We performed comparative genomics analysis of *Amborella* and these flowing plants, and found that the more complicated genome ployploidy, the less number of homologous blocks and genes between *Amborella a*nd other flowering plants. According to the length of homologous blocks was greater than 20, there were 62 homologous blocks and 1,776 homologous genes between *Amborella* and grape, which was the longest blocks in the study. The least number of homologous blocks and genes existed between *Amborella* and *Arabidopsis*, including 1 homologous block and 20 homologous genes. Finally, this study would provide a basis for studying the angiosperm evolution.

Complete pear mitochondrion genome assembly revealing 129 pear samples classification and maternal inheritance

Ming-Yue Zhang, *Jun Wu*

Nanjing Agriculture University

Mitochondrion is an important organelle mainly responding for energy metabolism. We assembled the complete pear mitochondrial genome, and genome size is 458,897 bp, with G+C contents of 45.2%. A total of twenty-eight open reading frames in the assembled mitochondrial genome were annotated, including fifteen electron transport complex, one intron maturase, one transport membrane, five cytochrome C biogenesis. What is more, twenty tRNA, three rRNA genes and eight ribosomal subunits were also presented. There were 129 pear samples distributed around the world to reveal the pear classification and wild origin in our study. Occidental pears manifested great differences from the oriental pears in the genetic level, and the same species varied because of geographic distribution. Maternal inheritance should be the main inheriting method for pear mitochondrion and chloroplast, but ‘Chikusui’ is an exceptant. Furthermore, we suppose pear mitochondrial genome is less diverse than the chloroplast genome based on mutation rates and tandom repeats. The co-linearity of mitochondrion from distinct species varied a lot, but the gene region had a relatively high co-linearity. Comparative mitochondrial gene expression revealed a potential tRNA gene perhaps responsible for pear post mature character.

Field-based phenomics platform: Image-based methods for analyzing morphological traits and agronomic performance under different nitrogen treatments for sweet potato

Yu Zhang

The University of Tokyo

Spatial variability in a crop field creates a need for precision agriculture. Early detection and management of problems associated with crop yield indicators can help increase yield and subsequent profit. Remote sensing can be used to assess spatial variability in crop yield. While highly predictable spatial variability may be amenable to multiple approaches of site-specific N management, strong temporal variability is much more difficult to manage. Remote sensing techniques that use the crop to indicate its N status show considerable promise for improving N management. Infrared and near-infrared (NIR) imaging systems are advantageous in their ability to visualize plant grown in field, but are currently limited by their small analysis volume and often low resolution and precision, as well as their cost, accessibility, and low-throughput. With further advancements, IR/NIR technologies have the greatest scale-up potential for the eventual non-destructive imaging and phenotyping of field-grown plant root systems. Although these current root growth systems and imaging technologies are still unable to accurately visualize and quantify complex, mature plant root systems grown under field conditions, they have contributed greatly to increase the precision and efficiency of 2D and 3D spatial. Management of fertilizer and watering in agriculture is very difficult. A part of N is lost in the atmosphere or leached into groundwater, lakes, and rivers, which causes severe environmental pollution. Despite that major crops can utilize only 30 – 40% of the applied N. In addition, plant response to each N source show stage specific difference and very sensitive. To solve this case of problem, development of remote sensing technology is useful to evaluate agronomic performance. In this study, we set up three different N application fields to make different yield performance with diverse genotypes of sweet potato as one simulation of different agronomic performance.

3D modeling and estimating of leaf and stem shape of nursery Paprika plants by a novel multi-camera photography system

Yu Zhang

The University of Tokyo

In plant growth and phenotyping, accurate measurements of plant structure parameters are very crucial. Over the past three decades, 2D imaging has been applied to a variety of aspects, ranging from structural analysis, stomata movements and photosynthetic diagnosis, herbicide control, disease detection and yield estimation. However, as 2D imaging is not robust against the occlusion of plant organs, such as overlapping leaves and stems and changing shapes during the measurement, most of these applications are either for large-scale analysis or for simple plant variables' measurements at the early growth stage. Recently, 3D imaging technologies for the robust measurement of plant growth and phenotype parameters have emerged and been applied for solving this problem owing to the advance of sensing technology. Among the most noticeable applications of 3D imaging technology in agriculture are the 3D model construction for plant and the properties estimation for plant growth. In this research, a novel solution was proposed to improve surface representation and construct 3D plant models through automated feature extraction and key point matching across images based on the Structure from Motion (SfM) algorithm. Our method could solve some problems or limitations of other methods, such as high cost, self-occlusion, low accuracy, information missing, noises, and so on. This study aimed at estimating and comparing plant parameters with different cameras and lenses for 3D imaging. We have, therefore, developed a high-efficiency multi-camera photography (MCP) system combining Multi View Stereovision (MVS) with Structure from Motion (SfM) algorithm. In this study, we measured six variables of nursery paprika plants and investigated the accuracy of 3D models reconstructed from photos taken by four lens types at four different positions. The results demonstrated that error between the estimated and measured values was small and the root mean square error (RMSE) for leaf width/length and stem height/diameter was 1.65mm (R^2=0.98) and 0.57mm (R^2=0.99), respectively. The accuracies of 3D model reconstruction of leaf and stem by 28 mm lens at the first and third camera positions were the highest and the percentages of the number of leaf and stem whose 3D model shape surface area reconstructed over 95% to real shape were about 47% and 100%, respectively. The results confirmed the feasibility of the proposed new methodology for the reconstruction of fine-scale plant model and accurate estimation of the plant parameters. It also displayed that our system is an ideal system for capturing high-resolution 3D images of nursery plants with high-efficiency.

Construction of a high-density genetic map and its application to QTL identification for fiber strength in upland cotton

Zhen Zhang
Institute of Cotton Research of Chinese Academy of Agricultural Science

Cotton (Gossypium sp.) is an important worldwide cash crop that provides a competitive renewable natural fiber supply for the demands of textile industry. The development of new textile technologies and the improvement of living standards increase the demands for both fiber quantity and fiber quality. '0–153' is an upland cotton cultivar with excellent fiber quality derived from Asiatic cotton sources, especially with regards to fiber strength. To identify quantitative trait loci (QTLs) for fiber strength in this line, a recombinant inbred line population consisting of 196 lines was developed from a cross between it and 'sGK9708'. A genetic linkage map consisting of 2393 loci was constructed using this recombinant inbred line population, with single nucleotide polymorphism (SNP) markers from the IntlCottonSNPConsortium_70k chip. Quantitative trait loci for fiber strength were detected across 11 environments using both single-environment and combined multipleenvironment models. A total of 63 QTLs controlling fiber strength were detected by the single-environment model. Sixteen QTLs were identified by the combined multipleenvironment model. These QTLs could make a contribution to the improvement of fiber quality via marker-assisted selection and provide useful information for QTL fine mapping and functional gene research activities as well.

De novo assembly and characterization of the transcriptome and development of microsatellite markers in a Chinese endemic *Euphorbia kansui*

Xueyan Zhao[2], *Xia Cai*[1]
1. Northwest University
2. Shaanxi Institute of International Trade and Commerce

Euphorbia kansui Liou is an endemic and traditional medicinal plant in China. Despite the value, the genomic and transcriptomic information of *E. kansui* is limited. Next generation sequencing (NGS) technology has been widely applied to transcriptomics and the development of molecular markers, and functional gene studies of non-model species. In the present study, a total of 43,211,690 high quality reads were generated using Illumina paired-end sequencing technology. After assembly, 58,362 unigenes were recovered with an N50 length of 1,683 bp. 36,396 (62.36%) of these unigenes had at least one blast hit against the multiple public databases. Based on Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analyses, unigenes were discovered to encode known enzymes that catalyze the formation of the terpenoid backone and diterpenoid. In addition, the unigenes related to casbene synthase which catalyzes the formation of the major active constituents (diterpenoids) in *E. kansui* were identified. For functional marker development, 7,016 candidate simple sequence repeats (SSR, microsatellites) were identified from 6,150 unigenes, and 40 SSR loci were selected randomly and amplified in two populations of *E. kansui*. A total of 28 loci were amplified successfully and 23 loci exhibited polymorphisms. The number of alleles of each locus ranged from 2 to 8 alleles and the mean number of alleles per locus was 3.391. The observed heterozygosity and expected heterozygosity varied from 0.100 to 1.000 and 0.099 to 0.809, respectively. These microsatellite markers developed here will be useful for studies on population genetics of this endemic species. Moreover, the information of transcriptom will be provided useful resource for the future researches on metabolism, regulation of the terpenoids, genetic studies of *E. kansui*.

Application of capillary electrophoresis to genetic diversity evaluation of *Glycine soja*

Yong Zhao[1,2], *Hongkun Zhao*[2], *Yingshan Dong*[1,2]
1. Jilin Agricultural University
2. Jilin Academy of Agricultural Science

The 60 pairs of SSR primers were selected and the genetic diversity of 102 northeast *Glycine soja* accessions were evaluated by means of simple sequence repeats (SSR) and capillary electrophoresis (CE). The results showed that: 385 alleles were detected by 40 pairs of SSR markers, with an average of 9.6 alleles for each locus. Shannon-Weaver diversity indexes averaged 2.0560, *Glycine soja* has a rich genetic variation in northeast China; SSR technique had such characteristics as intervarietal recognizability, environmental stability and accuracy, and could be applied to evaluating the genetic diversity of *Glycine soja* accessions; CE is a kind of effective separation technology, which has characteristics as high efficiency, celerity, sensitivity and less sample consumption.

Screening for salinity tolerance in soybean germplasm

Yong Zhao[1,2], *Hongkun Zhao*[1], *Guangxun Qi*[1]
1. Jilin Academy of Agricultural Science
2. Jilin Agricultural University

Salt and alkali stress are two of the main environmental factors, which can induce a series of complex physiological and biochemical reactions and then result in a dramatic decline of production in soybean. Planting salt-tolerant soybean is the main strategy to use saline-alkaline soils effectively. The aim of our research were to select salt tolerant and high yield soybean varieties and to develop a genetic map of major salt tolerance QTLs for soybean improvement for the long term. A total of 134 soybean germplasm accessions, including 2 parental lines (ZYD00659 and Jikedou 1) and 132 Progeny populations, were evaluated for the salt injury index under 140Mm NaCl treatment at the seeding stage over three biological replications. Salt-tolerant ZYD00659 and salt-sensitive Jikedou 1 were used as the controls. As a result, the salt injury index for ZYD00659 and jikedou 1 were 89% and 65%, respectively. The salt injury index for 25 accessions were higher than 89%. The salt injury index for 73 accessions ranged from 65% to 89%. All these accessions will be used in genetic mapping in the near future. Previous studies have evaluated the salt tolerance in soybean using germination and seedling stage physiological index; however, the tolerance at the adult stage as indicated by yields are usually ignored. In this study, all of the 134 accessions were cultivated in a aline-alkaline soils, and the salt tolerance at the adult stage will be evaluated by investigating yield before long.

Genetic diversity of half-sib offspring of sour jujubes from Huanghua Ancient Chenier

Xingjuan Zheng[1], *Jin Zhao*[2], *Mengjun Liu* [3], *Jiurui Wang* [1]
1. College of Forestry, Agricultural University of Hebei
2. College of Life Science, Agricultural University of Hebei
3. Research Center of Chinese Jujube, Agricultural University of Hebei

Exploration of genetic variation of half-sib families is a basis for their utilization in plant genetic improvement. In addition to phenotypic, physiological and biochemical variation, variation revealed by molecular markers can provide direct insight into the genetic variation of half-sib families. Sour jujube (*Ziziphus acidojujuba* C.Y. Cheng et M. J. Liu), one of the most popular wild fruits and important medicinal plants in China, belongs to the genus of *Ziziphus* Mill. of family Rhamnaceae and regarded as the ancestor species of cultivated Chinese jujube (*Z. jujuba* Mill.). Huanghua Ancient Chenier is close to the Bohai Bay, where the germplasms of sour jujube are potential resources for root-stocks with resistance to saline-alkali. In order to evaluate, preserve and utilize the endangered sour jujube germplasms, genetic diversity of two half-sib families of sour jujube sampled at Huanghua Ancient Chenier were investigated by SSR markers in this study. 155 offspring from two half-sib families consisted of 96 and 59 progenies of sour jujube B07 and B16 respectively and genomic DNA of leaf from them was extracted by modified CTAB method. 29 SSR primers pairs which produce repetitive and clear bands were used and PCR reaction products were detected by LabChip GX Touch. The date was analyzed by the POPGENE software, which had been transformed into the format of software identification. A total of 146 alleles were obtained and each locus had an average of 5.034 alleles. The number of alleles varied from 3 to 7. The observed and expected levels of heterozygosity ranged from 0.2500 to 0.8431 (the mean 0.5193) and from 0.1990 to 0.7932 (the mean 0.5721), respectively. Shannon's average index was 1.0718 and Nei's average information index was 0.5702. The coefficient of gene differentiation in different sites was slight different and the maximum and the minimum was 0.3189 and 0.0069, separately, with an average of 0.0852. It indicated that 8.52% of the total genetic variation was from the different groups and most of them from offspring individuals. The genetic diversity of progeny of sour jujube B16 (expected heterozygosity = 0.5468, Shannon's average index = 0.9944, Nei's average information index = 0.5421) was more abundant than that of sour jujube B07 (expected heterozygosity = 0.5134, Shannon's average index = 0.9475, Nei's average information index = 0.5106), The results showed that the genetic diversity of the two half-sib families was rich, and the half-sib offspring has potential in breeding.

A468

Application and evaluation of fluorescent SSR markers detection technique with capillary electrophoresis in *Phalaenopsis* genotypes

Zuo Li[1,2], *Wenfang Xiao*[1,2], *Heming Chen*[1,2], *Fubing Lv*[1,2]
1. Environmental Horticulture Research Institute of Guangdong Academy of Agricultural Sciences
2. Guangdong Provincial Key Laboratory of Ornamental Plant Germplasm Innovation and Utilization

Phalaenopsis, one of the most popular potted flower plants, this species have attracted a great deal of attention worldwide, regarding their long-lived and gorgeous flowers and various pigmentation patterns. However, the understanding of this ornamental genus remains limited and little genomic research has been done. This research used fluorescence simple sequence repeat (SSR) markers detection technique with capillary electrophoresis (CE) system to analyze the genetic relationships among *Phalaenopsis* cultivated germplasm collections. In total, 10 out of 55 SSR primers including genomic-SSR and EST-SSR, were screened and selected for detection in this study. Screening all the collected accessions using those 10 selected SSR primers yielded a total of 145 amplified bands in the range of 130 to 532 bp, of which 144 were polymorphic (99.31%). The number of polymorphic bands per primer ranged from 4 to 21, with an average of 14.4. The averages of PIC and MI were 0.66 and 27.42, respectively. Although the polymorphism revealed by genomic-SSR is lower than by EST-SSR, it can effectively differentiate diverse genotypes as well. The results suggest that the *Phalaenopsis* germplasm collection in this study has a high level of genetic diversity. This should facilitate subsequent studies on genetic mapping and molecular breeding. Compare with traditional agarose gel electrophoresis, capillary electrophoresis with fluorescence detection has the advantages of higher accuracy, sensitiveness, reliability and effectiveness. And a comprehensive research on the genetic diversity of *Phalaenopsis* make significant sence, would both protect the diversity of germplasm resources and make sustainable utilization of those resources. This research was financially supported by National Natural Science Foundation of P. R. China (Grant No. 31201650), Guangdong Provincial Science and Technology Project (Grant No. 2014A030304046, Grant No. 2016B070701014, Grant No. 2015B020231005, Grant No. 2014A020208063, Grant No. 2013B060400032).

Analysis of inter-specific SNPs linked to petal texture traits using SLAF-Seq technology in *Phalaenopsis*

Zuo Li[1,2], *Wenfang Xiao*[1,2], *Heming Chen*[1,2], *Fubing Lv*[1,2]
1. Environmental Horticulture Research Institute of Guangdong Academy of Agricultural Sciences
2. Guangdong Provincial Key Laboratory of Ornamental Plant Germplasm Innovation and Utilization

Orchidaceae species are famous ornamental plants all over the world because of their gorgeous flowers and various flower characteristics. Inter-specific and inter-generic hybridization within and between species of the *Orchidaceae* has further enriched the genetic diversity. In Orchid family, as popular potted flower plants, *Phalaenopsis* flowers owned two kinds of special natural flower texture characteristics, namely waxy petal texture and velvety petal texture. This study was concerned with the genes which associated with the petal texture in *Phalaenopsis*. The genetic control of plant architecture is a promising approach to breed desirable varieties, especially in ornamental flowers. In this study, the F_1 offspring characteristics separation on petal texture derived from a cross-bred combination of *Phalaenopsis* 'Ruey Lih Beauty' (female parent, velvety petal texture) with *Phalaenopsis.* SH127 (male parent, waxy petal texture) were studied. Twenty velvety and waxy petal texture seedlings were pooled and subjected to a specific-locus amplified fragment sequencing (SLAF-seq) method. In this study, the sequencing reads couldn't map to the reference genomes *P. equestris* and *Vanilla planifolia,* in the orchid family (Orchidaceae), thus *Oryza sativa* was used as control to assess the effectiveness of enzyme digestion. The results coming from the alignment between the sequences of CK *O. sativa* and its reference genome indicated that the construction of SLAF library fitted well to the standard, with its paired-end mapped reads reaching 84.37%, normal digestion ratio reached 91.03%. With the help of sequencing alignment as well as other bioinformatics technologies, a total of 79.75 Mb reads were obtained. The average values of Q30 was 87.72%, and the average value of GC content was 37.51%, which was low enough to process the sequencing. After SLAF library construction and high-throughput sequencing, a total of 362,381 high quality SLAF tags were obtained and 101,551 polymorphic SLAF tags were identified, with a polymorphism rate of 28.02%. And then 16,639 SNPs selected to do association analysis, by one genotype deriving from male parent and the other from female parent. Finally, 121 SLAF markers with SNP index of > 0.375, including 186 SNPs, were found. However, annotation of those SNPs were useless for now, only some microsatellite sequences of *Phalaenopsis* with undiscovered function. In next step of this study, a direct comparison of the two progeny pools, abandoning the parents, will be done to find more useful markers related candidate regions. This paper provided results that SLAF-seq technology can be further used for the analysis of population evolution and developing specific SNP markers. This research was financially supported by Guangdong Provincial Science and Technology Project (Grant No. 2014A030304046, Grant No. 2016B070701014, Grant No. 2015B020231005, Grant No. 2014A020208063, Grant No. 2013B060400032).

Conservation and diversification of the miR166 family in soybean and potential roles of newly identified miR166s

Xin Xie, Lulu Zhai, Yanming Hou, Shaomin Bian, ***Xuyan Li***
College of Plant Science, Jilin University

MicroR166 (miR166) is a highly conserved family of miRNAs implicated in a wide range of cellular and physiological processes in plants. miR166 family generally comprises multiple miR166 members in plants, which might exhibit functional redundancy and specificity. The soybean miR166 family consists of 21 members according to the miRBase database. However, the evolutionary conservation and functional diversification of miR166 family members in soybean remain poorly understood. In this study, we identified 5 novel miR166s in soybean by data mining approach, thus enlarging the size of miR166 family from 21 to 26 members. Phylogenetic analyses of the 26 miR166s and their precursors indicated that soybean miR166 family exhibited both evolutionary conservation and diversification, and 10 pairs of miR166 precursors with high sequence identity were individually grouped into a discrete clade in the phylogenetic tree. The analysis of genomic organization and evolution of *MIR166* gene family revealed that 8 segmental duplications and 4 tandem duplications occurred during evolution of the miR166 family in soybean. The cis-elements in promoters of *MIR166* family genes and their putative targets pointed to their possible contributions to the functional conservation and diversification. Further, the expression patterns of the 5 newly identified *MIR166*s were examined during seed development and in response to abiotic stresses, which provided important clues for dissecting their functions and isoform specificity. These findings have laid a foundation for elucidating functional conservation and diversification of miR166 family members, especially during seed development or under abiotic stresses.

Transcriptome sequencing and analysis of male sterile flower buds in *Catalpa bungei*

***Hongwei Liang**, Weibing Mao, Faju Chen, Changlan Wang*
Three Gorges University

Objective: In order to revealed molecular mechanism of *Catalpa bungei* male sterility from the gene expression levels, we research the regulation of gene expression patterns for *C. bungei* male sterility in the natural state. So this research can provide new and meaningful reference on male sterility for *C. bungei* and other Woody plants. Method: The transcriptome sequencing was carried out on the flower bud of male sterile and fertile flower bud. We use the method of comparative analysis to deal with the fertile bud and sterility bud transcript through bioinformatics, and predict and filter genes about *C. bungei* male sterility. Results: Transcriptome sequencing produced a total of 27.18 Gb data. Finally we obtained 86 076 Unigene after assembling and removing redundant. Then we make use of the seven function database ((NR, NT, GO, COG, KEGG, Swissprot and Interpro)) annotating the all Unigene, eventually Unigene that can be annotated at any one database in a database of seven is 64 600 (75.05%). We analyze the expression levels of Unigene between the experimental group (male sterility flower buds) and control group (fertile flower buds). Different expressed genes which are different expression and high reliability were screened out. In the noise distribution (Multiple differentially expressed in 2 above, Credibility in 0.8 above), 6 915 up-regulated genes and 3 504 down-regulated genes were selected from the experimental group. Poisson distribution (Multiple different expressed in 2 above, The incidence of errors under 0.001), in three biological repeat SL-1-VS-FL-1, SL-2-VS-FL-2, SL-3-VS-FL-3 obtained different up-regulated expressed gene respectively 13979,13513,13055 and different down-regulated expressed genes respectively 12 170,13 807,10 411. By GO functional analysis for different expressed gene showed that the terms which are significantly enriched and higher cluster frequency reproductive process, during the development of the reproductive, reproductive system development, development of reproductive structures in the biological processes. In molecular function the Auxin efflux transmembrane transporter activity is significantly enriched. By the KEGG pathway analysis for different expressed genes, different expressed genes are mapped to 127 different biological pathways. Those which are significantly enriched and larger number of different expressed genes in metabolic pathways mainly contain metabolic pathways, biosynthesis of secondary metabolites, spliceosome, RNA transport and Metabolism of Glycerophospholipid and Starch and sucrose. By comparing different expressed genes with these genes that are related to male sterility that have been reported. 246 High homology Unigene were distinguished. The COG function classification most gathered in RNA processing and modification, cell cycle control, cell division and chromosome partitions, transcription, *etc*. The different expressed genes which are high homology with the male sterility genes are mapped to the pyruvate metabolism, the plant hormone signal transduction pathway. Conclusion: Male sterility of *C. bungei* possibly due to the involvement of pyruvate metabolism process appeared abnormal, leading to brassinosteroid synthesis abnormal so that the tapetum appear dysplasia and further affect the meiosis of microspore. Eventually *C. bungei* pollen become abortive.

Eneumeration of begomovirus particles by Real Time PCR (RT-PCR) and proteomic analysis for agroinnoculated plants

***Bhavin Bhatt**[1], Achuit Singh[2]*
1. Shree Ramkrishna Institute of Computer Education and Applied Sciences
2. Senior Scientist, Crop Improvement Division, ICAR - Indian Institute of Vegetable Research

Begomoviruses have emerged as major constraint for vegetable production. French bean is one of the most important vegetable crops of India which is consumed widely. Dwarf mosaic disease (DMD) and Yellow mosaic disease (YMD) are two premier challenges for the quantitative production of, not only French bean, but major legume plants. We have cloned and sequenced begomoviral genomic components associated with disease manifested leaf samples from Varanasi and Bengaluru, India. Sequence analyses confirmed bipartite nature of begomovirus. *Mungbean yellow mosaic India virus* (MYMIV) is causal agent of DMD in Varanasi and *Horsegram Yellow Mosaic Virus* (HgYMV) is c causal agent of DMD in Bengaluru. Compatible pathogen incidence on plants changes spatial and temporal expression of genome of host plants. Partial tandem repeats (PTRs) were generated for each viral clone in plant binary vector pCAMBIA 2300 and agroinnoculated on *N. benthamiana* and *Phaseolus vulgaris*. Viral component accumulation in agro-inoculated plants was carried out by real time PCR (RT-PCR). During the exponential phase of PCR, the amplified products emit fluorescence signal which are directly proportional to the amplicons generated. Thus, RT-PCR enables quantification of the viral copy numbers into inoculated plants. Absolute quantification of virus DNA was carried out through SyBr Green based RT-PCR. Quantitative polymerase chain reaction results suggest that associated DNA - B molecule is absolutely essential for systemic movement and maintenance of helper virus inside plants. Twenty protein spots were identified and in response to begomovirus infection on French bean by Two-dimensional gel electrophoresis (2-DE). The relative expression levels of most of identified proteins were upregulated. These proteins were mainly involved in defense, signal transduction, energy and metabolic regulation. In our studies, molecular characterization in conjugation with proteomics approach was implemented to get information for molecular events occurring during plant virus interaction. Moreover, our analysis revealed that mock plants had no significant protein profile alteration as compared to virus inoculated plants demonstrating that virus infection initiates modulation of proteomic profile.

Fern genomes on the horizon

Fay-Wei Li
1. Boyce Thompson Institute

2. Cornell University

Ferns are the final frontier in plant comparative genomics. Although ferns are known to have notoriously large genome sizes (average 1C>10 Gb), our ongoing work has identified some small-genome species. As a community effort, we have assembled and annotated two complete heterosporous fern genomes: *Salvinia cucullata* and *Azolla filiculoides*, and here I will highlight some of our key findings. I will also present our progress on three additional fern genome projects, which together with *Ceratopteris*, will provide a broader picture of fern genome evolution.

OsbZIP23 mediated transcriptional regulation work together with H3K4me3 modification to regulate gene expression under drought stress in rice

Wei Zong[2], ***Jun Yang***[1], *Lizhong Xiong*[1]
1. Huazhong Agricultural University
2. Southern University of Science and Technology

Under drought stress conditions, thousands of genes were differentially expressed (DEGs) in rice. However, the regulatory mechanism of these DEGs remains largely unclear. Here, we revealed an interplay between histone H3K4me3 modification and bZIP transcription factor OsbZIP23 regulation of four clustered dehydrin genes under drought stress in rice. Four dehydrin genes could be rapidly and highly induced by drought stresses, whereas the transposon gene within the cluster could not. The whole chromatin status of this region except the transposon gene was significantly affected after drought stresses. By modulating H3K4me3 modification levels in rice, the expression levels of the dehydrin genes were positively affected and the binding levels of OsbZIP23 to the promoter of the dehydrin genes were enhanced under drought stress. Moreover, H3K4me3 modification and gene expression levels of the dehydrin genes under drought stress were down regulated in *osbzip23* mutants. Taken together, our study uncovers a connection between transcriptional and chromatin regulation under drought stress in rice, which will help us to further understand the gene regulation mechanism under stress conditions in plants.

Genetic control of phenotypic variability: An often overlooked dimension of genetic variation

Simon Forsberg, *Örjan Carlborg*
Dep. of Medical Biochemistry and Microbiology, Uppsala University

Genome Wide Association Studies (GWAS) have been widely used to identify loci contributing to quantitative traits. Such studies typically look for genetic effects on the trait mean, ignoring potential effects of alternative alleles on trait variability. This traditional approach might thereby overlook this important dimension of genetic variation. By searching for loci where alternative alleles are associated with a difference in trait variability (vGWAS), interesting genetic mechanisms can be unraveled that might otherwise have gone unnoticed. Through a vGWAS in *Arabidopsis Thaliana*, we identified multiple functional alleles in the vicinity of the *MOT1* gene, affecting molybdenum accumulation. Such multi-allelic loci are problematic in a GWAS setting, which typically uses bi-allelic genetic markers. They might, however, give rise to an effect on the trait variability that can be detected even with such markers. Here, we identified two structural polymorphisms in the promoter region of *MOT1* that displayed strong effects on the molybdenum levels in the plants. We also revealed two additional associations to molybdenum levels, and by evaluating T-DNA insertion alleles, we were able to suggest two novel candidate genes (*COPT6* and *AT2G27030*) involved in molybdenum homeostasis. Collectively, these alleles gave rise to the observed effect on trait variability that we detected in our vGWA analysis. Searching for genetic effects on variability can also reveal signatures of selection. We found one such case on the gene *CMT2* in *A. Thaliana*. Plants carrying a disruptive mutation in this gene were present across a wide range of climates, possibly indicating environmental plasticity. Plants with the alternative allele were confined to a narrower climate range. This disruptive mutation was further found to affect the genome wide methylation pattern and conveyed increased heat tolerance. Finally, a difference in trait variability between alternative alleles might also be caused by interactions (gene-by-gene or gene-by-environment). If we observe such a locus, it might thus be an indication that it is interacting with some other unknown factor. vGWAS might therefore also be used as a shortcut to detect epistatic loci. We demonstrated this in a large yeast cross, where we characterized extensive networks of interacting loci. We further studied higher order interactions involving up to six loci in these networks, revealing how their phenotypic effects where mutually dependent on each other. In particular we found many examples of genetic capacitors, with the ability reduce or completely negate the phenotypic effects of many other QTLs. In summary, since traditional mean focused GWASs ignore genetic effects on trait variability, they might miss important links between genotype and phenotype. We demonstrate how vGWAS is a valuable tool to detect novel associations of biological importance in natural populations.

H2A monoubiquitination in *Arabidopsis* is generally independent of LHP1 and PRC2 activity

Yue Zhou[1], *Francisco Romero-Campero*[2], *Ángeles Gómez-Zambrano*[3], *Myriam Calonje*[3], ***Franziska Turck***[1]
1. Max Planck Institute for Plant Breeding Research, Department Plant Developmental Biology
2. University of Sevilla, Department of Computer Science and Artificial Intelligence
3. University of Sevilla, Institute of Plant Biochemistry and Photosynthesis

Polycomb group (PcG) complexes PRC1 and PRC2 repress gene expression at the chromatin level in eukaryotes. The classical recruitment model of PcG complexes in which PRC2-mediated H3K27 trimethylation recruits PRC1 for H2A monoubiquitination was recently challenged by data showing that PRC1 activity can also recruit PRC2. However, the prevalence of these two mechanisms is unknown, especially in plants as H2AK121ub marks were examined at only a handful of PcG targets. By using genome-wide analyses, we show that H2AK121ub marks are surprisingly widespread in Arabidopsis, often co-localizing with H3K27me3 but also occupying a set of transcriptionally active genes devoid of H3K27me3. Furthermore, by profiling H2AK121ub and H3K27me3 marks in *atbmi1a/b/c*, *clf28/swn7* and *lhp1* mutants we found that PRC2 activity is not required for H2AK121ub marking at most genes. In contrast, loss of AtBMI1 function impacts the incorporation of H3K27me3 marks at many PcG targets. Our findings show the relationship between H2AK121ub and H3K27me3 marks across the *Arabidopsis* genome and unveil that ubiquitination by PRC1 is largely independent of PRC2 activity in plants, while the inverse is true for H3K27 trimethylation.

Isolation and characterization of anthocyanidin synthase (ANS) gene from callus cultures of roselle, *Hibiscus sabdariffa* L. (Family Malvaceae)

Therese Julienne Medina, *Lourdes Cardenas*
Institute of Biological Sciences, University of the Philippines Los Baños

Characterization of anthocyanidin synthase (ANS) gene of *Hibiscus sabdariffa* was done based on the isolated partial sequence derived from its callus cultures. The partial ANS gene isolated from roselle was made up of 345 bp that is translated into 115 amino acids (GenBank accession number KX818221). The partial sequence showed significant similarities in ANS gene nucleotide and amino acid sequences to *Gossypium hirsutum* (84%) and *Theobroma cacao* (84%). Based on the alignment of amino acid sequences, the partial ANS gene showed homology to the members of the family of 2-oxoglutarate-dependent oxygenases. The information gathered in this study can be used in the improvement of anthocyanin production of *H. sabdariffa in vitro* and possible molecular modification of the ANS gene that would target on the promotion of its expression.

De Novo transcriptome assembly and profiling of antioxidant transcripts in the mature seed embryos of *Moringa oleifera* Lam.

Vivian Panes, *Divina Discar*
Department of Biology, School of Science and Engineering, Ateneo de Manila University

Moringa oleifera Lam. is a widely used crop that produces seeds with a plethora of benefits encompassing nutrition, medicine and bioremediation. These benefits are attributed to the compounds present in the seeds including secondary metabolites. Exploring the transcriptome of the seeds paves the way for the discovery of the expressed secondary metabolites. Although various phytochemical researches reported the presence of the secondary metabolites in *M. oleifera* Lam. seeds, there is a lack of information on the expression of genes that encode for enzymes leading to the synthesis of secondary metabolites through transcriptome analysis. In the present study, RNA sequencing was used to analyze the transcriptome of the mature embryo of *M. oleifera* Lam. More than 41 million sequencing reads were generated and assembled *de novo* using Trinity and SOAP assemblers. Trinity assembly produced 177,417 contigs, of which 52.73% (93,546 transcripts) were annotated from NCBI non-redundant database. The SOAPdenovo assembly produced 49,170 contigs of which 57.83% (28,433 transcripts) were annotated from the NCBI non-redundant database. Biological pathway analysis revealed genes encoding 18 enzymes involved in the catalytic steps in the phenylpropanoid pathway and 11 enzymes involved in the catalytic steps in the flavonoid pathway. Furthermore, there are 19 genes involved in the catalytic steps of the alkaloid pathway. This study provides the transcriptome profile and the candidate set of genes for the biosynthesis of major secondary metabolites such as the phenylpropanoids, flavonoids and alkaloids in the *M. oleifera* seeds. This may serve as a baseline information on the secondary metabolites expressed in the mature *M. oleifera* seeds that may pave the way for improving the yield and quality of the secondary metabolites in the seeds of *M. oleifera*.

Enhanced photosynthetic-H_2 production regulated by non-coding RNAs in eukaryotic microalga *Chlamydomonas reinhardtii*

Hui Li[1], *Zhiyong Zeng*[2], *Yuting Wang*[1], *Sulin Lou*[3], *Xiulan Zhu*[1], *Xiaoqi Cai*[2], *Jiangxin Wang*[3], *Chaogang Wang*[2], *Zhangli Hu*[1]
1. College of Life Sciences & Oceanography, Shenzhen University
2. Guangdong Technology Research Center for Marine Algal Bioengineering, Shenzhen University
3. Shenzhen Key Laboratory of Marine Bioresource & Eco-environmental Science, Shenzhen University

Hydrogen (H_2) is considered as the most attractive alternative fuel and photosynthetic-H_2 produced by green microalgae is regarded as the most promising biofuel. However, incompatibility in the simultaneous O_2 and H_2 evolution from green microalgae prevented the H_2 production applications. How to make the normally cultured algae produce H_2 in a continuous and sustainable way is still the biggest barrier for this issue. Recently, a new strategy on regulation of H_2 production by a model eukaryotic microalga *Chlamydomonas reinhardtii* was investigated in our lab by understanding the functions of non-coding RNAs (ncRNAs). For the first time, microRNAs (miRNAs) and long non-coding RNAs (lncRNAs) have been successfully identified and characterized in *C. reinhardtii*. Several heat-inducible expression vectors, which contain either artificial miRNAs or endogenous miRNAs targeting photosystem II related genes have been constructed and transformed into *C. reinhardtii*. With a more rapidly O_2 consumption, some transgenic algae showed that miRNA gene knock down was correlated with the higher H_2 production. Without imposing any nutrient deprived stress, this novel strategy provided a convenient and efficient way for regulation of photosynthetic-H_2 production in green microalgae by simply “turn-on” the expression of a designed ncRNA.

Genomic variation associated with local adaptation of weedy

rice during de-domestication

Jie Qiu[1], *Yongjun Zhou*[2], ***Lingfeng Mao***[1], *Chuyu Ye*[1], *Weidi Wang*[1], *Yongyi Yu*[1], *Michael P. Timko*[3], *Song Ge*[4], *Longjiang Fan*[1], *Yongliang Lu*[2]

1. Institutue of Crop Science & Institute of Bioinformatics,Zhejiang University, Hangzhou 310058

2. China National Rice Research Institute, Chinese Academy of Agricultural Sciences, Hangzhou 310006

3. Department of Biology, University of Virginia, Charlottesville, VA 22904

4. State Key Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences, Beijing 100093

De-domestication is a unique evolutionary process by which domesticated crops are converted into 'wild predecessor like' forms. Weedy rice (Oryza sativa f. spontanea) is an excellent model to dissect the molecular processes underlying de-domestication. We collected 155 weedy and 76 locally-cultivated rice accessions from four representative regions in China and sequenced their genomes to an average 18.2× coverage. Phylogenetic and demographic analyses indicate that Chinese weedy rice were de-domesticated independently from cultivated rice and experienced a strong genetic bottleneck. Although evolving from multiple origins, critical genes underlying convergent evolution of different weedy types can be found. Allele frequency analyses suggest that standing variations and new mutations contribute differently to japonica and indica weedy rice. A Mb-scale genomic region present in weedy rice but not cultivated rice genomes was identified with evidence of balancing selection suggesting that there might be more complexity inherent to the process of de-domestication.

Origin and evolution of the *MORC* gene family in green plants

Wei Dong, *Fei Chen, Liangsheng Zhang*

Center for Genomics and Biotechnology, Fujian Agriculture and Forestry University

Microrchidia (MORC) protein is a kind of novel epigenetic regulator that contains a typical GHKL (Gyrase, Hsp90, Histidine kinase, MutL) ATPase domain. Here, we conducted a comprehensive evolutionary analysis of *MORC* genes in green plant lineage. The MORC sequences revealed a successive highly conserved motif composition in addition to the ATPase domain. We defined these conserved motif composition as the MORC domain.This complete MORC domain distributed widely among all examined green plants and its origin could be traced back to the common ancestor of Streptophyta. The MORC domain was present in the Charophyte algae but not in the earlier Chlorophyte algae, showed that it originate from the Charophyte. Phylogenetic analysis showed that the *MORC* gene family in green plant lineage could be divided into two major groups designated as Group I and Group II. Moreover, Group II could be further subdivided into Group II-1 and Group II-2. Group II-2 only contained seed plants that revealed that they divided at least before seed plants. Among them, Group I and Group II-1 had undergone several gene duplication events that resulted in the expansion of *MORC* gene family in angiosperms. Synteny analysis showed that there were both eudicot-shared ancient whole genome duplication and subsequently several family-specificwhole genome duplications occurred in Group I and Group II-1. In Group II-2, only one copy was found in most species, suggesting the Group II-2 was relatively conserved compared with the Group I and Group II-1. Expression of *MORC* genes in Arabidopsis, soybean, and rice revealed that they exhibited relatively higher expression level in reproductive tissues and several paralogous gene pairs showed divergent expression patterns. Overall, our results systematically elucidated the evolutionary relationships of the *MORC* gene family in the green plant lineage, which would help to further reveal their functions in plant epigenetic regulation process.

Development and Characterization of Polymorphic EST-SSR of *Pteroceltis tatarinowii*, an endangered plant endemic to China

Yunyan Zhang

Nanjing University

With wide distribution in the genome, the microsatellite markers relied on expressed sequence tags (EST) can be linked to genetic traits and applied broadly in population genetics, molecular marker assisted breeding and molecular marker screening of target traits. However, the lack of the *P. tatarinowii* genomic and transcriptional dataset limits the application of molecular markers in genetic studies of its populations. In this paper, we used Illumina high-throughput sequencing technique to sequence the *P. tatarinowii* leaf transcriptome, based on which polymorphic microsatellite loci is developed. A total of 42477 unigenes with an average length of 815bp were obtained. After aligning with NR, SwissProt, GO, COG and KEGG databases, 23688 unigenes were assigned. These data provided the foundation for gene expression and function analysis of *P. tatarinowii*. Among the unigenes, a total of 6543 EST-SSRs were identified and130 EST-SSRs were selected for validation as EST-SSR markers by PCR amplification. Of these, 48 EST-SSRs were amplified successfully and 32 EST-SSRs were polymorphic among 47 *P. tatarinowii*individuals. Additionally, cross-amplifications of EST-SSR were detected in *Ulmus gaussenii* and*Ulmus chenmoui*, and the versatility and polymorphism were 25% and 87.5%, respectively. The development of the *P. tatarinowii* microsatellite markers provided the molecular basis for the study of the *P. tatarinowii* and other plants in family Ulmaceae.

Effects of endophytic fungi on perennial ryegrass growth and physiological characteristics under different PH latosol extraction

Zhenjiang Chen, *Xuekai Wei, Chunjie Li*

(State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou, China

The paper was conducted to compared the endophyte-infected (E+) and endophyte-free (E-) of ryegrass (*Lolium perenne*) on morphological and physiological changes under different pH laterite leaching solution, to analyze the effect of the endophytic fungi on the seeding growth and physiological charactristics of perennial ryegrass. The result showed that: 1) E+ and E– morphological indicators and free proline content (Pro), malondialdehyde content (MDA), superoxide dismutase activity (SOD) and peroxidase activity (POD) reached peak value under pH 6.12 (CK), and were significantly (P<0.05) higher than the other five treatments, but malondialdehyde were significantly (P<0.05) lower than soil/water treatments. 2) Endophyte-infected significantly (P<0.05) improved germination rate, germination energy, germination index, vigor index, shoot length, root length and dry weight and Pro content, SOD and POD activity, and decreased the content of MDA under pH value at 4.47 ~ 5.01, the root length of perennial ryegrassthatendophyte-infected (E+) had no significant differences (P>0.05) with endophyte-free (E-) at pH 4.47 ~ 6.12. The showed that endophytic fungi increased the growth of host, and plants had a wide application range of leaching solution pH, the perennial ryegrass can be used in acid soil improvement.

T6

A473

Effects of *Epichloë* on seed germination and seedling growth of *Lolium Perenne* under aluminum stress

Zhenjiang Chen, Chunjie Li

State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology, Lanzhou, China

Endophytic fungi is a kind of fungi that its partial or hole life history in plant tissue and doesn’t cause obvious disease to the plant. According to incomplete statistics, as many as 170 species of endophytic fungi have been found, which involved multiple fungal taxa such as ascomycete, basidiomycete, zygomycete, mitosporic fungi, mycelia sterilia and so on. Grass endophytes mainly focus in ascomycete class Clavicipitaceae family *Epichloë* and *Neotyphodium* genus. Grass endophytes mainly exist in the shoots of plants, which can promote the healthy growth of host plants through providing mineral nutrition for grass. Therefore the grasses infected by endophytic fungi play a important role in phytoremediation of heavy metal contaminated soil with the help of the heavy metal accumulation of grass endophytes hyphae, higher grass biomass and stronger grass root activity. In recent years, scientists have payed a close attention to grass endophytes can promote heavy metal tolerance of grass plant but the related reports are less. These research currently focused on heavy metal element such as Zn, Cd, Pb and Cu, but the study is rare that ryegrass endophytic fungi resistant to Al stress, especially the infection of endophytic fungi on the seed germination of perennial ryegrass under aluminum stress was less. This is the first study of aluminum tolerance effect on perennial ryegrass endophyte. An effort was made in this study to compareperennial ryegrass (*Lolium Perenne* L.) that was lendophyte-infected (E+) and endophyte-free (E-) in term of seed germination under different aluminum stress conditions through germination test on filter paper. Results showed that either control or stress conditions, the germination rate, germinative force, vitality index, embryo length, root tolerance indexes and root activity all decreased with the increase of aluminum concentration both endophyte-infected (E+) and endophyte-free (E-). This may be because that Al is not the essential element of plant mineral nutrition and trace Al can’t promote normal plant growth and physiological metabolism, while high concentration of aluminium ions will seriously affect the grass plant growth, physiological and biochemical metabolic pathways. All measurement indexes of seeds that lendophyte-infected (E+) seed were significantly higher than those seeds that endophyte-infected (E+) and endophyte-free (E-) (P<0.05). This implied that *Neotyphodium* endophyte can improve the germination rate, germination speed as well as growth of seedling after germination under aluminum stress. But we can see from the weight of embryo, the weight of radicle and tolerance index of seminal root that the decreased level endophyte-infected (E+) seed of seeds wes higher than endophyte-free (E-) seed, and with the increasing of aluminum ion concentration, the differences were gradually narrowing between lendophyte-infected (E+) and endophyte-free (E-) seed of seeds. When aluminum ion concentration reached a certain value there may be no difference ($P > 0.05$). In this study, Al stress inhibited the seed germination of perennial ryegrass, while endophyte infection was good for seed germination under Al stress.

Chinese names of plant taxonomists from traditional to modern system

Ling-Li Deng[1], **Jin-Shuang Ma**[2]

1. Shanghai Chenshan Plant Science Research Center, Chinese Academy of Sciences

2. Shanghai Chenshan Plant Science Research Center, Chinese Academy of Sciences

The authors of the Chinese plant taxonomists recorded in the earlier literature were mainly based on the Wade–Giles System, but nowadays, except for Taiwan, there are a few people who know and use the Wade–Giles system. At the same time, before the official use of Chinese phonetic alphabet, some scholars have also used Postal Spelling System for their names. In addition, the abbreviated names of the Chinese authors in the historical records abroad were also used, which often fall into the confused state. In all, it causes intangible and real problems in the current scholar’s reading and checking. In order to not only improve the various types of information and scattered information around international authoritative websites about Chinese names of modern plant taxonomists, but also to provide a clearer author name spelling method of historical background for the researchers who work on history of plant taxonomy, this paper mainly explores the causes of the phonetic transcription of the names of plant Chinese taxonomists, and summarizes the transformation rules of Wade–Giles system and Chinese phonetic alphabet. We also list some earlier records of the author’s name in the book of errata, eventually developed a more detailed modern taxonomic description of Chinese name information of plant taxonomists.

The involvement of serine/arginine-rich (SR) proteins in the response of *Arabidopsis thaliana* to iron deficiency

Junjiao Feng[1,2], Ping Lan[1], Wengfeng Li[1,2]

1. Collaborative Innovation Center of Sustainable Forestry in Southern China of Jiangsu Province, College of Biology and the

Environment, Nanjing Forestry University, Nanjing, P. R. China
2. State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing, P. R. China

Iron (Fe) is essential micronutrients for plant growth and development, and the deficiency of Fe will reduce the yield and quality of crops. Alternative splicing (AS) is a main source of transcriptome and proteome diversity in metazoans and plants, and AS patterns will be dramatically changed in response to various biotic and abiotic stresses, including Fe deficiency. Serine/arginine-rich (SR) proteins, the significant modulators of constitutive and alternative splicing have been involved in variety of abiotic stresses. However, whether the SR proteins participate in plant iron deficiency response and its mechanism remain unknown. In this study, homozygotes of SR T-DNA insertion mutants, confirmed by DNA sequencing were used to test their roles in iron deficiency. Results showed mutation in one of the SR proteins resulted in more severely yellowing in the leaves than that of wild type plants, which is consistent with the lower content of total chlorophyll in the mutant. Moreover, the mutant plants were showed smaller in size and shorter in the root length than that of wild type plants under iron deficiency. Underlying mechanisms of this SR protein associated with iron deficiency are under the way.

Identification and analysis chemical composition of essential oils from the peel of 6 species of mandarins

Lulu Feng, *Yunzhi Mao, Hui Ran, Shiyao Liu*
College of Horticulture and Landscape Architecture, Southwest University

Peel essential oil is one of the important characteristic traits of citrus, different species of citrus there are significant differences in the composition and content of essential oil components, between different varieties of the same species of essential oil components is also different, Therefore, citrus essential oil can be used as the basis for the study of citrus origin, genetic relationship and classification. in this study, the peel essential oils from six species of mandarins:Nanfeng tangrine (*Citrus kinokuni* Hort. ex Tan), Satsuma mandarins (*Citru-s unshiu* Marc), No 3 Ponkan (*Citrus reticulata* Blanco), Mangshanyegan (*Citrus nobilis* Lauriro), Cheokan (*Citrus tankan* Tanaka), tangerine (*Citrus tangerina* Tanaka), cultivated under the same pedoclimatic and cultural conditions. Their chemical composition was investigated by solid phase micro-extraction headspace GC-MS. The results showed that there were significant differences among the cultivars in composition and relatively content of volatile and content of essential oils, Cheokan peel essential oil content was the highest in 1.56%, No 3 Ponkan peel essential oil content was the lowest of 0.77%; Totally 64 volatiles belonging to various chemical classes were detected, and there are 8 kinds of common components, for unique components, Nanfeng tangerine contained 1, Satsuma mandarins and No 3 Ponkan both contained 5, Mangshanyegan contained 7, Cheokan and tangerine contained 2 and 6 components respectively;For the identified components, D-limonene (66.91-91.51%), γ-terpinene (tr-14.73%), β-myrcene (2.54-24.77%), linalool (0.1-3.23%), 1R-α-Pinene (0.54-2.43%) were characteristic elements of six kinds of mandarins peel essential oils. According to a cluster analysis, the 6 species of mandarins were divided into two categories corresponding two major chemotypes, limonene and limonene/ γ-terpinene. Nanfeng tangerine, Satsuma mandarins, Mangshanyegan and Cheokan belonged to limonene chemotype with a very high amount of D-limonene (70.04-91.51%), Which Satsuma mandarins and Cheokan closest relative, Mangshanyegan followed, Nanfeng tangerine far;No 3 Ponkan and tangerine contained limonene (72.54%, 66.91%) and γ-terpinene (14.22%, 14.73%) as the main components, so they belonged to limonene/ γ-terpinene chemotype.This study enriched the methods of classification and genetic relationship of mandarins plants, also revealed that the composition of the volatile constituents of the essential oil of the six species of original seed mandarins trees and to provide the basis for exploring the evolution of mandarins fruit flavor.

New ornamental plants in anthropogenically transformed environment in conditions of the steppe zone

Alexandr Glukhov, ***Ludmila Kharkhota***
Donetsk Botanic Garden

The Donetsk region is situated in the steppe zone of southeastern Europe. Tree plantations of this region exist in specific natural conditions of the southern steppe zone. The climate is continental with distinctly appearing droughts and hot winds, uneven annual distribution and high variations of rainfall from 223 to 655 mm. The climate is characterized by significant daily, annual and absolute air temperature fluctuations (from -35 ℃ to +39 ℃). Limiting factors for plant growth are the low temperature in winter and the high temperature in summer period, early autumn and late spring frosts, lack of moisture, soil and air dryness. Donbass is a region with a high concentration of modern industrial production resulting in the increased level of air, soil and groundwater pollution. Large energetic, coal mining, coking, metallurgical and engineering enterprises are located in towns of the region. On almost all indicators, the level of environmental pollution exceeds the current allowable concentrations in 3-5 times. Natural climatic conditions along with the intensive anthropogenic load lead to the decrease in longevity of tree plantations. The lifespan of woody plants is reduced in 3-4 times and rarely exceeds 50-60 years (only 4% of trees achieve this age). In such conditions it is important to enlarge the range of tree plantations for optimization of environment. Natural flora of woody plants in Donbass includes 107 species, not more than 40 of them are in culture, the basis of dendrocenosis is formed by 10-15 species. An important stage in solving the problems of phytooptimization of the environment in the region is connected with works of the Donetsk Botanic Garden (DBG) established more than 50 years ago. The collection fund comprising more than 1,000 species and sorts of woody plants has been created during this period. Nowadays a bit more than 200 species of trees and shrubs are used in landscaping of industrial towns of Donbass. The majority of them are trees and shrubs involved from other floristic regions and brought in culture as a result of intensive introduction activity of DBG concerning the use of valuable species of the world flora. From East Asian floristic region alone 272 species of plants have been introduced in DBG.

Such species as *Acer ginnala* Maxim., *Ailanthus altissima* (Mill.) Swingle, *Ampelopsis aconitifolia* Bunge, *Cerasus tomentosa* (Thunb.) Wall., *Chaenomeles japonica* (Thunb.) Spach, *Chamaecyparis pisifera* (Siebold & Zucc.) Endl., *Deutzia scabra* Thunb., *Larix leptolepis* (Siebold & Zucc.) Gordon, *Picea asperata* Mast., *Platycladus orientalis* (L.) Franco, *Sorbaria sorbifolia* (L.) A. Br., *Ulmus parvifolia* Jacq. have adapted well to local conditions and are widely used in ornamental plantations of the region. Accumulation of the collection fund of woody plants is continuing. Among the species which have passed through introduction, are *Prinsepia sinensis* (Oliver) Bean, *Stephanandra tanakae* (Franch. et Sav.), *Viburnum carlesii* Hemsl., species and cultivars *Berberis thunbergii* DC., *Juniperus chinensis* L., *Spiraea japonica* L. f. The effective methods for their propagation have been developed. During the adaptation to our climatic conditions, some of these species change the growth form. For example, *Buddleia davidii* Franch., being a high shrub from mountainous regions of the subtropical zone of China, every year frosts up to the level of root crown. However, in the next vegetative period it grows again up to the height of 1.5-2.0 m, gets an effective form, blooms abundantly, becoming a perfect decoration for exquisite landscape compositions. The use of dendrologic resources of the world flora and the enrichment of the species composition of plantations are of prime importance in their optimization and hardening in conditions of the technogenic environment.

A hexaploid triticale 4D (4B) substitution line confers superior stripe rust resistance

Daiyan Li[1], *Yujie Wang*[1], *Yi Wang*[1], *Xing Fan*[1], *Jian Zeng*[2], *Lina Sha*[1], *Haiqin Zhang*[1], *Yonghong Zhou*[1], *Houyang Kang*[1]
1. Triticeae Research Institute, Sichuan Agricultural University
2. College of Resources, Sichuan Agricultural University

Triticale lines tend to become less resistant to stripe rust and other fungal diseases over time, and exhibit relatively limited genetic diversity. Therefore, it is important that new triticale varieties with superior agronomic traits are continually produced to enrich the available genetic pool. In this study, a new hexaploid triticale line (K14-827-1), which was derived from the progenies of a wheat–rye–Psathyrostachys huashanica trigeneric hybrid, was identified and analyzed using genomic and fluorescence in situ hybridizations, seed protein profiling, and molecular markers. Meiotic pairing studies suggested that the mean chromosomal configuration of K14-827-1 was 2n = 42 = 0.24 I + 18.23 II (ring) + 2.65 II (rod). The in situ hybridization karyotyping results indicated that K14-827-1 was a 4D (4B) substitution line, consisting of complete R and A genomes and chromosomes 4D, 1B–3B, and 5B–7B. Simple sequence repeat analysis of K14-827-1 confirmed that wheat chromosome 4B had been substituted by chromosome 4D. The seed protein profiling results uncovered polymorphic 75K γ-secalin and low-molecular-weight glutenin subunits between K14-827-1 and its recurrent triticale parent (Zhongsi828). Furthermore, the K14-827-1 plants were highly resistant to the stripe rust pathogen (*Puccinia striiformis* f. sp. tritici) prevalent in China, including race V26/Gui22, than Zhongsi828 plants at the seedling and adult stages. This new hexaploid triticale line may be useful for diversifying triticale germplasms and breeding new varieties with improved forage grass traits.

The effects of the nitrogen form ratios on photosynthetic efficiency of Populus × euramericana 'Neva' under condition of phenolic acids

Hui Li
Linyi university

The objective of this study was to investigate the effects of nitrogen form ratio on photosynthetic productivity of poplar under the environment of phenolic acid. Poplar (Populus × euramericana 'Neva') seedlings were treated with 9 nutrient solutions composed by phenolic acid with three concentrations (T0, T1, and T2) and nitrate salts with three nitrogen form ratios (the ratios of ammonium nitroge to nitrate nitrogen (NO3--N) were 1:3,1:7, and 1:14). The photosynthetic physiology parameters, leaf nitrogen content, and total biomass of poplar were measured. Results showed that photosynthetic physiology parameters were influenced by both phenolic acid concentration and nitrogen form ratio. The nitrogen form ratio was the major factor on net photosyntheticrate (PN). When poplar were treated by solutions with NH4+-N to NO3--N ratio of 1:14, the major limitation factor of photosynthesis was non stomatal factor.When poplar were treated by solutions with NH4+-N to NO3--N ratio of 1:3, the major limitation factor of photosynthesis changed to stomatal factor. The leaf nitrogen content and total biomass were obviously positively related with PN ($P<0.05$). Phenolic acid inhibited photosynthesis of poplar in a major way and this effect decreased with increase of the content of NH4+-N. The order of PN values obtained from 9 treatments was T1-1:3, T0-1:3, T2-1:3, T0-1:7, T1-1:7, T0-1:14, T2-1:7, T1-1:14, and T2-1:14 (from high to low). The photosynthesis productivity and biomass of poplar reached the highest values when the ratio of NH4+-N to NO3--N was 1:3 in each treatment group, respectively. The study results could provide guidance on handling the continuously cropped poplar obstacle issue faced nowadays.

Synthesis and antifungal activity of bis (indolyl)methanes

Fei Liu[1], *Qizhi Wang*[1], *Shu Xu*[1], *Min Yin*[1], *Xiancui Guo*[2], *Jinyue Luo*[2], *Xu Feng*[1]
1. Institute of Botany, Jiangsu Province and Chinese Academy of Sciences, Nanjing Botanical Garden Mem. Sun Yat-Sen
2. Nanjing Forestry University

Bis (indolyl)methanes are a kind of alkaloids with important biological activity, and many bis (indolyl)methanes have been isolated from a variety of terrestrial and marine natural sources. We found 3,3'- (phenylmethylene)bis (1*H*-indole) can be gained in the asymmetric Friedel-Crafts Henry Reaction (F-C-H reaction) in the presence of $NiCl_2$. Therefore, we report the use of $NiCl_2$ as a cheap catalyst for the synthesis of bis (indolyl)methanes based on indole and benzaldehyde. By using the catalyst $NiCl_2$, the reaction was optimized in terms of the solvent, reaction temperature, reaction time, mole ratio of indole and benzaldehyde, mass fraction of catalyst. The suitable conditions for the synthesis of 3,3'- (phenylmethylene)bis (1*H*-indole) are as follows: when indole is 2.0 mmol, *n* (indole):*n* (benzaldehyde) = 2:1.1; the amount of catalyst ($NiCl_2$) is 5% of the amount of benzaldehyde; reaction time is 5 h and the reaction temperature is 40 ℃. The reaction was performed under the suitable conditions three times and the average yield of 3,3'- (phenylmethylene)bis (1*H*-indole) is 82.6% (the yields are 82.3%, 83.1% and 82.5%, respectively). The catalyst ($NiCl_2$) is easy preparation from hydrate ($NiCl_2 \cdot 6H_2O$) and cheap in the reaction system. Meanwhile, the reaction condition is mild and the post-processing is simple in this process. Then 5 bis (indolyl)methanes were synthesized by the synthetic process and high yield is obtained (more than 80%). The structure of the bis (indolyl)methanes purified by column chromatography was identified by infrared spectra, HRMS (high resolution mass spectrometer), ^{1}H NMR and ^{13}C NMR. Then the antifungal activity of bis (indolyl) methanes were studied by using the cross method. Compared with the control group, the inhibition ratio of the 3,3'- (phenylmethylene)bis (1*H*-indole) is 61.2% (*Sclerotiniasclerotiorum* (Lib.) de Bary) and 60.7% (*Botrytis cinerea* Pers. ex Fr.), respectively. The study of antifungal activity of bis (indolyl)methanes expands the application fields of bis (indolyl)methanes and it suggests that bis (indolyl)methanes maybe play a more important role in plant disease control.

Ethnic resources of medicinal plant in Guizhou province -- medicinal plants categories for treating nephropathy

Sizhao Liu[1], *Chunlin Long*[1,2]
1. Minzu university of China
2. Kunming Institute of Botany

Guizhou is particularly rich in biological resources which contains a plenty of medicinal plants. It has formed a variety of unique ethnic medicine after long-term practice. Based on the related literature research and modern chemical technology, the study has collated the main medicinal plants which can treat Nephropathy. It includes the following categories: *Dioscorea opposite Thunb* : the medicinal parts are its block and stem; *Atractylodes macrocephala* Koidz. : the medicinal parts are its tubers; *Plantago major* L. : the medicinal parts are the seeds and entire plants; *Eucommia ulmoides* Oliv. : the medicinal parts are barks. It and its tree farm have been planted a lot in Zunyi. *Cibotium barometz* (L.) J. Simth : the medicinal parts are its tubers. It is widely distributed throughout Guizhou. *Ficus pumila* L. : the medicinal parts are steams and branches, leaves and its fruits. It located in southwestern, central, southern, southeastern of limestone slopes in Guizhou. *Drnaria fortune* (Kunze) J. Smith : the medicinal parts are its tubers. *Psoralca coryliflia* L. : the medicinal parts are its fruits. *Lysimachia christinae* Hance : its entire plants can be used as medicine. *Allium tuberosum* Rottl. ex Spreng : the medicinal parts are its seeds, roots and leaves. *Cuscuta chinensis* Lam. : its seeds can be used as medicine. *Epimedium accuminatum* Franch. : the entire plants can be used as medicine. These plants not only play a prominent role in the treatment of nephropathy, but also play an important role in the treatment of other diseases. This paper hopes to provide the information of medicinal plant resource with reference values for the treatment of nephropathy in the pharmaceutical industry through this research, and promote the healthy development of Guizhou botanical medicine industry.

Origin of plant life unity of meteorite strike energy model and bioenergetic model

Ling Lu
Cological Society of Guangdong Province

Meteorite strike is a common and extensive geological process in the solar system, the Earth is no exception. Based on the causes of meteorite impact on the earth's crust, the cognition to celestial spiral motion and particle structure in the galaxy, as well as the comparison between meteorite strike energy model and various biomorph on the earth, matching between meteorite strike structure on ground rock stratum and plant and biota, it is inferred that the morphological characteristics of the life on the Earth, including fungi, plants and animals is highly consistent with the development of meteorite strike energy model. This study suggests that the said fact provides the key clue proving the mechanism of the origin of life, including plants, on the Earth. In the course of celestial bodies hitting the earth's surface, the superior potential energy converted into high-energy physics process such as kinetic energy, thermal energy and nuclear energy, causing the fission and fusion of the particles, the basic material objects of falling celestial bodies, when the structure of these particles is swelling, and the energy information exchanges, the space-time order of energy movement during the meteorite strike process can be "memorized". As the germ of life on the Earth and under certain conditions, the information they have memorized can express in sequence, such as "gene models". Plant energy model corresponds to the phase before the main clue of meteorite strike energy model ruptured, while the animal energy model extended to a later phase. The life embryo created during the meteorite strike process continued to develop and evolve under the specific ecological environment on the Earth.

Comparison and evaluation on nut quality of Chinese-grown pecan [*Carya illinoensis* (Wangenh.) K. Koch] cultivars

Xiaodong Jia[1,2], *Huiting Luo*[1], *Min Zhai*[1], *Yongrong Li*[3], *Jiping Xuan*[1], *Jiyu Zhang*[1], *Gang Wang*[1], *Tao Wang*[1], *Zhongren Guo*[1]
1. Institute of Botany, Jiangsu Province and Chinese Academy of Sciences
2. Institute of Botany, Jiangsu Province and Chinese Academy of Sciences
3. Nanjing Green Universe Pecan Science & Technology Co., Ltd.

14 Chinese-grown pecan [*Carya illinoensis* (Wangenh.) K. Koch] cultivars, including "Caddo", "Chickasaw", "Cheyenne", "Choctaw", "Desirable", "Kanza", "Mahan", "Pawnee", "Stuart", "Western", "Wichita", "Jinhua", "Lvzhou 1", "Shaoxing" were investigated. Their phenotypic characters, fatty acid, tocopherol, total phenolic (TP), condensed tannin (CT), total flavonoids (TF) content, and antioxidant capacity (AC) were evaluated for each

cultivar. The results of phenotypic characters analysis showed that among all pecan cultivars, “Desirable” had the highest mean nut weight, kernel weight and oil content (11.45 g, 6.60 g, and 79.73%, respectively), “Mahan” had the highest mean nut shape index (2.24), “Wichita” had the highest mean kernel rate (61.57%) and the lowest mean shell thickness (0.70 mm). Fatty acid composition was analyzed by Gas Chromatograph (GC). The results showed that the mean relative content of palmitic, stearic, oleic, linoleic, and linolenic acids were 6.03%, 2.09%, 68.93%, 21.93%, and 1.02% respectively. Unsaturated fatty acid (UFA) was the major fatty acid present and “Lvzhou 1” cultivated in China had the highest UFA content (93.72%) among all the cultivars. The total tocopherols content varied from 225.61 mg·kg^{-1} (“Kanza”) to 466.95 mg·kg^{-1} (“Pawnee”) oil, while the predominant gamma-tocopherol was determined to be 211.99 mg·kg^{-1} (“Kanza”) to 448.92 mg·kg^{-1} (“Pawnee”) oil. TP, CT and TF were quantified in acetonic extracts. Fresh kernel contained 1.14 (“Chickasaw”) to 2.14 (“Mahan”) g ellagic acid equivalents/100 g. A strong correlation was found between the content of TP and the antioxidant activity. The antioxidant ability of pecan kernels varied from 28.57 (“Choctaw”) to 134.38 (“Mahan”)μmol Trolox equivalent/g dry weight (ABTSradical-scavenging activity) and 57.64 (“Stuart”) to 126.97 (“Mahan”) mg Trolox equivalent/g dry weight (DPPH radical-scavenging activity). The results indicated that “Mahan” had stronger antioxidantabilitythan other cultivars and pecan can be considered as an important source of antioxidants.

Identification and application analysis of volatile components of the essential oils from leaves of *Lindera* Thunb. growing in Jinyun Mountain

***Yunzhi Mao**, Lulu Feng, Hui Ran, Shiyao Liu*

College of Horticulture and Landscape Architecture, Southwest University

Essential oils were kinds of volatile aromatic compounds, which contained components had a varietits of biological activities. *Lauraceae* was an important resource of the plant essential oils, common Lauraceae essential oils were included camphor, aromatic alcohol, safrole, eucalyptol (e), cineole and so on. *Lindera* Thunb. was rich in volatile components of plants, a large number of studies have indicated that the volatile components of essential oil in the genus *Lindera* Thunb. were observably different. In this paper, the essential oils obtained from the leaves of three species of *Lindera* Thunb. in Jinyun Mountain of Chongqing, were analyzed for volatile constituents and the application value by hydrodistillation, GC-MS, and physical and chemical properties. Results shown that the extraction rates of the essential oil from leaves of *Lindera glauca* (Sieb. et Zucc.) Bl, *Lindera megaphylla* Hemsl., *Lindera kwangtungensis* (Liou) Allen were 0.1738%, 0.0802% and 0.1510%, respectively; a total of 148 volatile compounds (59 kinds of alcohols, 43 kinds of alcohols, 14 kinds of ketones, 12 kinds of esters, 7 kinds of aldehydes, 6 kinds of organic acids, 1 kind of pyran and 6 kinds of others) were isolated from three kinds of leaf essential oils, among them, 16 kinds of common components (9 kinds of hydrocarbons, 6 kinds of alcohols, 1 kinds of others); *L. glauca*’s main ingredients were α- cadinol (9.41%) and (+)-δ-cadinene (8.32%), α-humulene (7.37%) and γ-muurolene (6.23%) can be used for the deployment of a variety of soap and cosmetics fragrance; *L. megaphylla*’s main ingredients were phytol (14.9%), α-cadinol (6.58%) and hexadecanoic acid (6.09%), dextrose-limonene (4.67%) had an effect on refreshing and promoting metabolism; *L. kwangtungensis*’s main ingredients were trans-nerolidol (48.44%), farnesyl alcohol (6.17%) and caryophyllene oxide (5.21%), among them, trans-nerolidol was important synthetic precursor of isophytol, medicine, cosmetics, spices and chemical synthesis intermediates. This paper revealed the volatile constituents’ regular pattern of essential oils of three kinds of native *Lindera* Thunb. plants leaves of Jinyun Mountain in Chongqing, analyzed the physical and chemical properties and application potential of the main volatile components, and provided a scientific basis for the development and utilization of native plant resources of *Lauraceae* in Chongqing.

Leaf venation and its taxonomical significance in Sect. *Denticulatae* (*Salix*) of China

*Xiangyu Meng, Huiying Yu, **Zhixiang Zhang***

College of Nature Conservation, Beijing Forestry University

Comparative observation on leaf venation of 17 species and 1 variety from *Salix* Sect. *Denticulatae* were made performed in order to provide new morphological evidence for the classification of *Salix* by the means of this section. The results showed that the venation of all taxa was found to be craspedodromously pinnate. Most species have intersecondary veins. Tertiary and higher level veins were divided into three types. The areoles are regular or irregular. Veinlets are branched or absent. The results also indicated that the areoles and veinlets were stable characters which showed significant differences bwteeen species. Based on the UPGMA analysis for venation pattern of Sect. *Denticulatae* C.K. Schneid., *S. praticola* Hand.-Mazz. ex Enander types and *S. delavayana* Hand.-Mazz. types were founed. Leaf venation characters provides new characters. They could be used, therefore, as important diagnostic features for identifying these species.

Determination of volatile components from *Trib. litseeae Mez* leaves by GC-MS in Jinyun Mountain Chongqing

***Hui Ran**, Lulu Feng, Yunzhi Mao, Shiyao Liu*

Southwest University College of Horticulture and Landscape Architecture

Lauraceae plants are important timber species, spices, aromatic oils and medicinal resources, with great economic value. Lauraceae resources are rich in Jinyun Mountain Chongqing, having identified the local Lauraceae plants 10 genus 22 species 3 variants. In this study, four kinds of plants were used to study the extraction of essential oil from leaves and the identification of volatile components by using distillation and GC-MS. The extraction rate of essential oil and the composition of volatile components were obtained. The extraction rates of essential oil from the *Neolitsea levinei Merr.*, *Neolitsea aurata var. glauca Yang*, *Litsea elongate* *var. subverticillate (Yang) Yang et P.H.Huang* and *Litsea mollis Hemsl.* were 0.2116%, 0.6982%, 0.2584% and 0.0634% respectively. By GC-MS qualitative analysis, 165 volatile components were identified from the 4 species, and *Neolitsea levinei Merr.*, *Neolitsea aurata var. glauca Yang*, *Litsea elongata var. subverticillate (Yang) Yang et P.H.Huang* and *Litsea mollis Hemsl.* contained 78,66,68 and 67 components respectively. There are 16 common components among the 4 species. For the identified components, the volatile components of the leaves were mainly composed of hydrocarbons and alcohols. *Neolitsea levinei Merr.* mainly contained volatile components such Borneol acetate, β-Eudesmol, 4-Terpineol; *Neolitsea aurata var. glauca Yang* mainly contained 4-Terpineol, Longifolene, β-Caryophyllene; *Litsea elongata var.subverticillate (Yang) Yang et P.H.Huang* mainly contained α-Bergamotene, α-Pinene, α-Caryophyllene; *Litsea mollis Hemsl.* mainly contained D-Limonene, β-Elemene, trans-Geraniol. The differences of composition of the volatile components among the 4 species were great, so the use value of them shuold be discriminatory. This study provides a theoretical basis for the development and utilization of essential oil in the leaves of Trib. litseeae plant resources in Chongqing area.

Analysis of nutritional components and evaluation of nutritional value for different hay of *Foxtail Millet* germplasm resources

Xiaoli Ren[1], *Shijia Song*[1], *Meng Liu*[1], *Zhigang Shi*[1], *Chunmei Nan*[1], *Fei Liu*[1], *Jihan Cui*[1], *Juan Wang*[2], *Xueyan Xia*[1], *Shunguo Li*[1]

1. Institute of Millet Crops, Hebei Academy of Agriculture and Forestry Sciences, National Foxtail Millet Improvement Center, Minor Cereal Crops Laboratory of Hebei

2. Shijiazhuang engineering vocational college

Foxtail Millet has strong adaptability to abiotic stresses, especially drought and poor soil. It also has high nutritional value. The objective of this study was to improve the selection and breeding efficiency of forage foxtail millet germplasm resources. The contents of 11 nutritional indexs in hay of 82 foxtail millet germplasm resources were detected, which were moisture (MC), crude ash (Ash), crude protein (CP), ether extract (EE), crude fibre (CF), carbohydrate (CA), phosphorus (P), calcium (Ca), ferrum (Fe), zinc (Zn), selenium (Se), then the analysis of correlation and clustering for nutrient quality characters were carried out by the SPSS statistics software 19.0. The results indicated that: (1) There were significant differences in the contents of 11 nutrient components in different millet germplasm resources; (2) Crude protein was significantly positively related to carbohydrate, phosphorus, calcium and zinc, but significantly negatively related to crude fibre; ether extract (EE) was not significantly related to other nutritional indexs; there was a significantly negative correlation between moisture and carbohydrate; crude ash was significantly positively related to calcium and ferrum; crude fiber was significantly negatively related to carbohydrate, phosphorus, zinc and selenium; carbohydrate was significantly positively related to phosphorus and selenium; ferrum was not significantly related to phosphorus; there was a significantly positive correlation between ferrum, calcium, zinc and selenium; zine was significantly positively related to phosphorus, calcium, ferrum and selenium; selenium was significantly positively related to phosphorus, calcium, ferrum and zine. (3) The 82 varieties of millet germplasm resources were classified into six types by hierarchical cluster analysis (squared euclidean distance). 25 varieties of the first type, such as Jigu 25, contain higher crude protein, carbohydrate and mineral, the content of crude fibre was lower, these were high quality forage varieties. The second type India 90-39 and other five varieties, carbohydrate and ether extract were relatively higher. The third type of Jigu 24, the contents of ether extract, crude ash, phosphorus and selenium were relatively higher. The founth type of Jigu 22 and other 46 varieties, rich in minerals. The fifth type of changsheng 06 and lvsuigu, ether extract was relatively higher, but the contents of ferrum and selenium were very low.The sixth type was Z281, the highest moisture and higher ferrum, the other indexes were lower. In conclusion, *Foxtail Millet* was a high quality grain and forage millet. The crude protein of the millet stalk after the harvest of grains was 4.29–9.56%, equal to sorghum, superior to wheat. The content of phosphorus was superior to the normal range of forage grass, the content of zine and selenium were on the normal range of forage grass. The study also showed that the Ca/P ratios of 64 varieties were on the optimal range of ruminants. It had great significance for the development and growth of livestock. This research provided an important foundation for breeding and reasonable utilization of high quality forage millet germplasm resources.

Studies on chemical constituents in the roots of *Suaeda glauca*

Yu Shan, *Qizhi Wang, Ming Wang, Fuqin Guan, Min Yin, Fei Liu, Yu Chen, Shu Xu, Xu Feng*

Institute of Botany, Jiangsu Province and Chinese Academy of Sciences, Nanjing Botanical Garden Mem. Sun Yat-Sen

Suaeda glauca (Bge.) Bge. belongs to the family Chenopodiaceae, which is one of the wild resources in saline soil. It is also a dominant species of halophyte in developing the seawater-irrigation agriculture. As a high-quality vegetable and plant resource with the value of health care, there is a broad prospect for its development, which is lack of system research. The chemical constituents and its activities in the roots of *S. glauca* were systematically studied in this paper. In our study, 21 compounds were isolated from the ethanol extract of *S. glauca* by a variety of modern chromatography and spectroscopic methods. Their structures were elucidated by spectroscopic methods, including 1D-, 2D-nuclear magnetic resonance (NMR) and high-resolution time of flight electrospray ionization mass spectrometry (HR-TOF-ESI-MS), including Fourteen flavones: 6,7, 2′-trimethoxy- 5-hydroxyisoflavanone (SG-2), Rutin (SG-8), 5,8-dimethoxy-7,2′-dihydroxy isoflavanone (SG-9), 5,7, 8,2′-tetrahydroxyisoflavanone (SG-10), 5,8, 2′-trimethoxy- 7-hydroxyisoflavanone (SG-11), 5,6-dimethoxy-5,2′-dihydroxyisoflavanone (SG-12), 5,6-dimethoxy-7,2′-dihydroxyisoflavanone (SG-13), Quercetin 3-O-β-D-glucoside (SG-14), 7,8, 2′-trimethoxy-5-dihydroxyisoflavanone (SG-15), 2′-hydroxy-6,7-methylenedioxy-S-methoxyisoflavone (SG-16), Kaempferol (SG-17), 5,6, 7,2′-tetrahydroxyisoflavanone (SG-18), 8,2′-dimethoxy-5,7-dihydroxyisoflavanone (SG-19), Quercetin (SG-23);

Five sterols: Ergosterol (SG-1), β-daucosterol (SG-3), β-sitosterol (SG-7-a), Stigmasterol (SG-7-b), Spinasterol (SG-7-c); One triterpenses: β-Amyrin (SG-4); One lignan: (-)-syringaresinol (SG-21). Among which, SG-11 and SG-13 are two new compounds, SG-2, SG-10, SG-15, SG-18 are four new natrual products, SG-9, SG-12, SG-16, SG-19 are isolated from the genus *Suaeda* for the first time. The pharmacological activities (cytotoxic effects, antioxidant effects) of isoflavones were evaluated in vitro. SG-2 and SG-12 show antiproliferation activity on human breast cancer cell lines (MDA-MB-231), with an IC50 value of 27.28 μM and 38.31 μM, respectively. The study provides essential chemical information for further development of *S. glauca*.

Function analysis of a glyceraldehyde-3-phosphate dehydrogenase gene from *Spartina alterniflora* under salt stress

Sheng Xu, *Lili Cai, Huiyan Yuan, Bin Sun, Bing Xia, Ren Wang*
Institute of Botany, Jiangsu Province and Chinese Academy of Sciences, Nanjing, China

Besides its role in energy metabolism, glyceraldehyde-3-phosphate dehydrogenase (GAPDH) has been demonstrated to be a multifunctional protein involved in various cellular processes in plants. In this study, a putative *GAPDH* gene from *S. alterniflora* (*SaGAPDH*) was identified based on the full-length cDNA library, and further its potential role in response to salt stress was addressed. The results showed that *SaGAPDH* was highly conserved from plant *GAPDH*s, and localized in cytosol. The expression of *SaGAPDH* gene is induced by salt stress. Expression of the recombinant *SaGAPDH* in *E. coli* BL21 (DE3) pLysS showed an increasing salt stress resistance. By using *Agrobacterium*-mediated gene transfer, we generated transgenic *Arabidopsis* plants ectopically antisense-expressing *SaGAPDH* under the control of cauliflower mosaic virus (CaMV) 35S promoter. Polymerase chain reaction (PCR) results showed that *SaGAPDH* was ectopically expressed in *Arabidopsis*, and a specific down-regulation of *AtGAPC1* and the GAPDH enzyme activity was observed. Compared to wild-type plants, transgenic *Arabidopsis* plants antisense-overexpressing *SaGAPDH* showed decreased tolerance to salt stress and down-regulation of some antioxidant defense genes including *superoxide dismutase* (*SOD*), *catalase* (*CAT*) and *guaiacol peroxidase* (*POD*). Furthermore, these results were confirmed by the aggravation of oxidative damage, as indicated by the enhancement of reactive oxygen species (ROS) such as superoxide anion ($O_2^{\cdot-}$) and hydrogen peroxide (H_2O_2) accumulation. Taken together, we proposed that *SaGAPDH* may play important roles in response to salt stress by the regulation of redox homeostasis and relative genes expression.

Research on genetic difference of *Desmodium styracifolium* by chemical mutagen on phenotypic traits and SRAP

Xiaomin Tang
Guangdong Pharmaceutical University

The seeds of *Desmodium styracifolium* were treated with chemical mutagens including sodium azide (NaN_3), ethyl methyl sulfone (EMS) and colchicine. As a result, a lot of macroscopic variations such as plant height, basal diameter and branch numbers occured. indexes including 13 plants with phenotypic variation were selected as materials. SRAP markers were used to conduct DNA molecular identification of the variants of *D. styracifolium* and the control plants. The results showed that a total of 3,285 DNA bands were amplified by 10 pairs of primers. and the percentage of polymorphic bands was 96.45%. The genetic similarity coefficients of the variants ranged from 0.326 to 0.476, which were relatively low. Experiments proved that genetic differences between mutants and the control materials of *D. styracifolium* were true.

Incidence and severity of common diseases of carrot and their pathogenic agents in Northern Nigeria

Nasir Hassan Wagini, *Aliyu Musa Yusuf, Asma'U Ibrahim Safana, Sama'Ila Abubakar*
Umaru Musa Yar'adua University Katsina

The incidence and severity of common fungal and viral diseases affecting cropping and dry season carrot were determined on the carrot growing field of the Sakijiki irrigation site, Batsari Local Government Area, 46 km western Katsina State located on latitude 12°45′05″ N, longitude 7°14′40″ E and 475 m above sea level in the Northern semi-arid ecological zone of Nigeria. The growth period was partitioned into three stages viz: seedling/vegetative stage (1), pre-flowering stage (2), and flowering/fruiting stage (3), during which the incidence of fungal, viral or mixed fungal and viral diseases were investigated. The aim was to identify the relative prevalence of the disease categories for each growth stages. Leaf blight and root knot diseases are the common infections observed during the investigation. The study indicates that *Meloidygene incognita, Cercospora carota* and *Alternaria dauci* were found to be the disease causing organisms in the samples analysed. *M. incognita* was isolated from samples infected with root knot disease, while *C. carotae* and *A. dauci* were isolated from samples infected with leaf blight disease. However, the results showed that plants in the earliest stage of growth with the lowest rate of infection. Nevertheless, viral disease incidence was the significantly highest (22.7%) at this stage. The incidence of double infections increased gradually from the second growth stage reaching 29% in the third stage. Comparatively, infection with virus alone in the third stage was 28.5%, while fungus alone was 0. 59%. The highest disease severity was in plants that were mixed infected by the two categories of pathogens. Such plants had significant retardation of growth (height and mean number of leaves/leaflets) and yield attributes such as the number of fruits produced per plant compared to singly infected and apparently healthy plants. Conclusively, this research work can be used as initial basis for research on carrot.

Sharing the routines at botanical gardens to satisfy demand of the public

Kang Wang
Beijing Botanical Garden

The routines, such as seedling, pruning, cutting, rooting, labeling, *etc.*, at botanical gardens seem very mysterious for the public. When learning more knowledge on botany and horticulture, the public will be more interested in everything about plants. It might be possible for the routine jobs to be a great resource for the education programs. In order to collect more admission fee, most botanical gardens in China are trying to accept more visitors as regular tourists. The public can enjoy the beautiful plants and flowers with nice landscapes as well, but the basic education program with stereotyped exhibitions and interpretation are very poor and not enough far away from the real demand. Beijing Botanical Garden started to open the steps and corners of daily routines to the registered visitors and friends of the garden as more as possible. The first success was made by professional horticulturists, who lead the special tours when the spectacular flower blossoms. Most participants enjoyed the face-to-face and interactive talks, even if everything they talked used to appear on the mounted interpretation or the printed brochures. According the survey, most local visitors want to learn more technical skill on horticulture and botany, which are the regular routines for the botanists and horticulturists at botanical garden. With benefits from internet, the education program made for the public needs locally will open a new gate, which is more widely than the one for the regular admission only. This might be a key step for Chinese botanical garden community to realize the importance of the localization.

The rediscovery of extinct *Lepisanthes unilocularis* Leenhouts (subgenera *Otophora*) endemic to Hainan, China

***Qing-Long Wang**, Zhu-Nian Wang, Qing Yang, Mao-Yuan Wang*
Tropical Crops Genetic Resources Institute, Chinese Academy of Tropical Agricultural Sciences

Lepisanthes unilocularis Leenhouts is an extinct plant species endemic to Hainan, China. In 2013, Nearly 80 years after it disappeared, the plant was found again in Ledong Hainan. The species belongs to *Lepisanthes* subgenus *Otophora*. It grows in the bushes near of the coast, rare. Whether the reproductive process of endangered plants exists weaknesses is the key factor affecting its extinction; while to the extinction fact of the critically endangered plant *L. unilocularis*, we will study the mechanism of this endangered species from the perspective of conservation biology, seeking practical technology to prevent its extinction. Through wild populations and environmental factors surveys, intends to understand the current distribution, habitat conditions, and wild populations. To analyze their weaknesses and limiting factors in the reproductive process, we focus on observing flowering phenology under various specific conditions, estimating outcrossing index, ovule ratio and detecting the quantity and viability of pollens, fertilization ability of stigma, advancing bagging experiment, ascertaining the pollinators and fruit set, pollination efficiency, researching seed germination characteristics under different pH, temperature and humidity. Explaining its propagation characteristics, ecological adaptability and the limiting factors in the reproductive process, revealing some scientific issues in the *L. unilocularis* endangered mechanism, propagation characteristics and ecological adaptability. This study can provide a theoretical basis for developing measures to rational conservation and management measures to prevent its extinction.

The power of technology: the practices of using mobile internet technologies to make botanical gardens more influential in the general public of China

Jimmy Wu
Beijing Lotosky Information Technology Co., Ltd.

Many botanical gardens in China have been very active in utilizing online technologies, since The Internet Plus concept was first presented by Premier Li Keqiang in March of 2015 when delivering the government work report, and unveils Internet Plus action plan to fuel growth of the country. A large proportion of botanical gardens have launched their official sites on the Social Network of Wechat, which is Chinese Facebook. Besides, the most influential botanical gardens in China published their official mobile applications to improve the access of the general public to the useful information of botanical gardens and their plants one after another, the gardens include Beijing Botanical Garden, Wuhan Botanical Garden, Lushan Botanical Garden, Chongqing Nanshan Botanical Garden, Hunan Forest Botanical Garden, Hangzhou Botanical Garden. There are also a number of very proactive cases of applications of IoT (Internet of Things) in public programs of Chinese botanical gardens and showed how IoT can facilitate the public programs and collect data of participants at the meantime, and how the data are processed and analyzed, such as Xishuangbanna Tropical Botanical Garden Chinese Academy of Science.

Landscape and gardening application of Zingiberaceae plants

***Zhi Wu**[1], Nian Liu[2]*
1. ShenZhen Techand Ecology&Environment CO., LTD.
2. Zhongkai University of Agriculture and Engineering

There are 1,500 species Zingiberaceae plants around the worth, and 210 species in China. As perennial herb, Zingiberaceae plants are the important component of tropical and subtropical plant community. Zingiberaceae plants always grow at understory, forest edge, and near stream. Some grow in limestone area, high altitude area, or on trees and stones. Some grow better under shade, or some under sun, or some in water. Some are evergreen or deciduous. Plant type, leave, flower and fruit of most Zingiberaceae plants appear to be abundant and various. Under special seasons and microenvironment, Zingiberaceae plants have irreplaceable role on allocation effect and ornamental value in garden, especially in health garden. According to local conditions, Zingiberaceae plants are used as garden flowers or ground covers in flower beds and flower borders, and as flowers for potted plant and combined potted plant. At present, Zingiberaceae plants *Hedychium coronarium*, *Alpinia zerumbet* and *Alpinia zerumbet* cv Variegata are used widely in landscape and gardening application. By field survey, introduction, domestication, and hybridization breeding, a series of Zingiberaceous plants were applied in landscape and gardening in Southern China. *Zingiber zerumbet*, *Costus speciosus* and *Alpinia polyantha* are suitable as cutting flowers, and have unique flower shape, fresh color, long rachis and long vase time. *Hedychium flavum*, *Hedychium cocineum* and *Costus speciosus* are suitable as understory flowers, and have better shade tolerance, outstretched leaves, tall plant, and upright rachis. *Alpinia pumila*, *Curcuma kwangsiensis* and *Kaempferia rotunda* are suitable as potted flowers, and have low plant, fresh leaves, unique flower shape and better stress resistance.

Antifungal activities of different solvent extracts and chemical components of *Tetradium ruticarpum*

Shu Xu*, Qizhi Wang, Bi Wang, Fei Liu, Yu Shan, Ming Wang, Xu Feng*

Institute of Botany, Jiangsu Province and Chinese Academy of Sciences/ Nanjing Botanical Garden Mem. Sun Yat-Sen

Tetradium ruticarpum is a medicinal plant commonly used in China. In order to investigate the antifungal activities of *T. ruticarpum*, *T. ruticarpum* fruits were successively extracted with petroleum ether, dichloromethane, ethyl acetate, and methanol by using a sonication method. Antifungal activities of these extracts against five plant-pathogenic fungi (*Sclerotinia sclerotiorum*, *Fusarium graminearum*, *Botrytis cinerea*, *Colletotrichum gloeosporioides*, and *Fusarium moniliforme*) were determined with mycelial growth rate method. Eleven compounds (six indole quinoline alkaloids, three quinolone alkaloids, and two limonins) were subsequently isolated from the dichloromethane extract by multi-column chromatography method and recrystallization method, and their antifungal activities were also determined. The results showed that the dichloromethane extract was most effective against these plant-pathogenic fungi, while other extracts had less or none antifungal activities, indicating that the effective components mainly distributed in the dichloromethane extract. Further investigation showed that evodiamine isolated from the dichloromethane extract accounted for most of the antifungal activities, while other compounds showed little effect against tested fungi. In conclusion, the dichloromethane extract of *Tetradium ruticarpum* showed the best antifungal activities among all four extracts, and evodiamine isolated from the dichloromethane extract was the dominant active component in it.

"iFlowers" ——an image-based immediate plant identification system

Min Li[1]*, Jing Xuan*[1]*, Zhi Liang*[2]

1. Institute of Botany, CAS

2. Robusoft (Beijing) Co., Ltd.

"iFlowers" is an APP for image-based plant identification developed by Institute of Botany, CAS and Robusoft Company. It is built by taking advantage of deep learning techniques and based on about 3 million classified plant photographs of over 25 thousand plant species from the database "Plant Photo Bank of China" (PPBC). Through comprehensive use of deep convolution network, image semantic analysis, fine-grained identification and other fields of technology to achieve the image recognition training and detection, the program has realized the immediate identification of plant species. The program's image recognition training has been completed for China's common wild or cultivated plant species, and the real-time shooting recognition has been achieved for more than 11,000 species that covering most of the common species. Not like other APPs, the images used for identification in "iFlowers" are not limited to specific parts of a plant, and the program have realized the identification of all types of vascular plants, such as ferns, gymnosperms and angiosperms. This program can provide service through APP on android and iOS, WeChat public platform (cn-flora) and the website (http://stu.iplant.cn).

The compilation of *Plants of China*—an illustrated toolbook for 20 thousand species

Min Li*, Jing Xuan*

Institute of Botany, CAS

The Plant Photo Bank of China (PPBC) is a full-time agency for plant picture management in Herbarium (PE) of Institute of Botany, CAS. Since founded in 2008, PPBC has collected about 3 million photographs of over 2,5000 species from 4,146 genera in 538 families. Based on the photograph data, we've started to compile a set of books named *Plants of China*, which is divided into 65 volumes. The set of books is expected to cover all genera and families of native, invasive or naturalized and introduced plant species in China and the species involved are based on the latest classification system. Besides species photographs, their information including the common name, scientific name, distribution map, morphological characters is described in the book. The compilation work is conducted through online editing system which can realize online image selection, text editing and digital typesetting, *etc*. All books are expected to be completed by 2018.

Effects of season on chemical composition and nutrient digestibility of herbage on the Qinghai-Tibetan Plateau

Chuntao Yang[1]*, Peng Gao*[1]*, Fujiang Hou*[1]*, Tianhai Yan*[2]*, Shenghua Chang*[1]*, Zhaofeng Wang*[1]

1. College of Pastoral Agriculture Science and Technology, State Key Laboratory of Grassland Agro-ecosystems, Lanzhou University

2. Sustainable Agri-Food Sciences Division, Agriculture Branch, Agri-Food and Biosciences Institute

Livestock production relying on pastures has traditionally been the common practice in many areas of the world such as parts of China, New Zealand, and UK. The growth dynamics and productivity of grasslands in China are strongly influenced and restricted by the region's climate, especially in the continental cold/humid type with the rainy season in summer and dry season in winter. The response of grasslands to changes in climate influences the yield and quality of herbage, which affects livestock productivity, but limited information exists concerning herbage nutrient value and livestock performance and the relationship between them in grazing systems of the Qinghai-Tibetan Plateau (QTP). We therefore evaluated the impact of three grass growth seasons on the chemical composition and nutrient digestibility of herbage on the QTP for Tibetan sheep. Herbage was harvested on 14 consecutive days during each of the three annual grass growth seasons (primary-growth period: mid June, bloom phase: mid August, grass-withering period: mid December) from 2011 to 2013. At the same time, we carried out a metabolism trial with six male Tibetan sheep (body weight: 25.9 ± 3.1 kg (mean ± SD)) fed fresh herbage *ad libitum* for 14 days. Grass, feces, and urine samples were collected during the trial period to analyze the chemical composition and to calculate nutrient digestibility. The results shown that growth season affected both the content of all nutrients and digestibility of herbage. The crude protein (CP) content decreased significantly over the three growth seasons ($P < 0.05$). In contrast, the content of both neutral detergent fiber (NDF) and acid detergent fiber (ADF) increased significantly over the three growth seasons ($P < 0.05$). All of the following were highest during the primary-growth period, intermediate during the bloom phase, and lowest during the grass-withering period ($P < 0.05$): the digestibility of dry matter (DM), organic matter, CP, NDF, ADF, digestible energy, and the ratios of digestible energy/gross energy and metabolizable energy/gross energy. Nutrient digestibility and energy parameters correlated positively with the content of both herbage CP and gross energy but correlated negatively with the content of NDF, ADF, organic matter, and ether extract of herbage on the QTP. We found that the nutrient quality and digestibility of herbage on the QTP decreased over the three growth seasons, which may be one of the reasons suppressed ADG and DMI of Tibetan sheep. The parameters of herbage CP, NDF, and ADF content were most closely related to nutrient digestibility on the QTP. The results provided basic dataset better grazing utilization on the QTP.

Some medicinal plants used as folk medicine for rheumatism diseases in European Turkey

Gulden Yilmaz

Trakya University, Faculty of Science, Department of Biology

This paper includes some traditional medicinal plants which are used for rheumatism diseases as folk medicine in European Turkey. In this presentation the photographs of some of the plants, locations of them in European Turkey and information about how they could be used for rheumatism diseases as folk medicines, plant parts which were used for treatment, preparations, therapeutic effects, using dosages were given. The evaluation of relevant data in literature revealed that, roots of *Cynodon dactylon* (L.) Pers. var. *dactylon* Regel, branches and leaves of *Rapistrum rugosum* (L.) All., *Salix* sp., *Urtica urens* L., leaves of *Sambucus nigra* L., *Urtica dioica* L., *Tribulus terrestris* L., *Malva neglecta* Wallr., leaves and flowers of *Malva sylvestris* L. were used for rheumatism diseases as folk medicine in European Turkey. In spite of the well-developed medicinal facilities, the local people still use folk medicines for the treatment of rheumatism diseases. It is important to document the valuable information because the transmission of knowledge from the old to the new generation.

Taxonomic re-evaluation of some *Gelidocalamus* (Poaceae: Bambusoideae) taxa from Southeast China

Wengen Zhang, *Weijian Li, Ming Tang, Yuguang Liu, Guangyao Yang*

Jiangxi Provincial Key Laboratory for Bamboo Germplasm Resources and Utilization, Forestry College, Jiangxi Agricultural University

In the present study, we employed a classical taxonomic approach associated with information on micromorphological characters of the leaf epidermis to reassess the taxonomy of four *Gelidocalamus* taxa, a woody bamboo genus endemic to China. We propose that *G. subsolidus* is distinct from *G. tessellatus*, and *G. albopubescens* should be placed in synonymy under *G. subsolidus*. A formal taxonomic treatment is presented, including description, comments, illustrations, a distribution map, and SEM images of the abaxial leaf epidermis.

Genetic diversity of a range of *Taxodium distichum* genotypes and cultivars based on ISSR marker

Yuhong Zheng [1,3], *Bea Clack*[2], *David Creech*[1], *Yunlong Yin*[3]

1. Arthur Temple College of Forestry and Agriculture, Stephen F. Austin State University

2. Department of Biology, Stephen F. Austin State University

3. Institute of Botany, Jiangsu Province & Chinese Academy of Sciences

Taxodium is in the cypress family, Cupressaceae, one of several ancient genera in the family commonly known as cypresses. Once three separate species under the genus Taxodium, we are currently accepting Taxodium as one species with three botanical varieties: *Taxodium distichum* (L.) Rich.var. distichum (Baldcypress, BC), 2) *T. distichum* var. imbricarium (Nutt.) Croom (Pondcypress, PC), and 3) *T. distichum* var. mexicana Gordon (Montezuma cypress, MC). In recent years, Taxodium has found favor in coastal windbreak forests, tidal lands, and bottomland restoration projects and is appreciated for tolerance to flood, salinity, alkalinity and hurricanes. In this research project, the genetic diversity of the three botanical varieties, purported hybrids from China, were evaluated by Inter-Simple Sequence Repeat (ISSR) markers. A total of 135 individuals produced 108 polymorphic bands when amplified using nine simple sequence repeat ISSR primers. The Nei's gene diversity (h), the Shannon's Information index (I) and the Percentage of Polymorphic Loci (PPL) between different genotypes of baldcypress were 0.2581,0.3931 and 87.96%. For PC, they were 0.2278,0.3445 and 72.22%, respectively. For MC, the values were 0.2068,0.3120 and 61.11%. The results suggested rich genetic diversity between the genotypes of Taxodium, and less within the genotypes. Gene differentiation analysis showed that the gene flow (Nm) and coefficients of gene differentiation (Gst) of the three taxa were 0.7189 and 0.1955 for BC, 0.2696 and 0.2942 for

PC, 0.9861 and 0.0071 for MC. The results indicated that there was less gene exchange between genotypes in Taxodium that will lead to the population differentiation.

Selection of medium for cultivation of *Idesia polycarpa* Maxim. var. *vestita* Diels

Jingbo Zhou[1], *Zirui Zhao*[2], *Hong Chen*[1], *Yuan Jiang*[3]
1. Anhui Vocational & Technical College of Forestry
2. Shanghai Bohao Biotechnology Corporation
3. Anhui Agricultural University

Idesia polycarpa Maxim. var. *vestita* Diels is a kind of important energy plant that has the very high utilization value. In order to improve the seed germination rate and cultivate the high quality seedlings, there is need to find an optimal cultivation medium for seedling growth of *Idesia polycarpa* in a plastic cave tray (plug seedling). In this study, four types of media including M1 (soil), M2 (peat : perlite = 2:1), M3 (peat), and M4 (peat : perlite : vermiculite = 2:1:1) were tested in industrialized plug seedling. The seedling growth of *Idesia polycarpa* including plant height, crown diameter, leaf counts, ground diameter, the relative chlorophyll contents of leaves, *etc.* was measured. The results indicated that medium M2 was the best one for the increases in seedling height, crown diameter, leaf counts, ground diameter and the relative chlorophyll contents of leaves. Therefore, medium M2 is recommended in the industrialized nursery process for the seedling growth of *Idesia polycarpa.*

Exogenous salicylic acid and abscisic acid affect physiology *Epichloë-Achnatherum inebrians* symbiosis

Jing Liu, *Chunjie Li*
State Key Laboratory of Grassland Agro-ecosystems, College of Pastoral Agriculture Science and Technology

Drunken horse grass (*Achnatherum inebrians*) is an intoxicating grass that grows in the native grasslands of Northwest China. It forms a symbiotic relationship with *Achnatherum inebrians*, *Epichloë-Achnatherum inebrians* symbiosis, which can promote plants growth, and improve the biotic and abiotic resistance. To test physiological change of *Achnatherum inebrians* under exogenous salicylic acid (SA) and abscisic acid (ABA) treatment, endophyte-infected (E+) and endophyte-free (E-). *A. inebrians* were set experience and control group, respectively. The result showed that total chlorophyll content, proline acid content, superoxide dismutase activity, peroxidase activity and soluble sugar content increased, but malondialdehyde content decreased under both SA and ABA treatments in E+plants, comparing to E-plants. Under ABA treatment, chlorophyll content, proline acid content, superoxide dismutase activity and peroxidase activity significantly increased, and proline acid content and superoxide dismutase activity significantly increased under SA treatment in E+plants, comparing with E-plants. These results showed that *Epichloë* endophyte could alleviate the damage from exogenous ABA and SA stress in *Epichloë-Achnatherum inebrians* symbiosis.

Triterpenoid saponins from *Salicornia europaea* and their α-glucosidase inhibition activites

Xin Ma, Hui Lv, Fuqin Guan, Xu Feng, ***Yu Chen***
Jiangsu Key Laboratory for the Research and Utilization of Plant Resources, Institute of Botany, Jiangsu Province and Chinese Academy of Sciences

Salicornia. (Chenopodiaceae) is a genus of annual apparently leafless halophytic herbs that have articulated and succulent stems. *S. europaea* is used in traditional medicine for treating hypertension, cephalalgia and scurvy in China. Although the economic value of this plant has already been discovered and developed, its medicinal value has been ignored for a long time. The present study was carried out to examine the chemical constituents of *S. europaea* and their α-glucosidase inhibition activities to support further pharmaceutical research. Previously two classes of principle ingredients have been reported from this species, including flavones, and triterpenoid saponins. In the current research, a new triterpenoid saponin, 3-O-*β*-D-glucopyranosyl- (1→2)-[*β*-D-xylopyranosyl- (1→3)]-*β*-D-glucuronopyranosyl 30-noroleanolic acid 28-O-β-D-glucopyranosyl ester (Salieuropaea A), was isolated from the plant together with thirteen known triterpenoid saponins. Their structures were established by spectral analysis. The α-glucosidase inhibition activities of the isolated triterpenoid saponins were also investigated. Experimental results show that aglycones of the saponins give potent α-glucosidase inhibition activities, which indicated that the α-glucosidase inhibition activity of aglycone may precede that of saponin.

Antimicrobial *in vitro* activities of selected species of medicinal plants of Kaimosi in the Lake Victoria Basin

Leonard Sida Malweyi[1], *Donald F Otieno*[2], *Elizabeth W Njenga*[2]
1. University of Nairobi
2. University of Eldoret

The efficacy claims made by herbal practitioners in Kaimosi area on use of 11 medicinal plants for antimicrobial treatment in the area was investigated in 2009. The disc diffusion method was used to ascertain the efficacy of crude plant extracts against thirteen test microbes obtained using solvents of increasing polarity (petroleum ether, chloroform, methanol and water) and subsequently the minimum inhibitory concentrations of extracts with good results determined using the micro-dilution method. The extracts from *Lantana trifolia* were found to be most active against bacteria and those of *Fuerstia africana* against fungi with activity ranging from 1 mm to 7 mm for the former and from 1 mm to 2 mm for the latter. The isolates most susceptible to the extracts were Shigella sp., *Bacillus subtilis* and *Staphylococcus aureus* each out of 44 extracts. Chloroform and methanol extracts of *L. trifolia* had the largest inhibition zone of 7 mm diameter against *Sh. flexneri* and 6.5 mm against *S. aureus* respectively. *Fuerstia africana* produced the most promising results on both fungal and bacterial isolates, giving a MIC value of 0.051 mg/mL against *Shigella flexneri* and 0.102 mg/mL against *Staphylococcus aureus*. The results of this study supported the use of medicinal plants in management of infectious diseases in the study area.

Assessment physiological effects of gamma rays on trigonella (*In vivo* and *In vitro*)

Mahmoud Khater
National Research Centre

This investigation was carried out during two successive seasons 2013/2014, 2014/2015 at the Greenhouse and Tissue culture laboratory, Botany Department, National Research Centre, Giza, Egypt. Molecular studies were carried out at Genetics Department, Faculty of Agriculture, Zagazig University, Egypt. To study the physiological and molecular changes in fenugreek (*Trigonella foenum graecum* L.) *In vivo* and *In vitro* as a response to gamma rays with doses (0, 100, 150, 200, 250 and 300 Gy). Results revealed that callus induction frequency increased in response to the increase of 2,4-D concentrations and varied from one gamma-ray dose to another. The best interaction between gammaray and 2,4-D concentrations was between 2.0 mg/L 2,4-D and all doses of γ-rays especially 200 Gy which recorded the highest percentage of callus (above 90%). On the other hand, in RAPD analysis there were 44 bands (total bands) divided to polymorphic bands (25), monomorphic bands (2) and unique bands (17) with an average percentage 88.00% polymorphism and numerous molecular sizes that ranging from 265,122 to 1,911,225 bp, Moreover, results of ISSR analysis illustrated that there were 22 bands (total bands) divided to polymorphic bands (3), monomorphic bands (11) and unique bands (8) with an average percentage 76.00% polymorphism and different molecular weights that ranging from 260,582 to 1,333,384 bp.
